It is a very desirable thing to combine the extreme hardness of steel with the toughness and tenacity of iron. This is done by welding them together. It is in this way that edge tools are made. A bit of steel is welded to the iron on that side of the plate or bar which is to be worked into an edge; or the surface of a piece of iron is converted into steel by cementation, and the process is stopped before the carbon penetrates so far as to convert the whole piece into steel. This is called *case-hardening*. The piece of work, when nearly finished, is covered with a paste made of combustible matter. Certain animal substances, as horns and hoofs, chopped hair, bone, shavings, &c., are made up into a paste. The iron is covered with it, and the whole wrapped up in clay. This is first dried and hardened before the fire, and then put into a forge, and kept in a low red heat for an hour or two. When taken out, the surface is converted into steel. In this way almost all the parts of gun-locks are treated. Besides the superficial hardness that they thus acquire, it is well known that they have much less friction than while in the state of iron, and they are much less liable to rust. Every kind of iron is not suited to the manufacture of steel. English iron does not answer at all. The iron which answers best is made at Danemora, in Sweden, from the magnetic iron ore. The whole of the yearly produce of the Danemora mines, amounting to 8,000 tons, is imported into Britain, and converted into steel.

The *natural steel*, or *German steel*, is an impure and variable kind of steel, procured from cast-iron, or obtained at once from the ore. It is much cheaper than the cementation steel. It has also the property of being easily welded, either to iron or to itself. Its grain is unequally granular, sometimes even fibrous; its colour is usually blue; it is easily forged; it requires a strong heat to temper it, and it then acquires only a middling hardness. When forged repeatedly, it does not pass into iron so easily as the other kinds. The natural steel yielded by cast-iron, manufactured in the refining houses, is known by the general name of *furnace steel;* and that which has only been once treated with a refining furnace, is particularly called *rough steel*, and is frequently very unequally converted into steel. The best cast-iron for the purpose of making natural steel, is that obtained from the brown hæmatite, or from the sparry iron ore. If it contains manganese, this is thought to be an advantage. It should be of a grey colour. White cast-iron does not yield steel, unless its charge of carbon is increased, either by stirring the melted metal with a long pole, and keeping it melted a long time, that it may absorb charcoal from the lining of the furnace, or by melting it with dark-coloured iron. Black cast-iron yields a bad, brittle steel, unless the excess of carbon that it contains is either burnt away, or it is mixed with finery cinder. The cast-iron to be converted into steel is then melted in blast furnaces, and treated nearly the same as if it were to be refined into bar-iron, only the blast is weaker; the tewyre, instead of being directed so as to throw the wind upon the surface of the melted metal, is placed nearly horizontally; the melted metal is kept covered with slag, and is not disturbed by stirring. When the iron is judged to be sufficiently refined, and is grown solid, it is withdrawn from the furnace and forged. The natural steel made directly from the above-mentioned ores, in small blast furnaces, is a good steel for ploughs and similar machines: the best of it is excellent for saws and cutlery. The most esteemed steel of this kind comes from Germany, and is made in Styria. It is usually sold in chests or barrels, two and a half or three feet long.

STEELYARD. A balance for determining the weight of bodies by means of a single standard weight. See the article Balance. Ruthven's steelyard, invented upwards of 20 years ago, by Mr. John Ruthven of Edinburgh, is well suited to the use of farmers and of persons who deal in farm-produce. It comprises a longer arm, a shorter arm, a weight moveable along the former, a scale suspended to the latter, a rod with looped vertical uprights in the ends for suspending and confining the arms, and a stand for supporting and poising the whole machine. The longer arm has so limited a range of motion at its extremity as to prevent the jerks and long vibrations to which common steelyards are subject; the weight cannot escape at either extremity of the arm, and consequently can never be mislaid or lost; and the scale is ingeniously contrived to open one end and discharge its contents at a touch, and is therefore very convenient for weighing grain, flour, small seeds, and similar commodities.

STEEP. Any saline or medicated liquid for the immersion of seed-corn preparatorily to its being sown. See the articles Seed, Smut, and Wheat.

STEER. A young bullock.

STEG. A gander.

STELIS. A genus of tropical epiphytous plants, of the orchis family. Four or five species have been introduced to British collections, —but, as compared with other orchidaceæ, are

more curious than beautiful; and a number more are known.

STELL. See Sheep-Stell.

STELLARIA. See Stitchwort.

STEM. The part of a plant which rises from the root, and sustains the foliage, flowers, and fruit. In some plants, it is awanting; in others, it is identical with the mere flower-stalk; and in others, it bears only part of the foliage, the rest being radical; but in all the more perfect ones, or indeed in the great majority of all sorts of phænogams, it comprises a great mass of important organism intermediate between the root and the inflorescence. It is ligneous in trees and shrubs, and constitutes their trunk or boll; and it is herbaceous in herbs,—annual in some perennial-rooted ones, and perennial in others. It is cylindrical in some plants, compressed in others, and quadrangular in others; solid in some, tubular in others, and jointed or knotted in others; naked in some, and leafy in others; simple in some, and compound or branched in others; robust in some, and slender in others; upright in some, nodding in others, and decumbent in others; rigid in some, and flexuose in others; self-supported in some, climbing in others, twining in others, and creeping in others.

STEMODIA. A genus of tropical plants, of the figwort family. Two perennial species and five or six annual ones—chiefly with blue, red, or white flowers—have been introduced to British collections; and about as many more are known; but they do not possess any particular interest.

STENOCHILUS. A genus of ornamental, Australian, evergreen shrubs, of the myoporum family. Three species, the smooth-leaved, the long-leaved, and the spotted, all red-flowered and less than five feet in height, have been introduced to Britain; and the first has the recommendation of a capacity to bloom throughout most of the year; and all love a somewhat peaty soil, and are propagated from cuttings. The name stenochilus alludes to the narrowness of the flower-lip.

STENORHYNCHUS. A genus of ornamental tropical plants, of the orchis family. Two species, the showy and the orchis-like—the former scarlet-flowered and blooming from April till June, and the latter carmine-flowered and blooming in May—have been introduced to the hothouses of Britain; and both are terrestrial-rooted, evergreen and very beautiful, and love a soil of sandy peat, and are propagated by division of the plant. The name signifies 'narrow beak,' and alludes to the pointed form of the stigma.

STERCORARY. A collection of putrescent manure in a position of security from injury by the weather. A good ordinary kind of it, recommended ages ago by judicious and reflecting agriculturists, is simply a dung-pit instead of a dunghill, either dug in a bed of clay or chalk, or well-paved in both the bottom and the sides,—protected by a shed from rain, and by the nature of the ground from the influx of springs or of surface water,—filled up progressively with the cleanings and drainings of the farm-yard, both solid and liquid,—and augmented or modified at frequent and proper intervals with layers of mould or other mineral manure of a kind suited to fix the gases of the putrescent substances, and to render the whole contents of the pit peculiarly adapted to the soil and crop to which it is intended to be applied. See the articles Manure, Liquid Manure, and Farm-Yard Manure.

STERCULIA. A genus of ornamental, exotic, evergreen ligneous plants, of the byttneria tribe. About twenty species, varying in natural height from 6 to 35 feet, have been introduced to British gardens; and a number more are known. The name sterculia is formed from a word signifying 'ordure,' and alludes to the excessively disgusting fetor of some of the oldest known species. A bark used in India for some medicinal purposes, and popularly called 'stink-bark,' and possessing a smell very similar to ordure, has been thought, though perhaps erroneously, to be the produce of *Sterculia fetida*,—a species 8 feet high, with palmate leaves, introduced to British collections toward the end of the 17th century. The seeds of one or two species, though evolved out of a very fetid inflorescence, are eaten by the Hindoo peasantry, and occasion the carpels which contain them to be popularly called hill cocoa-nuts. The carpel of *Sterculia alata*—a very stately tree—is a very curious fruit,—an orbicularly pear-shaped follicle, about 4 inches long and about as much across, somewhat compressed, with walls half an inch thick, containing large and rayedly-disposed seeds. The majority of the introduced species have ovate or oblong leaves, either entire or three lobed; and most of the remainder have cordate five-lobed leaves;—and all love a soil of peaty loam, and are propagated from cuttings.

STERIGMA. A genus of interesting herbaceous plants of the cruciferous order. The woolly and the twisted species, both curious, yellow-flowered, hardy biennials, of about a foot in height, blooming from April till July, were introduced to Britain about 30 years ago from Astracan and Iberia. They are nearly allied to wallflowers.

STERNBERGIA. A genus of bulbous-rooted, ornamental, exotic plants, of the amaryllis order. Four species—all yellow-flowered, autumnal bloomers of from 3 to 8 inches in height, loving a soil of rich mould, and propagable from offsets—have been introduced to Britain from the north of Africa and the south and east of Europe.

STEVIA. A genus of ornamental exotic plants, of the eupatorium division of the composite order. Upwards of 30 species have been introduced to Britain, principally from Mexico and New Spain.

A few are herbaceous evergreens, with subshrubby stems and pink flowers; most are perennial-rooted herbs, with annual stems, and either pink, white, violet, or purple flowers; and nearly all have a height of between 15 and 30 inches, and bloom in the end of summer and beginning of autumn. Most love a soil of peaty loam; and all are propagated by radical division.

STEWARD. See AGENT.

STICKLEBACK, — scientifically *Gasterosteus*. A genus of fishes, of the mailed cheeked family of acanthopterygians. The common stickleback, *G. aculeatus*, abounds in the fen-ponds, canals, new ditches, and other fresh-water accumulations of many parts of Britain; and is obtained in large quantities and extensively used for manuring land and feeding hogs. It has commonly a length of not more than two or three inches. Its back and sides have an olive green colour; and its belly is perfectly white. It has three dorsal spines; and one variety of it has scaly plates only on the pectoral region,—while another variety has them to the very end of the tail.—The lesser stickleback, *G. pungitius*, is a very small fresh-water fish, and has nine very short dorsal spines.—The larger stickleback, *G. spinochia*, is a salt-water species of a slender and elongated form, with fifteen short dorsal spines.

STICTA. A genus of lichens, of the cænothalamous tribe. The lung species, *S. pulmonacea*, is useful for dyeing. It has a reticulated structure, an olivaceous colour, and a size of about two inches, and grows on the trunks of trees throughout the year. Eight other species inhabit the trees and woods and rocks of Britain.

STIFLE-JOINT. The lower joint of the hind leg of the horse. It comprises the tibia or lower bone of the thigh and the patella or knee-pan; and it is much strengthened by some of the tendons of the strongest muscles of the upper part of the thigh passing into it and over it, and co-operating with its own proper ligaments to give it force and tension.

STIGMA. The summit of the style or pistil of a flower. It has no cuticle, and is either humid or papillose.

STIGMAPHYLLUM. A genus of ornamental tropical plants, of the Barbadoes cherry tribe. It takes its name from the foliaceous structure of its stigma. Two species, the auricled-leafed and the awn-leafed, the former about 10 feet high, the latter about 20 feet high, and both yellow-flowered, evergreen climbers, propagable from cuttings, have been introduced into British collections from Brazil.

STILE. A fixed means of enabling a foot passenger to go over or through a fence. It has a great variety of forms; but ought, in every instance, to be substantial, facile, and of such structure as neither to weaken the fence nor to induce any passenger to make trespasses or dilapidations. A common and very good kind consists of strong bars about three feet wide, fixed in upright posts, with a step nailed crosswise to stumps on each side, and raised half way up the frame; but a much more convenient and, in all respects, better kind, is a cage wicket. See the article CAGE-GATE.

STILLINGIA. A genus of exotic yellow-flowered plants, of the spurge tribe. A herbaceous evergreen and a deciduous shrub of it have been introduced to British collections from North America, and two tall evergreen shrubs from China and Ceylon; and one of the latter, the tallow-bearing, though a mere hothouse curiosity with us, possesses economical adaptations in its native country. This genus was named in honour of Dr. Stillingfleet.

STILT, — *Himantopus Melanopterus*. A rare and curious bird, of the long-billed family of waders. Its total length is about 13 inches; its legs are remarkably long and slender; and, together with the toes, have a pink colour; its head, neck, and breast, and the under parts of its body are white; and its back and wings are nearly black, tinged with green. It has sometimes been killed in some of the counties of England; but is only an occasional visitor to our shores; and has not been often or closely observed in its habits.

STIMULANT. A substance which increases the irritability of the living animal or vegetable fibre. In veterinary medicine, internal stimulants require to be used with great caution; but external ones, in many cases, are obvious and valuable remedies. See the articles CORDIAL and EMBROCATION.

STING. A small, tubular, awl-shaped organ or process, for discharging a minute quantity of a powerfully venomous fluid. The sting of an insect is nearly allied in structure to an ovipositor; and the sting of a vegetable is a process of the stem or leaf, and is well exemplified in the common nettle. See the articles INSECT and NETTLE.

STINKING HOREHOUND. See BALLOTA.

STIPA. A genus of grasses, constituting, with the genera aristida and chætaria, the family Stipaceæ in the one-flowered paniculate tribe. One species grows wild in Britain; about a dozen species have been introduced from America, Siberia, and Continental Europe; and about twenty-five more are known. All the introduced species are hardy; all but one are perennial; about one half have a height of two or three feet; and the majority have a curious or interesting appearance; but none are fitted to rank as agricultural plants.

The feathered species, popularly called feather-grass, *Stipa pennata*, inhabits the dry mountainous rocks of some parts of Britain, and has a place as an ornamental or curious plant in many a garden, yet is a doubtful native. Its root is fibrous and perennial; its culms are from 12 to 24 inches high, and thickly covered with foliage; its leaves are long, narrow, acute, roughish, and

dark green, and grow in dense tufts on the culms; its sheaths are striated and very long; its stipules are oblong and obtuse; its flowers grow in simple, erect panicles, six or seven in each panicle, and bloom in July and August; and its awns are nearly a foot long, and have a beautiful feather-like appearance, and adhere to the seeds, and serve as sails to waft them on the breeze over a wide extent of country. "When a seed with its feathered arrow alights on the ground, it enters the soil vertically, and, in a few hours, the base and sulcated part of the awn becomes twisted and the feathered portion becomes horizontal; in consequence of which it is blown round by the autumn winds like a vane, and every turn screws it farther down into the earth,—for the hollows and ridges which, when it remained upon the plain were only longitudinal sulci, have now given rise to the hollows and elevations, in a word, to the threads of a screw. Thus it is moved down, and whatever is gained is prevented from being undone by a reverse motion of the vane, in consequence of the stiff hairs upon the glume, which act as barbs." The feathered awns distinguish the plant in general appearance from all other grasses, and render it worthy of a place on the flower-border, and are sometimes worn by ladies instead of feathers. The seeds abound in some of the pastures of Hungary, and, when carried about by the wind, make a lodgment on the back of a sheep, and work their way through the wool and skin and flesh into the intestines, and excite throughout the system a powerful morbific action, which the veterinarians of the country call *stipæ noxa*, and which shows itself in restlessness, sleeplessness, and loss of appetite, and terminates in fever, inflammation, and death. The plant, however, does not readily grow in Britain from seeds, and requires to be propagated in gardens by parting and planting the roots. It is of small value for agricultural purposes; and when raised on a heathy soil in the Woburn experiments, it yielded per acre 9,528 lbs. of produce at the time of flowering, 3,454 lbs. of dry produce, and 409 lbs. of nutritive matter.

STIPE. The stalk of a fern or the stem of a fungus.

STIPULE. An appendage of the base of a leaf-stalk. It commonly resembles a miniature leaf, with a subulate termination; but has a less firm texture than a leaf.

STITCHWORT, — botanically *Stellaria*. A genus of herbaceous plants, of the carnation tribe. A number of species which formerly belonged to it are now assigned to other genera; but eight species still belonging to it grow wild in Britain, nearly 20 have been introduced from other countries, and a good many more are known. All are white-flowered; most have a height of between 6 and 20 inches; nearly all present a weedy appearance; and some are annuals, some biennials, and some annual-stemmed perennials.

The common stitchwort, or common chickweed, or mediate chickweed, *Stellaria media*, is one of the most vivacious, generally diffused, perennially blooming weeds of our cultivated lands, and even of the most contrasted soils and situations of a waste nature; and it particularly abounds in the neglected nooks and borders of gardens. Its root is annual, small, and tapering; its stems have seldom a height of more than a few inches in the garden, but sometimes attain a height of twenty in the woods; its foliage is small, pale green, and profuse, and spreads out in all directions; and its flowers are small, stellate, and white, and bloom from March till December. The herbage is refused by goats, disrelished by sheep, eaten by cows and horses, and greedily devoured by hogs; and it is said to be nutritive, and suitable for being boiled and eaten in the manner of spinach, —and has the reputation, when boiled in vinegar and salt, of possessing virtue to cleanse eruptions of the hands and limbs. The leaves and tender stalks, and especially the seeds, are eaten by poultry and wild birds. The flowers serve, in some degree, as a natural barometer; for when rain is approaching, they remain closed,—and in dry weather, they are regularly open from about nine o'clock in the morning till noon.

The forked stitchwort, *S. dichotoma*, is an annual weed of the cultivated grounds of Britain, and has a height of about 20 inches, and blooms throughout the greater part of the year.—The grove and the Holostea stitchworts, *S. nemorum* and *S. holostea*, are perennial-rooted indigens of the moist woods of Britain, and have a height of about a foot, and bloom from April till June.—The marsh or glaucous stitchwort, *S. glauca*, is a perennial-rooted indigen of the wet meadows of Britain, and has a height of 8 or 10 inches, and blooms from May till August.—The grass-leaved stitchwort, *S. graminea*, is a perennial-rooted weed of the hedge-banks of Britain, and has a height of about a foot, and blooms from April till June.—The scape-bearing stitchwort, *S. scapigera*, is a perennial-rooted indigen of the brook-banks of some parts of Scotland, and has a curious appearance and a height of only 2 or 3 inches, and blooms in June and July.—The cerastium-like stitchwort, *S. cerastoides*, is a perennial-rooted indigen of some of the lofty mountains of Scotland, and has also a curious appearance and a height of 5 or 6 inches, and blooms in June and July.

STOAT,—scientifically *Mustela Erminea*. A small quadruped of the weasel genus and digitigrade family of Carnivora. It closely resembles the weasel in structure, habits, agility, and mischievous pursuit and destruction of hares, game, and poultry, and does not differ much from it in size, and is often confounded with it in name. Its height is about two inches; its tail is $5\frac{1}{2}$ inches long, very hairy, and tipped at the point

with black; the edges of its ears and the extremities of its toes have a yellowish white colour; and the other parts of its body exactly correspond in both shape and colour to those of the weasel. In the most northern parts of Europe, it regularly in winter changes the colour of all its body except the point of the tail to white, and is then called the ermine; and its fur at that time is sought after by hunters as a well-known and valuable article of commerce. It sometimes is found white during winter also in Britain, and is then commonly called the white weasel; but its fur in this case is of small value compared with that of the foreign ermine, being very inferior in at once thickness, closeness, and whiteness. Pontoppidan says respecting the Norwegian stoat or ermine, "It lives among the rocks; his skin is white except the tail, which is tipped with black. The furs of Norway and Lapland preserve their whiteness better than those of Russia, which soon acquire a yellowish cast; and upon this account the former are in greater request even in Petersburgh. The ermine catches mice, like the cat, and when practicable carries off his prey. He is peculiarly fond of eggs, and when the sea is calm, he swims over to the islands, which lie near the coast of Norway, where there are vast quantities of sea-fowls. It is alleged, that, when the female brings forth on an island, she conducts her young to the continent upon a piece of wood, piloting it with her snout. This animal, although small, kills those of a much larger size, as the reindeer and bear. He jumps into one of their ears when they are asleep, and adheres so fast by his teeth, that the creatures cannot disengage him. He likewise surprises eagles and heathcocks, by fixing on them, and never quitting them, even when they mount in the air, until the loss of blood makes them fall down."

STOCK,—botanically *Mathiola*. A genus of ornamental plants, of the cruciferous order. Two species grow wild in Britain; nearly twenty have been introduced from other countries, principally those around the Mediterranean; and nearly a dozen more are known. Six or seven of the species in Britain are hardy annuals; five or six are biennials; and the rest are herbaceous evergreens or subshrubby evergreen undershrubs. A few have a height of only from 3 to 8 inches; and the rest have a height of from 12 to 30 inches. The petals of two are obovate and purple; those of seven are oblong and yellowish purple; and those of the rest are obovate, and either white, red, scarlet, purple, violet, or various-coloured. One of the indigenous species, the scollop-leaved stock, *Mathiola sinuata*, is a violet-flowered biennial of about a foot in height, inhabiting the sandy sea-coasts of Cornwall and Wales, and blooming from May till August; and the other, the hoary gilliflower or great sea-stock, *Mathiola incana*, is a purple-flowered, evergreen undershrub of from 12 to 25 inches in height, inhabiting high maritime cliffs in the south of England, blooming from May till November, and comprising three very distinct varieties, with respectively white, scarlet, and variegated flowers.

But the chief interest of the genus is concentrated in the well-known stocks or gilliflowers or stock-gilliflowers of the flower border. These have long been high favourites with all sorts of florists, and are fondly cultivated in all sorts of flower-gardens, from the humblest to the most princely, for the sake of both their beauty and their exquisite fragrance. They were originally introduced from the South of Europe, but they include many varieties, and have been abundantly hybridized; and they comprise three great groups, —ten-week stocks, queen stocks, and Brompton stocks, which are regarded by some botanists as separate species, and by others as broadly marked and very permanent varieties. All are capable of being brought to flower and killed by frost in the same year in which they are sown, and so appearing as annuals,—and of not flowering till the second year, and continuing to live and flower during several years, and so appearing as short-lived perennials; but the ten-week kinds are peculiarly liable to die after one flowering, and are therefore commonly called annuals,—and the other kinds seldom thrive or bloom so well after the first flowering as before, and are therefore commonly called biennials. All were classed by the old botanists with wallflowers; but they are readily distinguishable from them by the hoariness of their leaves, by the comparative succulence or fleshiness of their stems, by the greater compactness or less shrubbiness of their habit, and by the greater brilliance and warmer colour of their flowers.

The following are Miller's descriptions of the three principal stocks:—"The ten weeks' stock rises with a round smooth stalk about a foot high, dividing into several branches upward. These are garnished with spear-shaped hoary leaves, rounded at their ends, and placed without order, sometimes being almost opposite, at others alternate, and frequently three or four together, of unequal sizes. At the ends of the branches the flowers are produced in loose spikes, placed alternate. The empalement is large, erect, and slightly cut into several acute parts at the top. The petals are large and heart-shaped, spreading open in form of a cross. The pods are long, cylindrical, and have a longitudinal furrow on one side, which opens in two cells, filled with flat roundish seeds, having a thin border. It flowers in July and August, and the seeds ripen in October. Of this sort there are the red, the purple, the white, and striped, with single flowers, and the same colours with double flowers. If the seeds are sown at two or three different times, the flowers may be continued in succession near three months.—The queen's stock rises with a strong stalk, which is almost shrubby, a foot high or more, having oblong, spear-shaped, hoary

leaves, which are frequently waved on their edges, and turned downward at their extremity. From the stalk are sent out many lateral branches, garnished with the same shaped leaves, but smaller. These side branches are each terminated by a loose spike of flowers, each having an oblong woolly empalement, and consists of four large roundish petals, indented at the end. These usually appear in May and June, but the same plants frequently continue flowering most part of summer. The seeds ripen in autumn, and the plants generally perish soon after; but when any of them grow in dry rubbish, they will last two or three years, and become shrubby. Those with single flowers are not worth preserving after they have perfected their seeds. The flowers of this sort vary in their colour; some are of a pale red, others of a bright red, and some curiously variegated; but those of the bright are generally most esteemed. There are always a great number of double flowers produced; if the seeds are well chosen, frequently three in four of the plants will be double; and as they divide into many branches, make a fine appearance during their continuance in flower.—The Brompton stock rises with an upright, strong, undivided stalk to the height of two feet or more, garnished with long hoary leaves, reflexed, and waved on their edges, and at the top form a large head. Out of the centre of these arises the flower stalk, which, when the plants are strong, is frequently a foot and a half long, putting out two or three short branches toward the bottom. The flowers of this kind have longer petals than any of the other sorts, and are formed into a pyramidal spike; but those with single flowers are loosely disposed, because the flowers having but few petals, do not fill the spike, as those do which are double; for these often have so many petals, as to render each flower as large and full as small roses; and when they are of a bright red, make a noble appearance, being excelled by none of the flowery tribe. But the plants of this sort produce but one spike, in which it differs from all the other kinds."

Almost all persons who profess to grow large quantities of stocks in pots for the market have favourite subvarieties of their own, which cannot easily or at all be identified with the normal plants of any botanical species or leading varieties; and all the principal seedsmen of the present day, besides vending many sorts of ten-weeks, queen, and Brompton, sell also great groups under the name of German, smaller groups under the name of Prussian, besides numbers of special sorts under such names as Victoria, Prince of Wales, New Emperor, New European, Scarlet intermediate, Purple intermediate, Chamois, and Superb. The German florists have been eminently successful in raising and perpetuating very numerous and distinct varieties,—especially in the tints and shades of the colouring of the flowers; and seeds of annual stocks alone imported to Britain from Continental Europe produce many distinct shades from white to deep red, from white to deep purple, and from white to dark slate colour, and run into no fewer than between 40 and 50 different characters, all tolerably true.

"The most extraordinary fact with regard to the culture of stocks," says the editor of the Horticultural Magazine, "is that they come double from single seed, or rather from seed saved from single ones, and that without the slightest reference to there being any double ones near them or in the same ground. Many are almost superstitious as to the period at which they are to be sown; and it has long been proved to our satisfaction that culture has something to do with it, because we have seen a packet, or rather packets, of seed divided between two people, one producing nearly all double, and the other nearly all single. The ordinary mode of sowing ten-week or annual stocks is on a slight hot-bed; and when they are up to give them plenty of air, even by entirely removing the glasses in fine weather. Those who want them early in spring sow in the autumn; those for summer bloom are sowed in spring. We have no conceit about the particular period. Here they may be sown in March, April, May, and even June, and grow till they are large enough to plant out, giving them no more water than is absolutely necessary to keep them from flagging. When planted out, they should be watered in well, and then, being placed 9 inches apart, they will only require to be kept clean from weeds, and grow until they flower. If you are choice in the purchase of your seed, you may, of the German stocks alone, have forty very distinct shades of colour. The Prussian stocks are not so numerous. In saving seed, select the single stocks with the widest petals, and with five petals, if you can find them, which is not at all uncommon; but you may as well plant double brickbats as double stocks, to influence the seed of the single ones you save from. The autumn-sown stocks may be sown a month apart in the same way, for keeping in pots through the winter. All you have to do is to see them strong enough to plant into pots before the winter is too cold for them. They require no heat, but they are, in that young state, unable to stand much frost. Plant three in a pot if you fear the quality, that you may be able to draw one or even two single ones out, should there be such, and take out the weakest of them if they all run double. Among the best cultivators of the biennial stocks, we have known some who grew them in pots for sale, and we have seen hundreds in frames growing well, and nearly all double. Of all these we have made various inquiries, and it was evident that while they were in the seed-bed they partly starved them if for planting out in the open ground; but, if for potting, they put them out rather small than otherwise, and starved them there; that is to say, they kept them all the early part of their

career what we should call rather short of moisture. Some persons have been in the habit of sowing the spring ten-week stocks broad-cast in the bed they are to grow in, and, when they become large enough, drawing them out to thin them to 9 inches or a foot apart. The objections to this are, that the stocks are not left in even rows; for this is next to impossible. Those drawn out generally run more double when carefully taken away and planted. The best way is to water the bed well first, and in half an hour you may draw them out without damaging the roots. It has been thought by many that the check which stocks get under the transplanting system is beneficial in producing the double flowers; but, generally speaking, we think high culture induces it. Certain it is, we never saw a self-sown stock come double when left to bloom in the place in which it came up; and some kinds are very apt to come single, and cannot be prevented. Biennial kinds of stock should be sown in May or June, and as nearly as possible that time in the next year they will flower. The months mentioned as those in which they bloom, supposes them to be sown at the ordinary time for biennials, that is, midsummer, or rather later. These are best sown in a good sound border of loam and peat, though the soil of a kitchen garden not fresh dunged will do for them. Here they may remain until they have made some considerable growth, and from thence taken to where they are to bloom, whether this be in beds, borders, or pots. They must, if potted, be only one in a pot, of the forty-eight size; and in the spring, all that indicate double flowers should be transferred to size twenty-four pots, as they will grow very much, and the flowers be greatly assisted by the additional room. But the Giant Brompton, and some of the large kinds of biennial stock, are much too large for pots, and will grow, on good ground, three, and occasionally four, feet high. They should be planted out time enough to establish themselves in the ground before the winter sets in, and are only fit for extensive gardens. The biennial stocks are well worth propagating from cuttings, and they produce flowers in a much more dwarf state. These are taken from the side shoots and come soon after the bloom; indeed, if left on the plant they would bloom. When taken for cuttings, they should be stripped off with part of the heel, or cut very close to the plant, and placed under a hand-glass; but they should always be taken as soon as they are large enough to handle well; and if they should indicate bloom before they have grown to any size, which they will sometimes, it must be pinched out as soon as you can get hold of it. When they have rooted well, they may be planted out the same as seedlings."

STOCK. The stem of a living, growing, young tree, used for receiving a graft or bud. See the articles GRAFTING and BUDDING.

STOCK. Moveable property possessed in connexion with productive industry. The stock of a farm is usually classified into living and dead, —the former comprising the animals, old and young, and the latter comprising the implements, manures, and vegetable produce. See the article LIVE STOCK.

STOCK DOVE. See PIGEON.

STOCK FARMER. A farmer whose business mainly consists in rearing live stock, and who therefore occupies a pastoral farm. See the articles FARM and FARMER.

STŒBE. A genus of ornamental, Cape-of-Good-Hope, evergreen undershrubs, of the thistle division of the composite order. Four species, all about 2 feet high, and blooming in the early part of autumn, have been introduced to Britain; and they love a soil of peaty loam, and are propagated from cuttings.

STOKESIA. A beautiful blue-flowered, evergreen, herbaceous plant, of the thistle division of the composite order. It constitutes a genus of itself, and takes the specific name *Cyanea* or azure-flowered. It is a native of Carolina, and was introduced to Britain in 1766. It has a height of about 2 feet, and blooms in the early part of autumn; and it thrives in any common soil, and is propagated by radical division.

STOLON. A shoot from the side, summit, or collar of a root, extending laterally either within the soil or upon its surface, and terminating either in a tuber or in a young perpendicular root. The string which connects a potato tuber with the root is a good example of a subterranean, tuber-ending stolon; and the runner of a strawberry-plant is a good example of a surface, root-ending stolon.

STOLONIFEROUS PLANT. A plant which naturally propagates itself by means of stolons. The strawberry-plant and fiorin grass are good examples.

STOMA. See STOMATA.

STOMACH. The first or digesting portion of the alimentary canal of an animal. The arrangement of it into four parts in ruminants, together with the manner in which these severally and co-operatingly perform its aggregate function, is noticed in the article RUMINATION; the first and the third parts of it in ruminants are described in the articles RUMEN and MANYPLUS; and the physiology and offices of it in animals in general are discussed in the article DIGESTION.

The horse's stomach has peculiarities of size, situation, structure, and habit which ought to be well understood by all persons who manage horses. It is remarkably small in proportion to the other parts or general bulk of the body; and has a form somewhat similar to the bag of a bagpipe; and is situated behind the diaphragm, principally on the left side, with its expellent orifice extending across the spine to the right; and being pressed by every motion of the diaphragm, and necessarily offering resistance to that motion during all the periods of its disten-

tion by food, its singular smallness is a beautiful provision to prevent painful or injurious interference with the process of respiration. "The situation of the stomach," remarks Youatt, "will at once explain the reason why a horse is so much distressed and sometimes irreparably injured, if worked hard immediately after a full meal. The stomach must be displaced and driven by every contraction of the diaphragm or act of inspiration, and in proportion to the fulness of the stomach will be the weight to be overcome, and the labour of the diaphragm, and the exhaustion of the animal. If the stomach is much distended, it may be too weighty to be forced sufficiently far back to make room for the quantity of air which the animal in a state of exertion requires. Hence the frequency and labour of the breathing, and the quickness with which such a horse is blown, or possibly destroyed. Hence also the folly of giving too full a meal, or too much water, before the horse starts on a journey or for the chase, and, in like manner, the absurdity and danger of that unpardonable custom of some grooms to gallop the horse after his drink, in order to warm it in his belly, and prevent gripes." The stomach has two surfaces, which may be called its sides, though one is posterior, and the other anterior,—and two extremities, a larger and a smaller,—the latter of which receives the œsophagus or gullet, while the former ends in the duodenum, and, when the stomach is distended, extends farther back than the other. The stomach is externally covered by the peritoneum, which adheres closely to it by means of its cellular membrane; and it has within this a coat or system of muscular fibres, which are stronger than those of the stomachs of oxen and sheep. These fibres run in various directions, but are principally longitudinal and circular; and the latter are very thick and strong around the extremity in which the gullet terminates. The inner covering of the stomach consists of two portions, a cuticular and a villous. The cuticular portion extends over nearly one half, and is possessed in common with the horse by only such other animals as live chiefly on grain; and it may be considered as, in a slight degree, a kind of gizzard, acting compensatorily for the want of power of thorough mastication. The horse, notwithstanding the grain-grinding structure of his teeth, is urged by the wants of his system to feed greedily and swallow hastily, so that he does not sufficiently masticate his food; and he therefore enjoys a peculiarity of coating over his stomach which acts in a triturating way, and ensures the digestion of half ground grain. The insensibility of the cuticular coat occasions many medicinal substances which act with great power or virulence on man, such as emetic tartar, verdigris, sugar of lead, blue vitriol, white vitriol, and arsenic, to have little effect on the horse. The villous coat is much more extensive than the muscular, and is thrown into comparatively large folds; and these are largest toward the gullet, and become less toward the duodenum, and form there a kind of valve which prevents a return of the food and regulates its passage out; and they afford in the aggregate an ample secreting surface for the gastric juice, and everywhere apply it equally to all the parts of the substances which are undergoing digestion. The terminating fibres of the gullet pass obliquely through part of the muscular and cuticular coats, and then arrange themselves at the orifice in a manner intermediate between that of a valve and that of a sphincter muscle, so as to present an insuperable obstacle to the regurgitation of food. A horse, therefore, cannot vomit.

STOMACHIC. A medicine which strengthens the stomach and excites appetite. In veterinary practice, it is closely allied to a cordial, but produces a more durable effect.

STOMACH (Inflammation of). See Gastritis and Braxy.

STOMATA. The minute orifices or pores in the epidermis of the leaves of plants. Most, though not all, have an oval outline, or appear like areolæ, with each a slit in its centre; but the edges seem like a sort of thickened sphincters capable of opening and shutting, and the slits vary in both size and form. They usually occur on the under surface of leaves which are freely exposed on all sides to the air, and on the upper surface of leaves which float on water; and they perform very important functions in the general economy of vegetable life and growth. See the article Absorption in Plants.

STONE. A piece of rock. When water-worn and small, it is a pebble; when water-worn and large, it is a boulder; when scarce, small, and beautiful, it is a gem; when cubical, compact, quarried and cut for building or for sculpture, it is a block; when stratified and fashioned into a slab for a floor or a foot-path, it is a paving-stone; and when laminated and split and dressed for roofing, it is a slate. A mass of pebbles, from the size of a pea to that of a small potato, constitutes gravel; a deposit of this with intermixtures of sand and organic remains constitutes gravelly soil; and any kind of diluvium or alluvium, containing either loose or landfast boulders or a considerable proportion of large pebbles, constitutes stony soil. See the article Gravel.

"It has been argued, and is not yet determined," said a distinguished agricultural writer of eighty years ago, "whether stones are hurtful or beneficial to arable lands. Examples are not wanting on both sides of the question; though in general, it seems rather to be carried for them. However, nothing can excuse leaving a stone in any ground so large as to interrupt the plough. If they are very large, they should be blown to pieces with gunpowder, and then be carried off. Some spots very fertile in several kinds of grain seem to consist of nothing but stones; and in-

stances are given of fields being rendered barren by taking away the stones which covered them. Theophrastus accounts for this in a hot country, where it happened to the Corinthians, by saying, that the stones shelter the earth from the scorching heat of the sun, and thereby preserve its moisture. The same holds true even in our colder latitudes, where the heat of the sun is less apt to hurt us; and Mr. Evelyn is clearly of opinion that husbandmen rather impoverish than improve those grounds which are almost covered with stones, especially where corn is sown, if they pick them off too minutely, because they thereby expose the land too much to the effects of heat and cold. Certain it is, that a moderate mixture of small gravel preserves the earth both warm and loose, and prevents too sudden exhalations. But it seems highly probable that there must be some further reason, beyond what has yet been assigned, for the benefit arising from stones." One 'further reason' is the assisting to keep open spongy and adhesive soils—and this has ceased to apply to the multitudes of once wet fields which have been improved and dried within the modern era of subsoil draining; and another and far more important 'further reason' is the composition of most of the kinds of stones,—and this both explains how the constant though slow disintegration of basalts, greenstones, clay porphyries, and especially calcareous limestones by the combined action of tillage implements and the weather maintains fertility by supplying alkalies and salts for the nutrition of crops, and shows how the presence of sandstones, quartzose stones, and pieces of stubborn plutonic rocks either adds very little powdery matter of any description to the soil, or adds only such as contains scarcely any food for crops, and therefore does no appreciable good. Some stones, too, which have a widely different composition, or resolve themselves into widely different granules, from those of the mineral portion of the diluvium or alluvium in which they are imbedded, may do good by correcting the mechanical defects of the soil by their debris, or by contributing principles which chemically co-operate with those in the soil for producing recombinations of an alimentary nature to plants. Hence, any farmer who has a fair knowledge of the nature and functions of soils, and of the composition of all the most common kinds of rocks, may generally determine at a glance whether the stones in any field are beneficial; and any farmer who has not such a knowledge, and who wishes to determine whether the clean removal of stones in any case will do good or harm, ought by way of experiment to clear them away from one corner or small portion of the field, and observe the effects upon the next year or two's cropping.

The lifting and removal of large landfast boulders is a principal operation in the reclaiming of some waste lands, and has sometimes been found perplexing and very difficult. An excellent apparatus for lifting the stones is a tripod machine described upwards of twenty years ago, by Professor Low, in the Edinburgh Philosophical Journal and in the Transactions of the Highland Society. This consists simply of a set of sheerpoles, about 14 feet in length,—a powerful tackle of pulleys suspended from the head of the poles,—an iron plug, comprising a ring, a flat part, and a cylinder of about an inch in diameter and two inches in length hooked to the lower block of the tackle, —and a windlass six feet or more long, worked by levers, and having at each end a winch. It is placed over the stone to be raised by extending the poles on three sides, and then the windlass is attached. If only a very small part of even a huge stone appear above the surface, it is enough; a circular hole must be drilled in it, with a mallet and the common steel-boring chisel of masons, about a sixteenth part of an inch less in diameter than the cylinder of the iron plug, and about two inches deep, and as nearly perpendicular as possible; the plug must be driven into the hole, to the depth of an inch or so, with a stroke or two of a hammer; and with no other fastening than this simple plug, the turning of the winches by as many persons as may be requisite will tear up the boulder, no matter though it should be of the utmost weight which a waggon can carry, through every opposing obstacle. The secure holding of the plug seems to result principally from the friction produced by the elasticity of the stone between the surfaces of the plug and the bore, and is so far exactly similar to the firm holding of a pin driven into a block of timber, with the difference that the elastic power of stone is incomparably greater than that of any timber; and perhaps it also arises partly from the circumstance that a line passing through the axis of the cylindrical plug will seldom if ever coincide with the vertical line passing through the stone's centre of gravity when suspended by the plug, so that the plug's resistance upon the sides of the bore is oblique, and occasions difficulty or impossibility of disengagement so long as the stone is in suspension. But when the stone is let down again, either on a cart or on the ground, the plug is loosened and let out simply by a smart stroke or two of a hammer near the edge of the bore. "We shall often be surprised, in trying the experiment on large pieces of rock," says Professor Low, "to observe with how slight a seeming hold of the stone the masses will be torn up. Sometimes the iron pin is not driven above the fourth part of an inch into the stone before it becomes immoveable, and capable of raising a weight of many tons from the earth. When we consider the greatness of the elastic power of the harder stones, as shown by this simple experiment, we may perhaps wonder that the ingenuity of man has not hitherto more applied so surprising a property to practical uses. It appears that, with a

little piece of iron driven into a stone, with a force which a child might exert, the largest vessels might be moored,—that, by the same means, masses of granite might be nailed as it were together, with a force which could hardly be overcome, and rocks suspended as by a touch in the air."

Another facile contrivance for both lifting and removing large landfast boulders is a modification of the well-known sling-cart,—a machine which seems to have been first brought out at Woolwich, and was long ago used there for the removal of heavy ordnance, and was afterwards employed at Arbroath for the removal of the large stones used in the erection of the Bell-Rock lighthouse, and has of late years become common in the constructing of all sorts of huge masonry and great public works. The modification of this machine used for lifting and removing landfast boulders, and invented by Mr. W. F. Robertson of Hazlehead in Aberdeenshire, is described as follows:—"The carriage-wheels are about 7½ feet in height, to admit of the stone being freely suspended under the axle, and are defended by two or three concentric slender rings of iron, attached to the inward face of the wheels, to prevent the stone from chafing the spokes. The shafts are connected by cross frame-work, after the construction of the common open cart, with the exception of the main bar, which in this case is made very strong, and to which the axle of the carriage is attached. On the upper side of the main bar is placed the frame-work of the crab: this consists of two cast-iron cheeks, strongly bolted to the main bar, and carrying a toothed wheel, with a drum or barrel, on which the purchase-chain is coiled. The wheel is acted upon by a pinion, which is turned by the application of manual power to winch-handles. The proportions of the machinery of the crab are such as to enable two men at the handles to raise a stone of three tons' weight. A small platform is attached to the main bar on which the two men stand who work the crab. The purchase-chain, having one end fixed to the barrel of the crab, and a hook at the other end, completes the working parts of the machine. The auxiliary parts consist of a pair of common stone-shears, together with a sling chain of three or four yards in length, a pick-hammer, mattock, spades, &c. When a stone is to be raised, the only preparation necessary is to expose, by digging, as much of it as will admit of the stone-shears getting hold, and, for this purpose, a small indentation is made on each side of the stone with a pick-hammer. The machine is then brought over the stone, the shears hooked on to the purchase-chain, and their hooked extremities brought to take hold of the stone, at the indentations made for that purpose; a rest or prop is also put under the shafts, to ease the horse, and keep the machine steady while loading. The crab is then worked by the two men at the handles, until the stone is raised from its bed, and to such height that the sling-chain can be passed under it; the purchase-chain is then eased off; the shears disengaged, and the sling-chain being now brought to embrace the stone, is hooked to the purchase; and, by again working up the crab, the stone is elevated till it swim clear off the ground. The substitution of the chain for the shears is necessary, in order to allow the stone to be raised sufficiently high; for, though the shears must be used in the first place to raise the stone from the ground, their length prevents it from being raised so high as to admit of transportation. The stone being in this manner suspended, its removal from the field is easy and expeditious." Mr. Robertson found that, when the stones are prepared by being dug about and marked for the shears, he was able to remove from 50 to 60 blocks, each weighing from one to three tons, to the boundary of a field of eight or ten acres in one day, and at an expense not exceeding one-half of what he incurred by any other method. The use of the simple plug-lewis and tackle instead of the stone-shears and chain would perhaps be an improvement; and the drilling of the hole for the plug might not, in the average, cost more than the digging and hammering for the stone-shears.—One of the most obvious of the common methods of dealing with large landfast boulders, as well as with slight, occasional, rocky protrusions, is to blow them to pieces with gunpowder, and remove them in fragments.

STONE. A weight of commodities. The legal stone is 14 pounds avoirdupois; but provincial stones, and stones of particular commodities, vary from 5 to 16 pounds. The old stone of glass is 5 pounds; the old stone of fish is 8 pounds; the old stone of wool, in Herefordshire, is 12 pounds,—in Gloucestershire, 15 pounds,—and, according to statute in the reign of the seventh Henry, 14 pounds; the old stone of beef, in London, is 8 pounds,—in Herefordshire, 12 pounds,—and in the northern counties, 16 pounds; and a common stone, both old and modern, both British and Irish, in the case of some particular commodities, is 16 pounds;—and a ton of stones, long weight, is 21 hundreds.

STONE. A disease. See STONE-IN-THE-BLADDER.

STONECHAT,—scientifically *Saxicola Rubicola*. A British bird, of the warbler group of Passerinæ. Its total length is 5½ inches; its head, neck, chin, and throat are black; its breast is rich chestnut; and the sides of its neck down to the wings are white. It resides in Britain throughout the year. Its nest is built on the ground, at the base of some low bush; and consists of moss, grass, hair, and feathers. Its eggs amount to five or six; and have a pale greyish blue colour,—the larger end minutely sprinkled with dull reddish brown; and each measures about 8½ lines in length, and 7 lines in breadth.

STONECROP. See SEDUM.

STONE-IN-THE-BLADDER. The formation and irritating effects of calculi in the urinary organs. The nature of the calculi is treated in the article Calculus; and the surgical operations for extracting them, in the articles Lithotomy and Lithotrity.

In horses, calculi occur sometimes in the kidneys, sometimes in the urethra, and sometimes in the cæcum, but very seldom in the bladder. Calculi in the kidneys of the human subject naturally fall by their own weight into the bladder; while those in the kidneys of the horse, in consequence of the horizontal position of the abdomen, remain fixed where they are. The presence of a calculus in a horse's kidney is not indicated by any certain symptoms, and cannot be remedied or controlled; but the presence of a calculus in his bladder is indicated by symptoms similar to those of spasmodic colic, and by the irregular discharge and occasional suppression of urine, and may be certainly ascertained by throwing the animal and introducing the hand into the rectum while he lies on his back,—and is capable of being treated in a similar surgical way as in the human subject, but requires to be dealt with by an experienced veterinary practitioner.

In cattle, calculi in the bladder are both much more liable to form, and much more likely to be retained, than in the horse; for they form round the granules of earthy matter which cattle somewhat freely swallow with their food, and they are hindered from naturally passing away in consequence of the comparative smallness and sinuosity of the urethra. Their presence is indicated by much fever, frequent gazing on the flanks, trembling of the hind limbs, ineffectual efforts to evacuate urine, and evacuations of it in small quantities and mixed with blood; and it may be certainly ascertained by introducing the hand into the rectum, and feeling the bladder. In all cases of proper stone in the bladder of ordinary cattle in tolerable condition, the most profitable course is to send them without loss of time to the butcher; but in cases of proper stone in the bladder in valuable animals, or in animals too poor for the shambles, careful lithotomy may be attempted with due regard to the peculiar structure of the ox's urinary organs; and in all cases, which not unfrequently happen, of the calculi passing naturally away, and being detained in small pieces in the urethra, and so obstructing the canal as to endanger life, recourse ought to be promptly had to a suitable surgical operation. A bullock whose urethra becomes obstructed by a piece of calculus may be seen to stretch himself out for a few minutes, to make ineffectual attempts toward evacuation of urine, to stamp his feet as if suffering much pain, and to kick his belly as if suffering from colic. "Unless he is at this time relieved," says Professor Dick, "the pain rapidly increases, inflammation of the bladder follows, and it becomes ruptured either by over-distention, or from its own effort to force out its contents; the urine escapes into the cellular tissue, or the cavity of the belly, producing inflammation of the peritoneal coat, which is followed by dropsy and death. When the operation is to be performed on an ox, the chief circumstance to be attended to is this:—On making the incision on the part where the calculus is retained, it is advisable to draw the skin a little to one side before making the incision through the skin, and, having done this, the urethra may either be raised out from its situation in the loose cellular membrane, with which it is here surrounded, and the incision made into the canal, while it is thus roused, or, if it can be done with readiness, the incision may be continued through all the parts, while they lie in their natural position. This latter operation, however, requires more dexterity than the other, and is also more apt to lead to untoward consequences; because, if the incision is not made freely, and at once through all the parts into the canal, the repeated incisions produce more or less laceration of the parts; and there is a considerable degree of danger that, from this cause, some of the urine, as it escapes after the opening is made, will flow into the cellular membrane, and produce a troublesome if not a dangerous degree of inflammation and infiltration of the tissue. After the bladder has completely emptied itself of urine, the parts may be allowed to resume their natural situation. The skin having been drawn to one side before the operation was performed, will now be drawn over the opening in the urethra, and thus the wound in it will be closed. After the bladder has been emptied, the urine will not again pass along the canal for a short time, and thus the parts will have so far reinstated themselves by adhesion, and a deposition of coagulum, that the urine will at next evacuation flow along the natural passage, and the animal feel but little the effects of the operation."

STONE PINE. See Pine.

STONE WALL. See Wall.

STONY LAND. See Stone and Gravel.

STOOK. See Shock.

STOOL. The living and shoot-producing stump of a timber-tree. See the article Coppice.

STOOP. A prop or post resting on the ground and supporting either a rick or a piece of masonry.

STORAX,—botanically *Styrax*. A genus of ornamental, exotic, corolliflorous shrubs, constituting the type of the small natural order Styracineæ. All the species of this order are handsome ligneous plants; and most are natives of North America. Four true storaxes, all hardy, white-flowered shrubs, have been introduced to Britain; and three more are known.

The officinal storax, *Styrax officinalis*, is a native of the south of Europe and of the Levant, and was introduced to Britain toward the close of the 16th century. It attains a height of upwards of 20 feet in its native regions; but seldom

grows to more than 12 in Britain. Its young shoots have a reddish colour; its branches are numerous and slender, and are clothed with a smooth greyish bark; its wood is finely scented, and exudes a fragrant resin; its leaves stand on short footstalks without any regular order, sometimes singly and sometimes in pairs, and are elliptical, pointed, entire or slightly waved, about 2 inches long and 1½ inch broad, lucid green in the upper surface, hoary in the under surface, and somewhat similar to those of the quince-tree; and its flowers come out in bunches of seven or eight from the sides of the branches, and have a large, monopetalous, funnel-shaped corolla, and emit a delightful fragrance, and bloom in July, but are not succeeded in Britain by any fruit. This plant does best to be raised from seed with the same appliances and care as a greenhouse plant; and becomes fit for taking its place in a final situation of the open ground when it is six or eight years old; and needs a dry soil of sandy loam and a warm and well sheltered spot; but it may be propagated also by layering.

The resinous exudation of the officinal storax has a place in the materia medica under the name of storax balsam, and is used in several pharmaceutical compounds. It possesses somewhat stimulating and expectorant properties, and was formerly prescribed rather freely in cases of catarrh, asthma, phthisis, and menstrual obstruction; but it is now employed principally or solely as an adjunct on account of its fragrance. It is used also in the composition of pastilles. Two kinds of it occur in commerce,—the one in tears, which is pure,—and the other in lumps, which contains intermixtures of sawdust and other impurities; and both kinds are imported from the Levant, and are there obtained from artificial incisions in the bark of the tree. The balsam consists of resin, benzoic acid, and empyreumatic oil; and has a reddish-brown colour, and a pleasant, aromatic, sub-acidulous, slightly pungent taste; and is brittle at the ordinary temperature of the atmosphere, and breaks with a shining, resinous fracture. See the articles Benjamin-Tree, Benzoin, and Pastille.

STORE FARMER. See Pastoral Farm.

STORK,—scientifically *Ciconia*. A genus of large birds, of the cultrirostrous family of grallæ. Their bill is thick and moderately cleft; their mandibles are light and broad, and produce a clash by striking against each other; their legs are reticulated; and their anterior toes, particularly the external ones, are strongly palmated at the base.—The white stork, *Ciconia alba*, sometimes though rarely visits England, but is more common in France, and passes the winter in several countries of Africa. Its total length is about 3½ feet; its general plumage is white; its wing-quills are black; and its bill and feet are red. It builds its nest on towers, steeples, and similar situations, and returns to the same spot in successive years. It destroys snakes and other noxious reptiles, and is greatly venerated on the Continent.—The black stork, *Ciconia nigra*, is also an occasional yet rare visitant of England. Its total length is about 3 feet 4 inches; its general plumage is blackish, with purple reflections; and its belly is white. It frequents solitary marshes, and builds in forests.

STORK'S BILL. See Pelargonium.

STOT. A steer or young bullock.

STOVE. A horticultural building for the protection and culture of tropical plants. See the article Hothouse.

STOVEN. A shoot from the stool of a fallen tree.

STOVER. Fodder from the straw and chaff of thrashed corn.

STOWK. The handle of a pail.

STOWRE. A round of a ladder, a hedge-stake, or a stave in the side of a waggon.

STRAIN, or Sprain. A rupture of the cellular tissue and minute nerves of membranes, ligaments, or muscles. Strains frequently occur in horses,—and much more frequently in those who make sudden and violent exertions than in those who perform only slow and steady work. They do not, as is commonly supposed, consist in extensions of ligaments, but are ruptures of minute cells and vessels, followed by inflammation and swelling. In all kinds and degrees of them, rest is a grand and essential remedy; in moderate ones, embrocations and bandages are usually serviceable; and in very severe ones, bleeding, blistering, and opening medicine are sometimes necessary.

A very bad kind of strain to which horses are subject is noticed in the article Back-Sinews.—A strain in a horse's shoulder is indicated by his extending the limb with difficulty, inclining it a little outward, and carrying his head and neck a little to the one side. An ordinary case of it may require bleeding, the administration of opening medicine, the placing of a rowel in the chest, and the rubbing of the whole shoulder two or three times a day with ammoniated soap liniment or some similar embrocation; and a bad and stubborn case of it, which does not yield to these remedies and to a long continued rest, and which seems to involve a permanent contraction of the muscles, may possibly be alleviated by means of frequent swimming.—A strain in the muscles of the back sometimes accompanies ossification of the vertebral ligaments, and should be treated with bleeding, laxatives, stimulating embrocation, and the use of a fresh sheep's skin on the back. See the article Anchylosis.—A strain of the hip joint, though often identified by ignorant persons with almost every kind of obscure lameness in the hinder parts of the horse, is really of rare occurrence; and when it does happen, it may yield to rest and an extensive blister, but is more likely to prove incurable.—A strain of the stifle joint is indicated by swelling and tender-

ness of the part, and by difficulty in bringing forward the hind leg; and as it is commonly deep seated, it must be attacked by blistering.—A strain of the knee is generally complicated with other injuries of the part, and may require in addition to the common remedies for strains, the application of a large poultice by means of a stocking or a flannel bag. See the article Broken Knees.—A strain of the fetlock joint usually arises from some sudden and violent exertion, as in leaping, and is sometimes accompanied by displacement of the sesamoid bones; and must be attacked by bleeding, physic, and poultices. See the article Fetlock.—A strain of the coffin joint is indicated by the horse's being able to walk soundly while he is very lame in a trot, and by great heat in the foot, extending to the pastern, and sometimes accompanied by swelling round the coronet; and it requires the shoe to be removed, the sole pared thin, and the whole foot, after taking a considerable quantity of blood from the toe, to be wrapped in a large poultice; and if it be very bad or obstinate, it may require also the blistering of the pastern.

Cattle, or even working oxen, are vastly less subject to strains than horses, and do not require to have them treated with the same sedulousness and nicety. Any ordinary recent strain in cattle may generally be cured by frequent fomentations with warm water, and frequent bathings with a mildly stimulating embrocation; a severe one may require to be treated also with bleeding and physicking; and a very deep-seated one must be attacked with a free-rubbing in, every morning and evening, of a powerfully stimulating embrocation, such as one consisting mainly of olive oil and spirit of turpentine, and containing some oil of origanum and some cantharides. A strengthening plaster, in the form of a charge, may also be useful. An ordinary strain in the fetlock of the ox may be reduced by a diligent alternate use of a mild and of a powerful embrocation; but a bad one may require blistering or even the cautery; and if it be very stubborn, and involve considerable lameness, the nerve which comes down to the foot from above the fetlock may be divided so as to destroy sensation.

Strains sometimes, though not often, occur in the fetlock-joint of sheep; and must be treated with rest, fomentation, and poultices; and, if they be very bad, they may also require either a strongly-stimulating application or a mild blister.

STRAMONIUM,—botanically *Datura Stramonium*. A hardy, medicinal, annual plant, of the thorn-apple genus and nightshade order. It is a native of America, but has become naturalized in England, and occurs wild on rubbish and dunghills and by the sides of roads in the vicinity of London and in other places. Its stem is cylindrical, leafy, branching, spreading, and about two feet high; its leaves stand on long, cylindrical footstalks springing from the forks of the stem, and are large, triangularly ovate, sinuated, dark-green above, and pale below; its flowers stand on short erect footstalks, and are axillary, solitary, and large, and have a white funnel-shaped corolla, and bloom in July and August; and its fruit are large, ovate-roundish, four-cornered, fleshy capsules, armed with sharp, awl-shaped spines, and containing each a great number of compressed kidney-shaped seeds. The whole herb has a fetid narcotic odour, and a nauseous bitterish taste; and possesses stimulant and narcotic properties. The root, the leaves, the seeds, the capsules, the whole herb in a dried state, and the inspissated expressed juice of the leaves are variously used in medicine. But both the fresh plant itself and some of the herbal and pharmaceutical preparations of it act with great potency, and have been known to produce convulsions, dreadful delirium, paralysis, and death, and ought never to be used except according to the prescription of a regular physician. An analysis of the plant by Promnitz found 58 parts in 178 to be gummy extractive, 6 extractive, 64 chlorophylle, 15 albumen, 12 resin, and 23 phosphate of lime and magnesia. A peculiar principle called daturine exists in the seeds in the form of a malate; and, when separated, crystallizes with difficulty, yet has been obtained in quadrangular crystals; and it combines with acids to form neutral salts, and is nearly insoluble in water.

STRANGLES. A disease of young horses. It generally attacks them in their fourth or fifth year; and is regarded by some veterinarians as a specific or constitutional disease which every young horse is liable to have once, and which no horse has twice. It commences with swelling under the jaws, cough, dulness of the eyes, and some degree of fever; it passes into semipurulent discharge from the nostrils, soreness of throat, increased swelling, eventual suppuration, and disinclination or inability to drink or to take more than a very little food; and it sometimes becomes so violent and spreading as to prevent swallowing, to threaten suffocation, and to set up inflammation in the lungs, accompanied with very hurried breathing. Many colts at grass get through the disorder without assistance from man; yet even colts which are least seriously affected ought by all means to be assisted, and those who are most seriously affected may require the utmost efforts which veterinary skill and sedulous care can make. Constant fomentation, or the application of large poultices, or the appending of steaming mashes to the head, accompanied with stimulation or blistering of the jaw, ought to be practised till the tumour 'points' and ripens; and then the suppuration should be let out at the point, and a pledget of tow introduced to keep the abscess open for a few days, and the horse allowed only green food, and led occasionally into gentle walking exercise;

and when the symptoms relax and the appetite returns, abundant nourishment may be given, accompanied, in cases of great debility, with malt mashes and tonic medicines. Bleeding, in any of the active stages of the disease, is improper, and may be mischievous except when inflammatory action is indicated at all in the lungs or highly in the approaches to them; and then it becomes requisite for the reducing of the inflammation. "The period of strangles," says Mr. Castley, "is often a much more trying and critical time for young horses than most people seem to be aware of; and when colts get well over this complaint, they generally begin to thrive and improve in a remarkable manner, or there is sometimes a great change for the worse; in fact, it seems to affect some decided constitutional change in the animal."

STRANGURY. Inflammation or spasmodic affection of the neck of the bladder. It sometimes arises in the horse from blistering for other and more serious inflammations; and when it occurs, the horse should receive a dose of Epsom salt, a plentiful supply of linseed tea, and a dose every six hours of opium and camphor made up with treacle and linseed meal into a ball. See the article Inflammation.

STRANVÆSIA. A genus of exotic ligneous plants, of the rosaceous order. The grey-leaved species, *S. glaucescens*, is a hardy, evergreen, small tree, of about 20 feet in height, carrying white flowers in June; and was introduced to Britain about 20 years ago from Nepaul; and thrives in any common soil, and is propagated by budding. It is regarded by some botanists as a hawthorn.

STRAPWORT, — botanically *Corrigiola*. A genus of ornamental, trailing, herbaceous plants, of the purslane family.—The sand or shore strapwort, *Corrigiola littoralis*, grows wild on the southern coasts of England. Its root is annual, small, and tapering; its stems are flaccid, not much branched, and several inches long, and spread in every direction on the ground; its leaves are scattered, simple, linear-lanceolate, obtuse, glaucous, and somewhat fleshy; and its flowers grow in terminal or lateral subdivided or interrupted clusters, and are numerous and often sessile, and have a white, pearly colour, and bloom in July and August.—The Cape and the orpine-leaved strapworts, the former an annual from the Cape of Good Hope, and the latter a perennial from the South of Europe, closely resemble the indigenous species in at once flower, habit, and treatment; and all are propagated from seeds on the open border, in the manner of ordinary hardy annuals.

STRATH. A valley flanked by mountains. The word is Scottish; and is applied in some instances to a glen and in others to a plain,—in some to a single valley traversed by a stream, and in others to a chain or series of valleys without any reference to particular water-courses.

STRATIOTES. See Water Soldier.

STRATUM. See Geology.

STRAW. The dried culms of the cereal grasses, —and, by a loose or extended use of the word, the succulent culms of the cereal grasses, either the dried or the succulent stems of sarcolobous field leguminous plants, and either the dried or the succulent stems of some of the large, grass-like, non-gramineous forage plants. Straw, in the proper sense, is employed mainly and largely for litter and fodder, and very considerably for thatching; and straw in the extended sense, is employed mainly and in various ways for fodder; and they are largely discussed, both in articles on their aggregate uses, and in the articles on the several crops which produce them. See, in particular, the articles Fodder, Food of Animals, Feeding of Animals, Chaff, Haulm, Litter, Hay, Soiling, Horse, Wheat, Oat, Barley, and Rye.

The relative value of different species of straw for fodder is greatly controlled by the character of the soils on which they are grown, by the stage of growth or of ripeness at which they are reaped, by the condition in which they are harvested and kept, by the degree of freshness or of age at which they are used, and by the amount and kind of preparation which they undergo. "It is thought," says the Useful Knowledge Society's Treatise on British Husbandry, "that, when grown on gravelly or rich clay soils, straw is more valuable as fodder than when it is reared on black deep loam or cold moorish land; and it is now generally admitted that it possesses more succulence when the corn is rather green than when it is in a riper state. It is supposed by many that the straw of wheat is the most nutritive; it certainly makes the strongest manure, and is thought to be the best for either steaming or cutting into chaff; although that of oats is usually preferred as more soft and more palatable to cattle. That of barley is so poor and brittle, that it is only employed as litter; it is extremely difficult to save it in any tolerable degree of order; and though it has been said to possess more nutriment than that of wheat, yet, when the crop is fully ripe, the ears break off in handling, which has been contended as sufficient proof that it contains but very little sap. Rye-straw is so scarce in all except the northern counties and some parts of Wales, and is in such demand for thatching, brick-making, &c., that it is but seldom applied to other uses." Straw of any species in a well-harvested and perfectly fresh and sweet condition is greatly better than straw of the same species in an ill-stored or untidy or too old or somewhat musty state; straw cut into small pieces in the form of what is technically called chaff is greatly better than straw in its entire length; cut straw in mixture with some more nutritious substances is greatly better than cut straw alone or in mixture with comparatively innutritious substances; and a mixture of cut straw and more nutritious substances in a

steamed or boiled or otherwise cooked condition is greatly better than the same mixture in a raw condition.

A correct estimate of the relative nutritious values of the different species of straw and haulm, viewed intrinsically or without reference to the diversities in each arising from soil and culture and condition, could be formed only by striking the average of careful chemical analyses of specimens of each species, of the different qualities of it in use; and as this is unattainable and even unapproachable in the present state of our knowledge, an estimate by Veit, one of the ablest Continental agriculturalists, founded on extensive practical induction, may be substituted. "The straw of the common leguminous crops," says he, "especially of lentils, vetches, and pease, is more nutritious than the straw of seed clover. The greener the tips are, the less it is lodged, the better can it be dried and brought in, the more nourishing it is. The straw of lentils and seed-clover is the most preferable. The fine stalk vetch straw is also very nutritious; behind which stands somewhat the pea-straw, with its thicker stalk. All straw of leguminous fruit is particularly a welcome fodder to sheep, on which account therefore it is greatly prized by many sheep-owners, and considered equal to hay.—Oat and barley straw, is the straw for fodder of the cereal crops. Oat straw is most agreeable, and also most nutritious, on account of its peculiar taste for all species of cattle, because on the tips of the panicles are usually found unripe grains, and oats are generally cut before they are fully ripe. Barley straw has, on account of its moisture and short period of vegetation, a high value as fodder, and, other things being equal, is as nutritious as oat straw, if it were not, as is the case, fully ripe before reaping. Yet it is more liable to injure than oat straw, because after reaping it imbibes more moisture from the air and soil.—Straw of summer wheat, summer speltz, and summer rye, for fodder, stands after oat and barley straw; but in many farms, where the straw of the usual species of winter grains supplies the need of litter, it is employed for especially the moister straw of summer wheat, and summer speltz. That of summer rye is less nutritious.—The stalk of maize contains much saccharine matter, and therefore is very nutritious used fine, and agreeable to all kinds of cattle. The cobs, after the corn has been taken off, ground up, are likewise a very nutritious fodder, and the hard stalks may be chopped up for the purpose. Taking all these things into view, it stands next to the straw of summer rye in value as fodder.—Millet straw has a hard stalk, but contains at least as much nutritious matter as the straw of the winter cereals, at the same time that millet is cut before it is fully ripe. Buckwheat, on account of its quantity on a field of less fertility, and if of fine stalk, in which case its value as fodder from its straw being rich with leaves, is enhanced, is as good as the straw of the winter grain. The straw of the usual winter grain crops, as of barley, wheat, speltz and rye, has less value as fodder, and is therefore employed more for litter. Rye straw is the least valuable for fodder of the straw of all the cereals. Bean straw, in case its leaves have not fallen off or are decayed, and the ends of the stalk are green when it is cut, as many experiments have shown, has a much higher value as fodder than is usually supposed. If the very hard stalks are chopped fine, and scalded with juicy fodder mixed with it, the nutritious quality of it is little inferior to that of the straw of other leguminous plants."

The substances suitable to be mixed with cut and cooked straw as food for working animals and for milch cows, are various, and have already been partially discussed in the articles Horse, Cow, and Food of Animals. Some of the most nutritious are crushed oil-cake and the several preparations and mixtures of linseed, cole-seed, and oatmeal. "An American farmer obtained an excellent fattening substance for his oxen, by mixing with a decoction of lint-flower, straw heated in boiling water, colza-powder, and oatmeal, the whole seasoned with a little salt; for the same purpose a jelly has been employed in England, made of linseed, boiled for two hours, after being left to macerate in water during twenty-four hours. It is mixed with straw or wheat chaff. Several experiments of this kind, repeated in America, have afforded successful results in the fattening of cattle. Linseed has been boiled in a quantity of water sufficient to form a jelly of moderate consistence; the boiling should be continued for an hour and a half, and it is necessary to stir the mass frequently, that the seed be not burnt. To two measures of linseed there are added three of bruised barley; and when the whole is well boiled, it is mixed with four measures of chopped straw, and given warm to the animals which are to be fattened. Should they refuse this food, from not being accustomed to it, they are readily habituated to it, by mixing a little molasses with it, and by giving them but a very small quantity at first. Cattle may also be fattened by mixing straw while still moist and warm, with meal or flour, such as of barley, wheat, pease, oats, maize, &c., or with bruised seeds. It is proved that seed given entire produces the loss of a tenth part in nutrition, a tenth part being voided by the animals without undergoing any change. The seeds are bruised by passing them between two cylinders. If moistened and brought to germination, they are more nourishing. When the seeds cannot be bruised, they are rendered more digestible by being steeped in water for half a day. Bread crumbled and mixed with straw, affords a still more nutritious aliment than seed or meal, and it would probably be advantageous to give it in preference. Bran contains little alimentary substance, but it may be

increased by moistening it with water, and allowing it to ferment until it sours. When the object is to feed beasts well without fattening them, the quantity of the above substances, mixed with the straw, is diminished, or they are substituted by others, according to the products of each locality. Thus, pease, vetches, lupines, beans, millet, and especially maize, after being bruised or macerated in water, and mixed with straw, furnish an excellent food. The leaves of cabbage, and various leguminous plants, those of the elm, poplar, ash, maple, and oak, afford an advantageous mixture. Roots, especially carrots, turnips, and potatoes, are not less profitable. In wine countries, the refuse of grapes may also be employed; in short, almost whatever comes to hand of farm produce. Salt ought always to enter into these preparations. The liking which cattle of all kinds evince for this substance, proves how useful it is to their health, and how much it adds to the energy of their digestive powers. The leaves of various plants may be made to undergo preparations, rendering them more inviting and more salubrious to cattle. Those of most of our forest trees, dried, and sprinkled with salt, yield an excellent fodder, which may be mixed with chopped straw. In Prussia and some other parts of Germany, a kind of choucroute is prepared, by putting cabbage, and even clover, in large stone receptacles, after chopping them and sprinkling them with salt. The mixture is then allowed to ferment, and yields an excellent food. The peasants of Swabia preserve the leaves of cabbage, beet, radishes, salads, &c., for feeding their cattle. After throwing them into boiling-water, they heap them up in boxes, five or six feet square, which they construct of boards, fastened to four uprights; they then cover them with boards, on which they place stones. Every eighth day they add new layers of leaves, which they take care to salt. The whole becomes sour, and is preserved for winter use." [*Annales de l'Agriculture Francaise.*]

The use of straw for litter is noticed in the articles Litter and Stable; the proportioning and intermixing of it with fæces, in the article Farm-Yard Manure; the part which it plays as a fertilizer, in the article Manure; and the designs and principles of economizing it upon a farm, in the article Lease. "The stalks of wheat, barley, oats, rye," remarks Mr. Donaldson, "with occasional mixtures of spoiled hay, and the haulm of vetches, pease, and beans, being mixed with the fæces of the animals, much augment the bulk, and materially affect the quality of farm-yard manure. The constituent parts of those substances, as shown by chemical analysis, are principally earths and earthy and soluble salts, and in different proportions, which by entering into combinations with the animal and more easily soluble matters in the dung, retard the too rapid putrefaction of these substances, and constitute, with proper mixing and preparation, by far the most efficacious and durable fertilizer yet known." "All the various sorts of straw," says Sir John Sinclair, "answer the purposes of litter. Some farmers prefer the straw of rye, others that of wheat, which absorbs a great quantity of urine and moisture. The straw of pease and beans, when well broken by threshing, makes soft bedding; but, if well harvested, should be applied to feeding stock. Cattle, when soiled on clover, and other articles, or fed on turnips, are kept in a state of greater comfort when they have a sufficiency of litter. In the London markets, straw for litter is drawn straight in handsome trusses; and if threshed in mills, is less saleable, on account of its being more bruised, less sightly in the truss, and less durable in use, an object of some importance where straw is so dear; at the same time, it is probable, that the advantage of a softer bed for the horses would more than compensate for the additional expense. It is singular that the ancients were accustomed to break straw upon stones, for the purpose of rendering it more easily mixed with dung, sooner dissolved, and better adapted for litter; an operation which is now so effectually done by means of the threshing-mill. By some, littering stock with straw, has been considered to be unnecessary; others contend that all the straw of a farm ought to be exclusively appropriated to that purpose, and none of it applied to feeding stock: the truth seems to lie between these extremes. In Arabia, where the finest horses in the world are kept, no straw is used as litter. In Sweden and in Russia, instances are quoted of horses lying on boards, and of cattle standing and lying on a framing of wood-work, without any straw, or substitute for it, as bedding. Such plans, however, will not answer for horses, if exposed to severe labour, as, in that case, they require rest, in the most advantageous manner in which it can be given them. It may likewise be observed, that the principal advantage of littering, with a view to manure, arises from the straw absorbing the urine, for which purpose it is certainly well calculated. But wherever straw is scarce or dear, peat earth, or fine mould, might be advantageously employed for the mere absorption of urine. Other substitutes also might be used for litter, as fern, shellings of oats, or small shell sand, all of which have been found to answer. Straw, however, is the fittest article for this purpose, for, by fermentation, it is reduced into a gaseous state, and by moisture into a fluid state, and in either case, its whole substance is applicable as food for plants. The more of that article, therefore, that can be converted into manure, consistently with the other objects which require the farmer's attention, so much the more will his interest be promoted. Mr. Young was of opinion, that it was impossible to raise sufficient quantities of manure, more especially where soiling was practised, if any straw

were eaten; and the number of the best farmers in Norfolk maintain, that all straw should be used as litter, and trodden into dung, by animals feeding on much better food, as turnips, hay, or oil-cake. The principle is a good one; but it can never be generally carried into effect. All farms, as now cultivated, do not produce turnips, which is the best article to use for rotting straw, from the immense quantity of urine it produces; though there are many, in which that crop is now unknown, where a greater or lesser quantity of that valuable root might be raised. In regard to hay, or oil-cake, these articles are too expensive, and often too scarce, to make the use of them general; and, besides, such dry food furnishes little moisture to the dunghill, without which it cannot be so effectually converted into manure."

The proportion of straw produced on an acre or field or entire farm has been estimated roughly and averagely at twice the weight of the grain, —and more proximately as 100 lbs. of straw to 47 lbs. of grain in the case of winter wheat, 100 to 40 in the case of winter rye, 100 to 55 in the case of summer wheat, 100 to 45 in the case of summer rye, 100 to 63 in the case of oats, 100 to 66 in the case of barley, 100 to 43 in the case of pease, 100 to 48 in the case of vetches, and 100 to 42 in the case of beans; but it widely differs both in different varieties of one species in the same circumstances of soil and culture and season, and in the same variety of a species in different circumstances of soil and culture and season. In some leases, the straw of all the years of the tenure, and of all the crops raised, is required to be consumed wholly on the farm; and in others, it is allowed to be sold either according to the farmer's pleasure, or on condition of its being replaced on the farm by a compensating amount of some other fertilizer. In some, the straw of the last year's crops is reserved for the use of the landlord or of the incoming tenant without any remuneration; in others, it is reserved for the use of the landlord or of the incoming tenant upon a valuation according to the custom of the estate or of the county; and in others, it is allowed to be sold by auction or otherwise and removed to any place the purchaser pleases. When straw lies in a quadrangular compressed heap or rick, it may be sold by measure in the same manner as hay, 18 or 20 yards being reckoned for a ton according to the degree of the compression or comparative density; and when it lies in bundles, the weight of a small number of medium size may be ascertained by weighing them, and assumed as a datum for reckoning the weight of any great number or of the whole. Good straw suitable for the purposes of both fodder and litter has commonly ranged in market value between 20s. and 30s. per ton; wheat straw tied up is usually reckoned worth 10s. per ton more than wheat straw in a loose state; and the straw of barley and oats, when sweet and suitable for fodder, is commonly rated a few shillings per ton higher than loose wheat straw.

Straw, of various qualities and in various states, is used for mixing with argillaceous earth to make the walls and roofs of poor country houses,—for twisting into ropes to form drains and to serve other purposes,—for mixing with sea-weed to make a fertilizing compost, — for burning to yield potash from its ashes,—for bottoming chairs,—for stuffing horses' collars,—for manufacturing into paper,—for making straw mattresses,—for packing glass, china, and earthenware,—for manufacturing straw-hats, straw-bonnets, and several kinds of straw ornaments and trinkets,—and for a number of other purposes ranging from very coarse to very fine.

STRAWBERRY, — botanically *Fragaria*. A genus of hardy, evergreen, stoloniferous, fruiting herbs, of the rosaceous order. Two species grow wild in Britain; eleven have been introduced from other countries; and many permanent varieties, some natural and others the result of culture, occur in collections or in gardens. The appearance of all is similar; and that of the most common is so universally known as not to require any description. Three species are respectively red-flowered, yellow-flowered, and apetalous; and all the others are white-flowered. Most naturally bloom in April and May; but two or three naturally bloom at other periods; and varieties can be selected to yield a succession of fruit in the open air during seven or eight months of the year,—and to yield it with the aid of the forcing-house during the remaining four months. Most love a soil of rich loam; and all may be propagated from runners. Strawberry plants are favourites of most persons, and deserve to be high favourites of all,—their stoloniferous habit is so curious, their evergreen, low-spreading foliage so beautiful and refreshing to the eye, their elegant and charmingly scented blossoms so grateful to the sense of smell, and their handsome and brilliant fruit so salubrious and luscious and delightful to the palate. The popular name strawberry alludes to the ancient practice of placing layers of straw among the plants to prevent the fruit from being dashed by rain and polluted with the soil; and the botanical name fragaria alludes to the delicious fragrance of the fruit. But the fragrance, notwithstanding its great power and richness, soon dissipates after the fruit are gathered, and is so attenuated or decomposable as to escape every effort to catch and concentrate it by distillation; and the fruit, though popularly called berries, and though similar in appearance to some true berries, particularly to those of the bramble genus, are really not berries at all, but large, fleshy receptacles, having the seeds upon the exterior.

The common wood strawberry, *Fragaria vesca*, grows wild in the woods of Britain, and has long

been allowed a place in many a garden. It loves a soil of sandy loam, or a soil otherwise light, rich, and warm; and it may readily be raised from seeds, sown as soon as ripe, and cleared of pulp,—the seedlings to be finally bedded out in the following spring. Its fruit is red and small, and has a sweet tartish taste. A variety of it with white fruit, commonly called the white wood strawberry, ripens a little later in the season, and has a quicker and to some persons more grateful flavour, but is generally less prolific. Another variety with green fruit, commonly called the green strawberry, the green pine strawberry, or the pine-apple strawberry, has a small, firm, much-admired fruit of high, rich, peculiar flavour. It is late in ripening, and requires a dry soil and an open situation, and may be grown at such small distances as six inches from plant to plant, and either allowed to run together or kept separate.

The hautbois or hautboy or taller strawberry, *Fragaria elatior*, though not indigenous in Britain, grows wild in some of our woods, and is a wide-spread native of other lands, and probably was introduced to Britain from both the old world and the new. It is supposed to have got its name from being found wild in the high woods of Bohemia; and it was long a chief favourite among the cultivated strawberries of British gardens. Some of its flowers are occasionally or perhaps constantly defective, or, in popular phrase, "blind;" and the plant, though belonging to the Linnæan class Icosandria, has some claims to be considered diœcious. Its fruit are middle-sized, round, and somewhat depressed, —dark red when exposed to the sun, but otherwise dull white; and the pulp is substantial, greenish, very sweet, and has an agreeable musky flavour. This species loves a light, sandy soil, kept moderately rich by biennial applications of manure; and when it is wished to produce large crops without fastidious regard to quality, it may be allowed to overrun the whole surface of the ground, and it will then maintain itself in vigour and yield a prolific produce for a series of years, with the simple aid of an occasional top-dressing of old hot-bed dung.—A variety of it called the prolific hautbois strawberry, not only bears well at the usual season, but sometimes yields a second crop in autumn. The fruit is large, dark red, swollen at the base, and contracted toward the point; and the pulp is solid, greenish, and of a fine musky flavour. This variety, however, is in its prime in the second year, and becomes exhausted in the third.—Two other varieties, called the globe and the flat, differ from the normal plant principally in the shape of the fruit.

The Chili strawberry, *Fragaria chilensis*, was introduced to Britain in 1727. It has large, thick, hairy leaves, on very strong hairy footstalks; and carries large and frequently deformed flowers in May and June; and is a vigorous grower, but an uncertain bearer. Its fruit are very large, irregularly shaped, often deformed, and of a brownish white colour, with a little red on the sun-exposed side; and the pulp is white, very firm, hollow at the centre, and of a rather flat flavour, especially when quite ripe. When this plant grows on strong land, in a shady situation, and is allowed to run together, its produce is sometimes tolerably bulky, and has the recommendation of being ripe for use about the time the crops of most other kinds of strawberries have been all consumed.

Wilmot's superb strawberry resembles the Chili in habit, but excels it in size of fruit and in certainty of bearing, and is one of the finest varieties in cultivation. The fruit is irregular in shape, has large prominences on two or three sides, attains a weight under good culture of upwards of an ounce, and sometimes of two ounces, and has a shining red colour, somewhat shaded with a deeper tint; and the pulp is coloured, firm, and almost solid, and has an excellent flavour. The stems which carry the fruit are strong, and in general clustered; and some of them are benefited by being tied up. New plantations of this strawberry should be made every second year; the soil chosen for it should be a fresh soft loam; no strong manure should be applied, and only occasional top-dressings; and the runners should be frequently cleared away to such an extent as to leave merely a sufficient number to form new plantations.

The scarlet Virginian strawberry, *Fragaria virginiana*, was introduced from North America in 1629; and long possessed a fame in British gardens similar to the hautbois; and is still one of the most generally suitable for cultivation whether in the open ground or by forcing. It is a good bearer; and loves a soil of rich loam; and ripens in the south and centre of England in the latter part or toward the end of May. The fruit is middle-sized, somewhat pointed, and of a bright scarlet colour; and the pulp is firm, and has a fine flavour.

The Duke of Kent's scarlet strawberry, or the Austrian scarlet strawberry, is a prolific bearer, and ripens in the south and centre of England about the middle of May, and is accelerated in ripening by being planted on a sloping bank or sloping border with a warm exposure. The fruit is less than middle-sized, nearly spherical, and of a scarlet colour; and the pulp is solid, juicy, and highly flavoured. New plantations should be made in such order as to allow all plants to be uprooted and thrown away after their third year; the soil should be a mild, kindly loam, not overdosed with manure; and the distances between the plants should be 12 inches from row to row and 9 from plant to plant.

The Lewisham or cluster scarlet strawberry is a prolific bearer, and produces a succession of fruit through a considerable period. The fruit resists the bad effects of wet weather better than

that of most other varieties, but requires to be perfectly ripe before being gathered for use. It grows in clusters, and is round, rather small, and of a dark red colour; and the pulp is firm.

The Grove-End scarlet strawberry ripens a little later than the scarlet Virginian, and is a good successor to it, and bears prolifically, and is well deserving of cultivation. The fruit are rather above the middle size, well shaped, and of a bright red colour; and the pulp is juicy and rather firm, and has a flavour similar to that of the Virginian.

The new Southampton scarlet strawberry, or Godfrey's new scarlet strawberry, is an abundant bearer, and well worthy of cultivation, and thrives best in a rather heavy rich loam. The fruit is middle-sized, of a dark red colour, and eminently suitable for jam; and the pulp is firm, very juicy, and of a rich vinous flavour.

Wilmot's late scarlet strawberry is a rather inferior bearer, and not at all remarkable for aggregate excellence; but it yields a long succession of large fruit, and on that account deserves a place in a large establishment. The fruit has a light red colour; and the pulp is firm, with a small cavity in the centre, and has only a middle-rate flavour.—Knight's large scarlet strawberry resembles Wilmot's late scarlet in at once size, colour, and general qualities.

The Roseberry strawberry bears well in the open ground, and is peculiarly suitable for forcing. The plant has a peculiar habit, and carries its fruit near the ground; the foliage is short and compact; the fruit is large, a little pointed, and of a pale scarlet colour; and the pulp is substantial and juicy, and has a fine pleasant flavour. Some soft substances, such as straw or lawn-grass, should be spread beneath the foliage before the plants come into flower.

The Pitmaston black strawberry is a late ripener, and produces a convenient and very desirable succession after the earlier varieties, and well deserves a place in every considerable garden. The fruit is somewhat oval, rather above the middle size, and of a deep red colour both without and within; and the pulp is firm, juicy, and finely flavoured. The soil most suitable is a rich hazel loam; and it should be enriched only with slight top dressings.

Keen's seedling strawberry is prolific, and produces its fruit in clusters, and is well adapted for forcing, and yields fine crops, with comparatively little expense or trouble, during April and May. The fruit is large, of a dark scarlet colour, and variously shaped, but chiefly spherical; and can be carried to a distance with less risk of injury than the fruit of most other varieties; and the pulp is substantial, coloured, and of a rich flavour. The plant is a vigorous grower, and, either on beds or in quarters, requires ample room; and the fruit grows in clusters, which need to be tied up. A variety called Keen's imperial strawberry also possesses good properties, yet is inferior to Keen's seedling.

The old black pine strawberry is one of the best of a considerable class of varieties called pine strawberries. It is very prolific, and requires more space for every plant than the old scarlet Virginian. The fruit is rather larger than middle size, generally pine-shaped or conical, but sometimes globular, and always of a deep red colour; and the pulp is firm, coloured, juicy, melting, and of a rich flavour.

The Downton strawberry is a peculiar and very splendid variety. The leaves have a shining green colour, and stand on very short foot-stalks; the fruit is large, various in shape, and of a deep red colour; and the pulp is firm, coloured, melting, and of a high and delicious flavour. The plant is prolific in the first and the second years, but becomes comparatively barren, though of increased size, in the third; so that it must not be kept longer than two years. Comparatively few runners are produced; and they must be well cared for, and allowed to remain where they grow till they become sufficiently strong for removal to their final destination. The trusses of fruit grow on long foot-stalks, and are peculiarly liable to sprawl on the ground, and to become damaged or destroyed by the weather and slugs and the soil; and they should be propped or tied up with short sticks. This variety thrives best on a moderately light and rather dry loam.

The British Queen strawberry is a somewhat recent and very remarkable variety. It is an abundant bearer and a very free grower, and produces large and beautiful fruit. "As to size," said a critical notice of it at the time when it began to challenge the attention of cultivators, "we have measured many which averaged six inches in girth; as to weight, we picked out 17 that weighed 16 ounces; as to productiveness, we have found several stems a foot high bearing from 5 to 7 strawberries,—and in two cases there were 10 and 11 on a stem; finally, as to quality, the variety is inferior to the old pine, but is better than Keen's seedling, having more flavour. It is, in fact, a very delicate, agreeable variety, without the insipidity and wooliness of the coarse and large strawberries. These are, we believe, its true characters. The next question is, how far it has claims to be regarded new? The only variety with which it can be compared is the Downton, itself one of our best strawberries, and sometimes nearly as large as this. We, however, do not think it the same; it has much less acidity, and does not require to be almost black before it is eaten; on the contrary, its greatest excellence seems to be when it is of a clear bright rose colour; nor is its flesh so firm as that of the Downton."

The old Carolina strawberry is a well known and much esteemed variety. It is a good bearer and a strong grower; and loves a rich fertile loam, rather moist than dry; and requires to

have its clusters of fruit tied up. The fruit is large, and of a scarlet colour, and various in shape,—sometimes conical and sometimes globular; and the pulp is coloured and juicy, and has a fine vinous flavour.

The red alpine strawberry is said to have been brought to Britain from the north of Italy; and is easily and frequently raised from seed. It is capable of bearing fruit through a long succession; but it cannot compare in quality with any of the most esteemed summer-bearing varieties; and it is employed principally for producing in autumn after all these varieties have ceased to bear. It is commonly planted in a north border, or other comparatively cool and shaded situation, and allowed to overrun the ground. Seed for it should be taken from the ripest and strongest autumn fruit, washed free from pulp, dried, and kept dry till about the middle of March, and then sown; and as soon as the young plants can be handled, they should be transplanted into beds.—The white alpine strawberry is a subvariety of the preceding, but has rather larger and less acidulous fruit, and does not produce so late in autumn, and is propagated, not from seeds, but from runners.

Many other kinds of strawberries might be named, either species, varieties, or subvarieties; but some are interesting more as curiosities than as useful plants, and few are comparable in value or excellence with the greater part of those we have described. Among the more remarkable are the one-leaved, introduced to Britain about 75 years ago, and blooming in May and June; the Canadian, a tall kind from North America, blooming in April and May; the hill green pine, introduced about 80 years ago from Germany, and blooming from April till the end of autumn; the plane-like, a red-flowered kind from North America, blooming from April till June; the Bresling, from France, blooming from April till June; the great-flowered pine, introduced about 90 years ago from Surinam, and blooming in April and May; the Indian, a yellow-flowered, peculiarly creeping kind, introduced about 45 years ago from India, and blooming from May till toward the end of autumn; the Buenos-Ayrean, an apetalous and very tall kind, blooming from April till June; Myatt's pine, producing a very beautiful and very richly flavoured fruit of a glowing vermilion colour, but so surpassingly intractable as almost to defy cultivation; Knight's Elton, bearing late in the season, and producing a large fruit, beautiful to the eye, and, when perfectly ripe, of very full, peculiarly grateful flavour, tending to acid; the Bostock,—Bishop's orange,—Wilmot's cockscomb,—and a great number of recent seedlings and hybrids.

Instructions for the cultivation of the strawberry might be spun out to a vast length, and rendered exceedingly diversified by incorporating with them the theories and rules of the most eminent horticulturists, and by adapting them to differences in the tastes and habits of the plants, in the soil and exposure of situations, and in the seasons and objects of respectively out-of-door and in-door cultivation. But we must necessarily content ourselves with showing only the salient points; and these may refer to the selection and management of runners,—to the preparing and planting of annual beds,—to the making and managing of triennial plantations,—to the general culture of all sorts of open-ground crops,—and to the best method of forcing.

In September, when the weather is mild, the ground is usually moist, the sunshine continues to be sufficiently genial, and all things conspire to render the preparation of strawberry-beds more facile and efficient than in any other month in the year, a stock of young plants will generally be found ready matured by the natural processes of growth, in the strawberry plantations of the preceding year or two years, for the immediate uses of the planter. Each young plant, in the case of by far the greater number of the good varieties, may be seen occupying a space equal to that of a full-sized saucer, with from four to six healthy leaves, around a bold, prominent, firm, central bud, and generally at the end of the stolon or runner which proceeds from the parent stock; and every such plant—provided that a certainty exists that the parent stock is fruitful—may be removed direct to a final destination in a new bed. The caution, however, requires to be borne in mind, that many of the largest and most beautiful parent plants are quite barren of fruit and eminently productive of runners, and that most parent plants which furnish the best fruit, and are in the most prolific state for bearing it, produce comparatively few runners.—But careful and economical cultivators, in addition to making sure work of the prolificity of their young plants, adopt measures to promote their vigour and to get them early ready. "The strongest are chosen after they have formed their own roots, which they readily do if lying close to the ground. And as it is an advantage to get them off the stools as soon and as well rooted as possible, some cultivators make small pits, or plunge small pots filled with fresh cucumber compost, on which the best runners are laid and pegged down, having their points pinched off. Here they soon make strong roots, and ready to be taken off to be planted in the open ground; or if required for forcing, those rooted in small pots may be shifted into larger, and put away in a proper shady place till they are wanted to go into the forcing house, strawberry pit, or hotbed."

The general rules for making prime annual beds of most of the good and the first-rate varieties of strawberry, is to prepare the ground three weeks before it is wanted,—to trench two feet deep, without bringing any of the lower soil to the surface, or with simply digging the lower spit, and turning and effectually pulverizing the

upper one,—to apply a moderate dose of rather recent stable dung on the top of the lower spit,—to choose a good, free, turfy, velvety loam,—and to make the plantation during a moist state of the soil, in the early part of September. Some eminently successful cultivators, however, make their annual beds a month or so earlier than we recommend; and the Rev. T. Garnier, one of these, says in the Horticultural Society's Transactions: "Early in August, or as soon as the gatherings are over, I destroy all my beds, and proceed immediately to trench, form, and manure them to receive the plants for the crop of the ensuing year, taking care to select for that purpose the strongest and best-rooted runners from the old rejected plants. If at this season the weather should be particularly hot, and the surface of the ground much parched, I defer the operations of preparing my beds and planting them till the ground is moistened by rain. Such is the simple mode of treatment which I have adopted for three successive years; and I have invariably obtained upon the same spot a great produce of beautiful fruit, superior to that of every garden of the neighbourhood. Depth of soil I have found absolutely necessary for the growth and production of fine strawberries; and when this is not to be obtained, it is useless, in my opinion, to plant many of the best varieties. It is not generally known, but I have ascertained the fact, that most strawberries generate roots, and strike them into the ground nearly two feet in the course of one season. The pine and roseberry succeed better than any other in stiff and shallow soils, but they should always lie in an open situation, and not, as is too commonly the practice, in shady and neglected parts of the garden."

In the triennial course of making and managing strawberry plantations, the preparing and manuring of the ground are the same as in the annual course. The planting may be done either in the form of single border rows, or in that of plots. If it be done in the former, the row should have an open space of from 12 to 18 inches of clear ground on each side of it; and the plants should be set by the trowel one foot asunder, securing the roots firmly in the soil, the fibres being expanded so as to be covered with earth in every part. If beds be adopted, the same distances are to be maintained, but the rows must be two feet asunder with alleys of approach by the sides laid with coal ashes. Water must be freely given from the rose of a water-pot in the evenings, till the plants stand firm and erect under the full sun; and afterwards the ground should be flat hoed, to bring the earth close around the base of each root, and to obliterate the smallest weed. In this system every blossom shown in the following spring is pinched off, not one plant being suffered to bear fruit in the first year; so that it will be proper to leave a few old beds to bear while the plan is in progress. The runners as they appear are cut away, and weeds are regularly destroyed. Throw a little fresh loam and a little reduced manure, mixed in equal proportions, along the rows on each side to enrich the ground while it protects the plants during winter; and in March take off the dead leaves and fork the spaces. This is to be the practice of each year. Suffer all the plants to bear in the second spring, and the crop will be in perfection: cut off runners and observe the other directions. In the third year the crop will be very fine; but now the end of the course is come, and the plants are to be rooted up. Therefore, to perpetuate the succession, new beds or rows must be begun every year, so that there shall always be a set of plants advancing through one or other of the stages. To provide new plants, a sufficiency of the finest runners of the third year's plants must be allowed to fix themselves in the ground of the intervening spaces, keeping them apart from the old plants to benefit by full exposure to air and sun.

A succession of fruit from plants in the open ground, during eight months of the year, or at the least during most of summer and a large part of autumn, is obtained partly by selecting varieties which naturally bloom and bear successively to one another,—partly by planting each in various aspects, as east, north, and south,—and partly by pinching off all the first flowers of early blooming varieties, so as to induce the natural bloom of the following spring to appear and fructify in the present autumn. All strawberry plants, howsoever situated, and whensoever expected or intended to bear, must be periodically or occasionally refreshed with water so as never to be allowed to become dry during the whole period from their beginning to show flowers till their ceasing to ripen fruit. All the varieties which are most liable to be dashed and sullied by heavy rains and plashy ground, must either be tied up or propped or otherwise protected by some artificial contrivance. One method is to lay slates or plain tiles along both sides of each row of plants,—and this not only keeps the fruit clean, but accelerates its ripening and improves its flavour; and another and more expensive and somewhat aristocratic method is to construct the strawberry beds of brick-work, in the form of a ridge of graduated steps, with interstices for the reception of the plants, and with a channel along the ridge for such an occasional or periodical application of water as will keep the soil beneath the bricks in the requisite state of moistness.

When plants intended for forcing have been well established in small pots, and shifted into larger, they should be removed to some suitable place in the open garden, and plunged in the earth to the rims, and supplied with water as often as necessary to keep them in a continually growing state. In November, they may undergo another shift; and at any time in January, from the ear-

liest day onward, they may be removed to a mild bottom heat of a fluid dung-pit, or old melon or cucumber bed, fresh lined,—the pots plunged,—the plants within a foot of the glass,—and a large portion of air admitted at all favourable opportunities,—the lights closed and covered with mats or straw shutters at night. They may remain in this situation, in an atmospheric heat of from 50° to 60° Fahrenheit, till the fruit be set; and then they may be removed to the stove to ripen,—any number of pots at a time, according to circumstances; and in this way, by a proper succession of removals, they will afford a constant supply of fruit from the beginning of March till the beginning of June,—and will do so though they should all be plants of Keen's seedling, or of any other one eminently good and suitable variety. During all the month of June, a supply may be obtained from Keen's seedling, the Grove-End, the roseberry, and other scarlets, grown on a south border of the open ground or at the foot of a wall; during the latter half of June and the former half of July, from the several varieties of pine, hautboy, and other common kinds, grown in the open quarters of the garden; during the latter half of July and the former half of August, from Keen's seedling, the Downton, and the pine, grown on a border facing the north, shaded by a wall; during the latter half of August and the whole of September, from Keen's seedling, transplanted from pots immediately after forcing, and grown on a well manured south border; during all October and the former half of November, from red and white alpines, raised in the preceding January from seed, and grown on a well manured south border; and during the latter half of November and the whole of December, from red and white alpines, raised from seed in the preceding January, and grown and ripened in pots in a heat of from 60° to 70° Fahrenheit. The seed of the alpines, when thus used, must be sown in shallow pans or boxes, with light rich mould; the pans or boxes must be placed in a stove or hotbed till about 6 or 7 weeks after sowing; the plantlets, at this period, must be pricked out, and set on a slight hotbed, about 3 inches apart, and protected with a frame and lights; and they must afterwards be well supplied with air and water, and defended with sufficient covering to protect them from all frost and severe weather till May; and in this month, part may be planted out for fruiting in the open ground, and the rest potted, one plant in a pot, to be kept in a growing state through the summer, and shifted into larger pots in August, and forced into fruiting in the closing months of the year. A very few varieties and a somewhat limited range of contrivances are thus sufficient for obtaining a constant supply of fruit during ten months of the year; and if all the naturally successional varieties were brought into play, and all the arts of the gardener in the open ground and in the forcing structures made to tell upon them, the supply might be ample and diversified to satiety,—but, of course, would be aristocratically costly.—*Rogers's Fruit Cultivator.—Philip's Fruits.—Haynes's Treatise on the Strawberry, Raspberry, and Gooseberry.—Paxton's Botanical Dictionary.—Loudon's Works.—The Transactions of the Horticultural Society.—The Gardener's Chronicle.—The Gardener's Gazette.—The Magazine of Domestic Economy.—Miller's Gardener's Dictionary.—The Survey of Mid-Lothian.*

STRELITZIA. A genus of ornamental, Cape-of-Good-Hope, evergreen, herbaceous plants, of the banana family. The queen's species, *S. reginæ,* was the earliest known to botanists, and the earliest introduced to Britain; and is still the most generally known, and may serve as an excellent specimen of the whole genus. It was discovered by Sir Joseph Banks, when acting as naturalist to the first expedition under Captain Cook; and was named in honour of the queen of England, a princess of the house of Mecklenburg-Strelitz; and was sent to Britain in 1773. It has a habit somewhat similar to that of a Calla, and commonly attains a height of about 6 feet. A vigorous plant of it may have 16 or 18 thrifty leaves about 3 feet high, and three strong flower stems, with their crowned heads of flowers towering above them. Each stem has three or four large flowers, which open successively from a curious spathe-like calyx, and stand up like a crest of gold; the petals have a rich orange yellow colour, and surround three broad stamens of the deepest purple; and a drop of pure nectar distils from each flower, and stands on the exterior like a brilliant gem. The plant commonly blooms in March and April, but can be urged forward to bloom in January; and it continues in bloom upwards of a month. Most authorities recommend for it a light sandy loam; but some gardeners have found it to succeed best in a rather heavy, rich, black loam, kept pretty moist. Of seven other species which have been introduced to Britain, one, the august, is white-flowered, and all the others are yellow-flowered; two, the august and the ovate-leaved, are respectively about 18 and 8 feet high, and all the others are about 5 or 6 feet high; three, the august, the ovate-leaved, and the mealy-stalked, bloom in February and March, and the others do not bloom till May; and two, the august and the ovate-leaved, as also the queen's, are propagated from suckers, and all the others are propagated

from seeds. All require a pretty high temperature, and make a very brilliant appearance.

STRENGTH OF MATERIALS. The force with which the particles of a solid body resist the forces that tend to separate them, and which constitutes their strength, may be found, in particular cases, by experiment. If the experiments be multiplied, both in respect to the species of substances, and to the size and circumstances under which portions of a given substance are employed, a general law might be finally obtained whence algebraic expressions of the relation between the strength, the dimensions, and the material, might be deduced. Or we may, by assuming an hypothesis to represent the probable manner in which bodies are made up, deduce from the general formulæ, which, applied to cases that occur in practice, will be sufficient, in almost every instance, to represent the phenomena.

Galileo was the author of the hypothesis that is most generally employed by writers on mechanics, and which will suffice in all usual cases. He assumes that all solid bodies are composed of a great number of parallel and equal fibres, perfectly inflexible and inextensible; that when they break, the several fibres give way in succession, and the body turns upon the fibre or fibres that are the last to give way, as upon a hinge. Leibnitz observing the flexure that takes place in bodies before they break, assumed as the basis of his hypothesis, the fact, that every body admits, before it breaks, of a certain degree of extension: the fibres, therefore, are both extensible and flexible; and he inferred that the strength of each fibre, instead of being equal, varied with its quantity of extension, or was proportioned to its distance from the fixed point around which the beam is supposed to turn. The hypothesis of Galileo has been recently extended by Barlow, who has, by introducing the circumstance of the occurrence of a flexure before the beam breaks, been enabled to explain all the cases which appeared, by a comparison of the hypothesis with experiment, to be anomalous.

The force which tends to destroy the aggregation of the particles of a solid body, may act in four different manners.

(1.) It may tend to tear the body asunder by exerting an action in the direction of its fibres.

(2.) It may tend to break the body across, by a transverse strain, exerted either perpendicularly or obliquely to the direction of its fibres.

(3.) It may tend to crush the body.

(4.) It may tend to separate the particles by means of torsion, twisting or wrenching the body, by an action in a plane perpendicular to its axis.

The resistance which bodies oppose to a force acting in the first of these modes, is called *the Absolute Strength.* In fibrous bodies, it is different, according as the force is applied in the direction of the fibre, or at right angles to it: for although by hypothesis we should conceive fibres to exist, even in the transverse direction, yet, in nature, none such are found; and the aggregation is far more easily destroyed in the latter case than in the former. The resistance to a fracture across the body, is called its *Respective Strength;* and we may call the resistance to a twisting force, *the Strength of Torsion.*

It needs no reasoning to show that the measure of the strength, even in the same body, will be different in each of these different cases; and such is the difference in the manner in which the particles of bodies of different natures are united, that there can be no general law that will represent the relations of these four species of resistance. But in conformity with our hypothesis, it will be obvious that, in all the several cases, the resistance to fracture will vary with the number of fibres, which, in homogeneous bodies, will depend upon the area of their sections. It must also depend upon the manner in which the force acts to break the body.

I. *Of the Absolute Strength of Materials.* When the strain is exerted in the direction of the fibres, the force that tends to break a body will be directly opposed to its force of aggregation, and the resistance must depend upon the cohesive force of each fibre, and upon their number, but upon no other circumstance.

The most valuable experiments that we have of this sort, are those of Barlow, upon wood. These were made upon cylindrical rods, and the strength, deduced for an element of the area of a square inch. The results are contained in the second of the following tables. The first table has been compiled from various other sources.

TABLE I.

Absolute Strength of the Metals.

Cast Steel,	140,000 lbs.
Gold, (*according to Morveau,*)	80,000
Wrought Iron, (Swedish,)	72,000
do. (English,)	56,000
do. do. in the form of chains,	48,000
Bronze, (Gun Metal,)	36,000
Wrought Copper,	33,000
Cast do.	19,000
Brass,	17,000
Tin,	4,700
Lead,	1,800

TABLE II.

Absolute Strength of different kinds of Wood drawn in the direction of their fibres.

Boxwood,	20,000 lbs.
Ash,	17,000
Teak,	15,000
Norway Fir,	12,000
Beech,	11,500
Canada Oak,	11,400
Russia Fir,	10,700
Pitch Pine,	10,400
English Oak,	10,000
American White Pine,	9,900
Pear Tree,	9,800
Mahogany,	8,000
Elm,	5,800

TABLE III.

Absolute cohesive Strength of Wood drawn in a direction at right angles to the fibres.

Teak,	818 lbs.
American White Pine,	757
Norway Fir,	648
Beech,	615
English Oak,	598
Canada Oak,	588
Pitch Pine,	588
Elm,	509
Ash,	359

II. *Of the Respective Strength of Materials.* To apply the hypothesis of Galileo to the case of a transverse strain, we shall suppose in the first place, the substance to have the form of a prismatic beam, that it is firmly inserted at one end into a fixed support, lies in a horizontal position, and is acted upon by a weight that presses at the end that is not fixed; that the fracture takes place at the point of support, beginning at the upper side, on which the weight presses, and terminating at the other. The beam then, its fibres being by hypothesis inflexible and inextensible, will turn around the latter point in a vertical plane. At the instant of fracture, the two forces that act are in equilibrio with each other, their respective moments of rotation must be therefore equal.

When a beam, lying in a horizontal position, rests upon two props, and is broken by a weight placed at an equal distance from the two props, we may consider the laws of its strength as included in the general case of a beam supported at one end only; for if, according to the hypothesis, it break without bending, we may conceive it to be formed of two beams, each inserted in a firm support at the place of fracture, and acted upon at each end by a force equal to half the weight that just breaks it, but which is directed upwards instead of downwards. This force, which is equal to half the weight, will act at a distance which is equal to half the length; its effort is therefore equal to no more than a fourth part of the effort of the same weight, applied to the same beam, if supported at one end only; and as this effort must be just equal, at the instant of breaking, to the transverse strength of the beam, the latter will be four times as strong as when supported at one end only.

In the case of a beam lying horizontally, and firmly fixed at each end, the resistance will be equal to that of a single beam supported by two props, added to those of two beams fixed at one end only; for it is obvious, that three fractures must be produced, one in the middle, and one at each end; at the first, the resistance will be equal to that of the supported beam, or four times as great as that of the same beam, if supported at one end only. The resistance in each of the latter cases, will be that of a beam of half the length fixed at one end only, or one fourth of the last resistance; the whole resistance will therefore be six times as great as that of the same beam when fixed at one end only.

When the weight that tends to break a beam is not accumulated at a single point, but is uniformly distributed over its whole length; its effort is diminished to the half of what it exerts, when, in the case of a beam fixed at one end, it acts at the opposite extremity; or when, in the case of a beam supported or fixed at both ends, it acts in the middle.

We have hitherto omitted the action of the weight of the beam itself. In small beams indeed, their own weights are of little importance, and need hardly be taken into account in the experiments; but in large beams this is not the case, as may easily be seen. The weight which breaks a beam is made up of its own weight, and the weight which is applied for the purpose: the former acts at the centre of gravity of the beam, which in prismatic beams is in the middle of their length.

We shall now recapitulate the results of our hypothesis, and state what discrepancies have been observed between them, and the inferences from actual experiment.

(1.) In any prismatic beam whatsoever, the strength is directly proportioned, to the area of its section, and to the distance of its centre of gravity from the point where the fracture terminates; and inversely, to the length of the beam.

(2.) The strengths of beams lying in a horizontal position, when fixed at one end only; when supported by a prop at each end; and when firmly fixed at both ends, are as the numbers 1 : 4 : 6,—that is to say, a beam firmly fixed at both ends, is six times, a beam merely supported at both ends, four times as strong as when it is fixed at one end only.

These several inferences from the hypothesis agree within all usual limits, with the results of experiments. The discrepancies are, that the strengths increase in a ratio a little greater than the square of the depth, in rectangular beams; and decrease rather more rapidly than the inverse ratio of the length.

The second of the above propositions admits of the following cases :—

(*a*) In beams of the same material, with equal and similar sections and unequal lengths, the strengths are inversely proportioned to the lengths.

The lengths being equal :

(*b*) In rectangular beams of the same materials the strengths are proportioned to the product of the breadth by the square of the depth ;

(*c*) In square beams, the strengths are proportioned to the cubes of the sides of the square sections ;

(*d*) In solid cylindric beams, the strengths are proportioned to the cubes of the radii ;

(*e*) In hollow cylindric beams, having the same quantities of material distributed around cylin-

dric cavities of different diameters, the strengths are directly as the diameters.

(3.) Large beams are weaker in proportion than small ones, for their own weight constitutes a part of the force that tends to break them; and in similar solid bodies, the stress growing out of their own weight increases as the cubes of their homologous dimensions, while the strength only increases with the squares.

We see from this, that models may be strong, and capable of bearing a stress far beyond any that can be applied to them; yet that machines constructed exactly similar to them in proportion and of like materials, but of increased dimensions, may become too weak to bear even their own weight; that there must be a limit to the size and extent of any structures that can be erected by the hand of man; and that a similar limit exists even in the works of nature. Thus, in organic bodies, mountains, hills, trees, the size they can attain, without risk of disintegration, is restricted within certain bounds. In the animal creation, the same principle applies, and the limit is sooner reached.

Our theory would show that when a body becomes weak in consequence of an increase of length, strength may at first be added by increasing its breadth, and still more by increasing its thickness, the length remaining constant. Here, however, the weight is increased in a greater ratio than the length, and finally becomes excessive. The same quantity of material may assume a stronger form by being fashioned into a hollow tube; yet here again a limit is reached when the circumference of the tube becomes so thin as to be liable to be crushed by the forces that act upon it.

In animals we find that the smaller classes have bones far more slender in proportion than those of the larger kinds. Their muscles are far less thick in proportion to their length; and their masses are diminished in a proportion much more rapid than that of the cubes of their similar dimensions. We find small animals capable of lifting weights greater in proportion to those of their own bodies, than larger animals can; and in spite of this additional effort, they are enabled to continue their exertions for a longer period without fatigue. To obtain the greatest possible strength with the least possible weight, the bones of animals have the form of hollow tubes, as have the quills and feathers of birds. In the vegetable kingdom, we find trees and plants made up of bundles of hollow tubes; and in those where great strength and comparative lightness are necessary, these are again arranged so as to form a hollow cylinder; as, for instance, in the whole family of the gramina.

(4.) When beams are in an inclined position, their strength, which we shall call F, becomes $F = W \cos. i$. This deduction from the hypothesis is true in practice, so long as the beam does not bend under the effort of the weight applied to break it.

(5.) When the pressure, instead of acting upon a single point, at the extremity of a beam fixed at one end, or in the middle of a beam supported or fixed at both ends, is equally distributed throughout the whole beam, twice the weight will be required to break it.

As far as we have recited the results of the hypothesis, they agree in all useful cases with the deductions from experiment. But some of the rules, deduced from the hypothesis, do not coincide with what occurs in practice.

Thus it has been shown that there is a difference in the strength of triangular beams, according to their position, with an edge or a face uppermost; and that this difference follows different laws, according to the manner in which the beam is supported. Experiment absolutely contradicts this; for in neither of the three different positions in which beams have been tried, has any important difference been found in the strength of a triangular beam, when placed with an edge, or with a face uppermost.

So also, hollow cylindric beams have not been found stronger, when the cavity has been nearer to the side where the fracture terminates, as they ought to be in conformity with hypothesis; neither is a square beam stronger when its diagonal is vertical.

These remarkable discrepancies, together with the less important ones that have been noted in the preceding section, arise from an omission in the hypothesis; this does not take into account the elasticity and consequent flexure which materials undergo before they actually break.

Table of the respective strength of various substances.

Metals.

Wrought iron, Swedish,	22,000 lbs.
do. English,	18,000 lbs.
Cast iron,	16,000 lbs.

Wood.

Teak,	4,900 lbs.
Ash,	4,050
Canada Oak,	3,500
English Oak,	3,350
Pitch Pine,	3,250
Beech,	3,100
Norway Fir,	2,950
American White Pine,	2,200
Elm,	1,013

We are without any good experiments on the respective strength of stone. It would, however, appear from some experiments of Gauthey, that, in soft freestone,

$$s = 68\ 7 \text{ lbs.}$$

In hard freestone,

$$s = 72{\cdot}75 \text{ lbs.}$$

And from some experiments recorded by Barlow, that in brick,

$$s = 64 \text{ lbs.}$$

This would make the respective strength of stone and brick far beneath that of wood or iron.

III. *Of the Resistance of Bodies to a Force exerted to crush them.*—The resistance of bodies to forces that act to crush them, would, at first sight, appear to follow the same law with the absolute strength; that is to say,—it must be proportioned to the area of the body, and the force of aggregation of its particles. Experiment, however, shows, that the thickness of the substance has an important influence on the pressure it is capable of bearing, without being crushed. In the first place, it is found that very thin plates are readily crushed; their resistance next increases with the thickness, until it reach a maximum; and finally decreases slowly, with a farther increase of thickness. This branch of the subject has been illustrated under the head PRESSURE.

In bodies whose sections are similar, it may be inferred that the resistance to a force exerted to crush them, is proportioned directly to the cubes of the homologous dimensions of the sections, and inversely to the squares of their lengths. The most complete set of experiments that we have upon the variation in the strength of columns of different lengths, are those of Muschenbrook, and they correspond closely with the above theory. The subject, however, has not been so fully tested as to authorize us to receive any theory with implicit confidence. We shall, in consequence, give the absolute results of experiments, in the terms of the weights and dimensions of the original record, without attempting to reduce them to a conventional unit.

TABLE.

Experiments made by Rondelet, on the Resistance of different species of Stone in cubic blocks, of the size of 5 centimetres in each dimension.

	Spec. Gravity.	Crushing Weight. Kilogrammes.
Swedish Basalt, . .	3·065	47 809
Basalt of Auvergne, No. 1,	3·014	44·250
Do. No. 2,	2·884	51·945
Do. No. 3,	2·756	28·858
Porphyry, . . .	2·798	50·021

White Veined Marble, .	2·701	7·455
White Statuary Marble, .	2·695	8·176

Experiments made at the same time upon cubes of stone, whose sides varied from 3 to 6 centimetres, showed that the strengths varied nearly in proportion to the areas of their bases, and were not influenced by the thickness. This corresponds to the law of absolute strength, and differs from that we have given for the resistance to crushing. On the other hand, when cubes of the same size were placed one upon another, a diminution in the resistance was found that does not differ much from the latter law.

By experiments made by Rennie, on the resistance of cast iron to pressure, it was found that the maximum strength was reached at thicknesses of from $\frac{3}{8}$ths to $\frac{1}{2}$ an inch, and that a prism a quarter of an inch square, and half an inch in depth, was crushed by 10,000 lbs.

A cube of cast copper, $\frac{1}{4}$ inch each way, was crushed by 7,318 lbs.

A cube of wrought copper, of the same size, by 6,440 lbs.

Of brass, by 10,304 lbs.

Of cast tin, by 966 lbs.

Of lead, by 483 lbs.

An inch cube of elm is crushed by 1,284 lbs.

Of American pine, by . . 1,606

Of Norway fir, by . . 1,928

Of English oak, by . . 3,860

IV. *Of the Strength of Torsion.*—By the experiments of Coulomb, the resistance of wires of the same material, to a force exerted to twist them, appears to increase with the fourth power of their diameters. A similar result follows nearly, from experiments by Rennie, on square bars of cast iron. It would also appear, from a simple course of reasoning, that the resistance must diminish with the distance of the point in the rod to which the twisting force is applied, from the place where it is fixed; for the rod tends, under the action of the force, to form a screw, the distance between whose threads is the same as the distance between the two points. And in the inclined plane which the screw forms when developed, the twisting force will act as if it tended to raise a weight along the surface of the plane, whose altitude is the constant lineal dimension of the base of the rod.

We have no experiments on the absolute resistance to torsion; the following are the relative resistances of different materials, deduced from the experiments of Rennie.

Lead, ...	1,000
Tin, ...	1,438
Copper, ...	4,312
Brass, ...	4,688
Gun Metal, ...	5,000
Swedish Iron, ...	9,500
English Iron, ...	10,125
Cast Iron, ...	10,600
Blister Steel, ...	16,688
Sheer Steel, ...	17,063
Cast Steel, ...	19,562

We are indebted for the above article to *Dr. Renwick's Elements of Mechanics.*

STREPTANTHERA. A genus of ornamental, bulbous-rooted, exotic plants, of the iris order. It takes its name from the twistedness of its anthers. The elegant species, *S. elegans*, is the oldest known one, and was introduced to Britain about 22 years ago from the Cape of Good Hope. It has a height of about 5 or 6 inches; and carries flowers of white and blue and yellow in May and June; and loves a soil of mixed sand and peat and loam.

STREPTANTHUS. A recently discovered genus of ornamental exotic plants, of the cruciferous order. The blunt-leaved and the hyacinth-flowered species are hardy, late-blooming

annuals, — the former from Arkansa, with a height of 20 inches and rose-coloured flowers, and the latter from Texas, with a height of 3 feet and bluish purple flowers.

STREPTOPUS. A genus of ornamental, exotic, perennial-rooted, herbaceous plants, of the smilax family. Five species, all between 10 and 24 inches high, mostly hardly, and blooming in May or June, have been introduced to Britain from North America, Hungary, and Nepaul; and all love a light soil, and are propagated from suckers.

STRICKLE. The whetstone carried on the extremity of the shaft of a scythe.

STRINGHALT. A sudden or very high lifting of the hind legs of a horse at his starting, as if he were affected with a spasm. The disease, or habit, or whatever it be, is not indicated by swelling, tenderness, or any other unhealthy appearance, and has been variously supposed to have its seat in the fetlock, in the hock, and in the spine; and when it is so great as to amount to lameness, it may sometimes be reduced by means of blistering or the cautery.

STROBILANTHES. A genus of ornamental exotic plants, of the acanthaceous order. The sessile species, *S. sessilis*, was introduced from India to Britain about 10 years ago. Its root is perennial; its stems are herbaceous, numerous, simple, erect, quadrangular, very hairy, and about 18 inches high; its leaves are opposite, subsessile, and ovate-heart-shaped; and its flowers come out in the axils of the bracts, and are sessile and solitary, and expand in succession from below upwards, several at a time, and have a pubescent, lilac-coloured, funnel-shaped corolla.

STROBUS. See Pine.

STRONTIA, or Strontites. The oxide of strontium. It was first obtained from strontianite, or native of carbonate of strontia, a mineral found at Strontian in the west of Scotland; and it may be prepared, in a pure state, from either that mineral or the nitrate of strontia. It is an alkaline earth; and resembles baryta in appearance, infusibility, and other properties. Strontium, the base of it, is a heavy metal similar to barium, and decomposes water, with evolution of hydrogen and fixation of oxygen. Strontia, when mixed with water, slakes, causes intense heat, and forms a white, solid hydrate, consisting of one equivalent of strontia and nine equivalents of water, and possessing the properties of solubility in boiling water, insolubility in alcohol, fusibility with a red heat, infusibility with the strongest heat of a wind furnace, and resolvability from hot saturated solution in water into transparent, thin, quadrangular, tubular crystals. The solution of strontia has a caustic taste and an alkaline reaction; and is a delicate test of the presence of carbonic acid in atmospheric air and other gaseous mixtures. The salts of strontia are most conveniently prepared from the carbonate, and are not poisonous; and the soluble ones are precipitated by alkaline carbonates. Two of the most important compounds of strontium, next to strontia or the oxide, are the chloride and the sulphuret.

STROPHANTHUS. A genus of ornamental, tropical, evergreen shrubs, of the dog's-bane family. Three species have been introduced to Britain from respectively India, China, and Western Africa; and two of these—the forked, with rose-coloured flowers, and the spreading, with yellow flowers—are about 3 feet high, and bloom throughout the greater part of the year, and love a soil of rich mould, and are propagated from cuttings.

STRUMARIA. A genus of ornamental, greenhouse, bulbous-rooted plants, of the amaryllis order. Ten species have been introduced to Britain from the Cape of Good Hope; and all love a soil of sandy loam, and are propagated from offsets,—most have a height of between 3 and 8 inches,—the majority have pink flowers, and the rest have either white or yellow flowers, —and most bloom in April or the early months of summer, and two or three do not bloom till late in autumn. The name strumaria is formed from a word signifying 'tubercle,' and alludes to the conformation of the base of the style.

STRUTHIOLA. A genus of ornamental Cape-of-Good-Hope, evergreen, small shrubs, of the thymelæa family. Nearly twenty species have been introduced to Britain; and all love a light soil of sandy peat, and are propagated from cuttings,—and most have a height of about two feet, and carry either white or yellow flowers from about the end of spring till about the beginning of autumn. Five of the handsomest are the striated, the shining, the side-flowered, the long-flowered, and the smooth,—all with yellow flowers. The name struthiola alludes to the beak-like form of the seeds.

STRYCHNOS. A genus of corolliflorous, tropical, evergreen, small trees, constituting the type of the natural order Strychneæ. This order is nearly allied to the dog's-bane family, and consists principally of tropical, poisonous, ligneous plants. About a dozen species of it, belonging to three genera, have been introduced to British collections; and six of these—all more or less poisonous, and several of them medicinal—belong to the genus strychnos. The best known species, and one which may serve as a good specimen of the whole, is noticed in the article Nux Vomica.

STUARTIA. A small genus of ornamental, hardy, deciduous shrubs, of the ternstrœmia family. The common or Virginian species, *S. Virginica*, called by Linnæus *S. malachodendron*, was introduced to Britain from Virginia in 1742. Its height, as grown in British shrubberies and pleasure-grounds, is commonly about 8 or 10 feet; its branches come out irregularly from the main stem, and are covered with a brown bark; its

leaves are alternate, and of similar size and shape to those of the common cherry-tree, with fine green upper surface and very acutely serrated edges; and its flowers come out from the sides of the branches, and have a white colour and an elegant and delicate appearance, and bloom from May till August. This plant loves a loamy soil, with some little admixture of peat; and is propagated from layers or from seeds.—The five-styled species, *S. pentagynia*, called by some botanists *Malachodendron ovatum*, was introduced from North America in 1785, and has a similar height to the preceding, and blooms in July and August.—The name Stuartia is honorary of an Earl of Bute who was skilled in botany; and the name Malachodendron is appellationally descriptive of the softness of the tree.

STUB. A wound in the foot or leg of a horse with a splinter. It ought to be carefully examined, and made clean of any part of the splinter which may be found in it, and afterwards treated in the same manner as any other punctured wound. See the article Wound.

STUBBLE. The lower part of the culms of the cereal grasses left standing in the field after the operation of reaping. The burning of stubble was a common practice in the ancient agricultural usages of the Eastern world; and was recommended by some Roman writers on husbandry as an excellent means of destroying the seeds of weeds; and is alluded to in such passages of Sacred Scripture as the following:—"Therefore as the fire devoureth the stubble, and the flame consumeth the chaff, so their root shall be as rottenness;"—"And the house of Jacob shall be a fire, and the house of Joseph a flame, and the house of Esau for stubble; and they shall kindle in them and devour them, and there shall not be any of the house of Esau remaining." The burning of stubble, and even of straw, has been tried also in the modern improved agricultural practices of Europe; but though in some instances seemingly beneficial, it really involves in every case a great waste of manurial matter. See the article Ashes. The leaving of long stubble, by cutting the corn high, was likewise a practice of many of the ancients, and is perpetuated by some of the moderns; but whether the portion of available straw left in the form of long stubble be eaten by cattle depastured upon it, or be simply turned into the soil with the plough, it cannot possibly be so productive of ulterior advantages as if it were cut down, and carried to the farmery, and there employed for fodder and litter. See the article Straw. All principles of good reaping require the culms of corn to be cut as low as possible.

STUBWOOD. Young wood rising from the stubs of felled trees, or any growing wood in hedge-rows different from timber, pollard, or quicks.

STUMP. The stool of a felled tree; or the standing part of a fractured or fallen tree; or any clubbish, lumpish, or basal remnant of a fractured, cylindrical, organic body.

STURDY. See Hydatid.

STURK. A young bullock or heifer. The word is provincial.

STY. A piggery or small structure for the housing of hogs.

STYLE. The middle part of the pistil of a phænogamous plant. It is an elongation of the ovary, and is crowned by the stigma. In some cases it is deciduous, and falls when the ovary is ripe; and in others, it is persistent, and adheres to the fruit.

STYLIDIUM. A genus of curious, ornamental, Australian, evergreen, calyciflorous plants, constituting the natural order Stylideæ. This genus or order is characterized by the position and character of the stigma, and has been the subject of much conflict of opinion among botanists. The stigma was supposed by the older botanists to exist at the base of the column; and was identified by later ones with the fifth lobe of the corolla or lip; but is now known to be situated at the top of the column, in a cavity surrounded by the anthers. The column assumes a position outside of the corolla, by bending back between its lobes; and when touched near its base in the slightest manner with a pin, it instantly leaps forward to the other side of the flower,—and after remaining for a short time there, it gradually resumes its former situation. About a dozen species have been introduced to the gardens of Britain; and nearly forty more are known. Most are natives of New Holland and Van Diemen's Land, and occur in wide dispersion and in comparative profusion from within the tropics to the southern shores. All are herbs or semi-herbaceous shrubs; and most have pink or rose-coloured flowers, adorned with glittering glands. The introduced species vary in height from 6 to 25 inches, and love a soil of sandy peat; and most bloom in summer, and require to be propagated from seeds.

STYLOSANTHES. A diversified genus of tropical, yellow-flowered plants, of the hedysarum division of the leguminous order. Six species,—variously annual, evergreen herb, evergreen undershrub, and evergreen creeper, and all requiring to be propagated from seeds,—have been introduced to Britain; and several more are known.

STYPANDRA. A genus of ornamental, Australian plants, of the asphodel family. Five species—all between 10 and 24 inches high—four of them herbaceous and the other shrubby—three of them white-flowered and the others respectively azure-flowered and violet-flowered—have been introduced to Britain; and the three white-flowered herbaceous ones love a soil of rich mould, and are propagated by radical division.

STYPHELIA. A genus of ornamental, Australian, evergreen shrubs, of the epacris family. Eight or nine species, varying in height from 3 to 7 feet, and carrying either green or pink or

crimson flowers for the most part in summer, have been introduced to the greenhouses of Britain; and most love a soil of sandy peat, and are propagated from cuttings. The name styphelia is formed from a word signifying 'rigid;' and alludes to the compact habit of the plants.

STYPTIC. A medicine or medicinal application used for stopping a flow of blood. Veterinarians cannot depend on any styptic; but must either tie the bleeding artery both above and below the wound, or have recourse to pressure or to the hot iron.

STYRAX. See STORAX.

SUBER. See CORK-TREE and OAK.

SUBLIMATE. See CORROSIVE SUBLIMATE.

SUBLIMATION. A chemical or pharmaceutical process similar to distillation, but yielding the product of the volatilization in a solid form.

SUBSOIL. See SOIL.

SUBSOIL DRAINING. See DRAINING.

SUBSOIL PLOUGH. See PLOUGH.

SUBSOIL-PLOUGHING. The stirring of the subsoil of arable land with a specially constructed plough. It differs from both deep-ploughing and trench-ploughing in its only stirring the subsoil and not mixing any of it with the soil, while they bring more or less of it to the surface. It performs similar effects on the subsoil to those which simple tillage produces on the soil,—pulverizing it, increasing its porosity, accelerating its decomposition or disintegration, and enlarging its capacity for the circulation of air and moisture; and when it is done on kinds of land which are improvable by it, and which possess either naturally or artificially a free and ample subterranean outlet for all excess of water, it materially improves the relations of the subsoil to both the soil and the drainage. But in all its offices within the subsoil itself, it acts in exactly the same way as deep-ploughing and trench-ploughing; and in all its relational offices to the soil and the drainage, in the case at least of all sorts of retentive lands, it does positive harm and no good without the preconstruction of a system of deep subsoil drains; so that a question has been extensively raised, and very warmly debated, whether mere subsoil-ploughing be not essentially useless,—or, in other words, whether all the benefits ascribed to it, and some more, may not in every instance be obtainable from deep-ploughing or trench-ploughing and from subsoil draining. It first came before the notice of agriculturists, as a special georgical operation, in connexion with Mr. Smith of Deanston's system of subsoil draining; and it soon became permanently associated with that system, in the notions and phraseology of multitudes of farmers, under the joint name of Deanstonizing; and in almost all the experimental trials of it which were published during several years, it was so invariably combined in practice with the subsoil draining, that no opinion could be formed from them as to the proportion of the results in any case which were due respectively to the draining and to the ploughing. In 1836, it acquired sudden and extensive popularity, both as a separate operation and as a component part of 'Deanstonizing,' in consequence of the official recommendation of it by Mr. Shaw Lefevre, who had sat as Chairman of the Committee of the House of Commons for enquiring into the distressed state of British agriculture; and it afterwards rose so soaringly into fame that a great and steadily increasing number of Smith's subsoil-ploughs were ordered from the principal manufacturers, not only for most of the agricultural districts of Britain, but for Sweden, Prussia, European Turkey, the West Indies, and America; but it was challenged from the first, by some of the most astute agriculturists, and even by Mr. Smith of Deanston himself, as a perfectly worthless or a positively mischievous operation apart from efficient subsoil-draining, and as not at all suitable for every kind of land; and it has eventually come to be regarded by a large body of the ablest georgists either as an operation which can never be preferable to deep-ploughing or trench-ploughing, or as one which can be economically practised only in particular circumstances or within a very limited range of adaptations. Many farmers, however, and even some agricultural writers, confound it with deep-ploughing and trench-ploughing, or regard all the three as simply varieties of one operation; and since the stirring of the subsoil in some way or other is generally allowed to be more or less advantageous on many kinds of lands, and very particularly so on some stiff and cohesive ones, we shall best consult the instruction and convenience of our readers by here discussing the whole subject. See the articles PULVERIZATION, AERATION, PLOUGHING, DRAINING, SOWING, and DRILL-HUSBANDRY.

"The chemical effect of pulverizing and breaking up a subsoil," says Mr. Cuthbert W. Johnson, in the 10th volume of the Quarterly Journal of Agriculture, "is certainly advantageous to the plant in two ways, besides others with which we are very likely at present unacquainted;—first, it renders the soil penetrable to a much greater depth by the roots or minute fibres of the plant, and consequently renders more available any decomposing matters, or earthy ingredients, which that substratum may contain; and secondly, it renders the soil much more freely permeable by the atmosphere, rendering, in consequence, a greatly increased supply not only of oxygen gas to the roots of the plants, but also yielding more moisture, not only from the soil, but from the atmospheric air, which moisture, let it be remembered by the cultivator, is in all weathers as incessantly absorbing by the soil as it is universally contained in the atmosphere, abounding most in the latter, in the very periods when it is most needed by the plants, that is, in the warmest and driest weather. This property possessed by the soil of absorbing moisture from the atmosphere,

and the importance of increasing that power by pulverizing the soil, is not nearly so well understood as is desirable, although the farmer has the means of convincing himself of the fact by the most simple experiments. It is, in truth, an almost unfailing test of the comparative value of soils, as was long since observed by Sir H. Davy,—a conclusion in which I have often had occasion to agree. 'The power of the soil,' says this great chemist, 'to absorb water by cohesive attraction, depends, in a great measure, upon the state of division of its parts; the more divided they are, the greater is their absorbent powers. The power of soils to absorb moisture from air, is much connected with fertility; when this power is great, the plant is supplied with moisture in dry seasons, and the effect of evaporation in the day is counteracted by the absorption of aqueous vapour from the atmosphere by the interior parts of the soil during the day, and by both the exterior and interior during the night. The stiff clays, approaching to pipe-clays in their nature, which take up the greatest quantity of water, when it is poured upon them in a fluid form, are not the soils which absorb most moisture from the atmosphere in dry weather; they cake, and present only a small surface to the air, and the vegetation on them is generally burnt up almost as readily as on sands. The soils that are most efficient in supplying the plant with water by atmospheric absorption, are those in which there is a due mixture of sand finely divided, clay and carbonate of lime, with some animal or vegetable matter, and which are so loose and light as to be freely permeable to the atmosphere. With respect to this quality, carbonate of lime and animal and vegetable matter are of great use in soils,—they give absorbent power to the soil, without giving it likewise tenacity; sand, which also destroys tenacity, on the contrary gives it little absorbent power. I have compared the absorbent powers of many soils with respect to atmospheric moisture, and I have always found it greatest in the most fertile soils, so that it affords one method of judging of the productiveness of land. One thousand parts of a celebrated soil from Ormiston, in East Lothian, which contained more than half its weight of finely divided matter, of which eleven parts were carbonate of lime, and nine parts of vegetable matter, when dried at a temperature of 212°, gained in an hour by exposure to air saturated with moisture at a temperature of 62°, eighteen parts; 1,000 parts of a very fertile soil from the banks of the river Parret, in Somersetshire, under the same circumstances, gained sixteen parts; 1,000 parts of a soil from Mersea, in Essex, worth 45s. per acre, gained thirteen parts; 1,000 parts of a fine sand from Essex, worth 28s. an acre, gained eleven parts; 1,000 of a coarse sand, worth 15s. per acre, gained only eight parts; 1,000 of the soil of Bagshot Heath gained only three parts.' And this absorbent power of atmospheric moisture is not only an inherent property in all fertile soils, and a property which is increased by their pulverization, but it exists in a still more remarkable degree in the commonly employed manures of the cultivator, and that, too, nearly proportionate to their commonly assigned value. The following are the results of my own experiments:—One thousand parts of horse-dung, dried at a temperature of 100°, absorbed, by exposure for three hours to air saturated with moisture at 62°, 145 parts; 1,000 parts of cow-dung, under the same circumstances, absorbed 130 parts; 1,000 parts of pig-dung absorbed 120 parts; 1,000 parts of sheep-dung absorbed 81 parts; 1,000 parts of pigeons' dung absorbed 50 parts; 1,000 parts of a rich soil worth two guineas per acre, absorbed 15 parts. This attractive power of the earths, and of manure, from the moisture of the atmosphere, is one of the most important facts to be kept in mind by the farmer, when he is considering the pulverizing and deepening his soils. It is also a property which all plants possess in a certain measure, but some in such a perfect degree as to depend entirely upon it for all the moisture they need. Thus, the aërial epidendron, *Epidendron flos aeris*, is often employed by the natives of the east, on account of the elegance of its leaves and flowers, and the exquisite odour which it diffuses, as an ornament, suspended by a silken cord from the ceilings of their rooms where, from year to year, it continues to vegetate, putting forth new leaves, new blossoms, a new fragrance, entirely supported by the moisture and gases of the surrounding atmosphere. Many of the native plants of the east nearly support themselves in the same way; some of the mosses of this country almost do the same. The quantity of water consumed by plants when in a state of healthy vegetation, is in fact so great, that, if it was not for the gentle steady supply thus imperceptibly furnished to the soil by the atmosphere, vegetation would speedily cease, or only be supported by incessant rains. Thus, Dr. Hales ascertained that a cabbage transmits into the atmosphere, by insensible vapour, about half its weight of water daily; and that a sunflower three feet in height transpired in the same period nearly two pounds weight. Dr. Woodward found that a sprig of mint, weighing 27 grains, in seventy-seven days emitted 2,543 grains of water; a sprig of spearmint, weighing 27 grains, emitted in the same time 2,558 grains; a sprig of common nightshade, weighing 49 grains, evolved 3,708 grains; and a lathyris of 98 grains emitted 2,501. It has been shown by the experiments of M. Saussure with some sprigs of peppermint, that, when supplied with pure water only, and allowed to vegetate for some time in the light, that they nearly doubled the portion of carbon they originally contained. This they could have procured only from the atmosphere; and under these circumstances, there is now little doubt of the cor-

rectness of the conclusion of M. Berthollet, that plants, by means of their leaves, have the power of decomposing the water as well as the carbonic acid of the atmosphere, and furnishing with these elements new combinations. How essential a free access of the atmosphere is to the roots of plants, was long since shown by M. Saussure, who found that oxygen gas is absorbed by the roots of plants, as well as by their leaves, and that it is at the roots united with carbon, and transmitted to the leaves to be decomposed. Even the branches absorb oxygen: in its absence flowers will not even expand. The advantages of a free access of oxygen to the roots of plants, has been still further shown experimentally: it has been proved that their vegetation is greatly increased by nourishing them with water impregnated with oxygen gas; hence, too, the superiority of rain-water. Some remarkable experiments were made by Mr. Hill, demonstrative of the great benefit plants derive from oxygen gas being applied to their roots. Hyacinths, melons, Indian corn, &c., were the subject of the experiments. The first was greatly improved in beauty, the second in flavour, the last in size, and all in vigour. This is another use of a free access of atmospheric moisture; for M. Humboldt has clearly shown that a dry soil is quite incapable of absorbing oxygen gas. Now, it must be evident, even to the most listless observer, that the more deeply and finely a soil is pulverized, and rendered permeable, the greater will be the absorption of both oxygen and watery vapour from the surrounding atmosphere.

"And by facilitating the admission of air to the soil, another advantage is obtained, that of increasing its temperature. The earths are naturally bad conductors of heat, especially downwards. Thus it is well known, that, at the siege of Gibraltar, the red-hot balls employed by the garrison were readily carried from the furnaces to the batteries in wooden barrows, whose bottoms were merely covered with earth. Davy proved the superior rapidity with which a loose black soil was heated compared with a chalky soil, by placing equal portions of each in the sunshine;—the first was heated in an hour from 65° to 88°, while the chalk was only heated to 69°. This trial, however, must not be regarded as absolutely conclusive, since the surfaces of the black soils naturally increase more rapidly in temperature when exposed to the direct rays of the sun, than those of a lighter colour. A free access of air to all soils also adds to their fertility, by promoting the decomposition of the excretory matters of plants, which otherwise would remain for a longer period, to the annoyance of plants of the same species.

"To the truth of these conclusions and laborious experimental researches of the chemist, does not the practical testimony of the ablest cultivators of all countries and in all ages concur? Thus, in enforcing the advantages of rendering the soil more completely permeable by the atmosphere, nearly two thousand years since M. P. Cato asked the Italian farmers, 'What is good tillage? To plough. What is the second? To plough. The third is to manure.' Cato, however, mistook the cause of the benefit, for he says, 'He who stirs his olive-ground oftenest and deepest, will plough up the very slender roots; if he ploughs ill, the roots will become thicker, and the strength of the olive will go to the root.' Virgil, where giving an erroneous explanation of the advantages of paring and burning, says, 'The heat opens more ways and hidden vents for the air, through which the dews penetrate to the embryo plants.' Do not, at this very period, Lord Leicester and all the best of England's agriculturists, find the greatest advantage from stirring the ground between their rows of drilled turnips, for the sole purpose of promoting the access of the air to their roots; and that, too, on soils where a weed is hardly to be seen? Is not one great object of fallowing to produce, by pulverizing and deepening the soil, the same result? Did not Jethro Tull labour long, and sometimes too sanguinely, in illustrating the same position? And does he not support the subsoilers' conclusions when he says,—'I have had the experience of a multitude of instances, which confirms it so far, that I am in no doubt that any soil (be it rich or poor) can ever be made too fine by tillage. For it is without dispute, that one cubical foot of this minute powder may have more internal superficies than a thousand cubical feet of the same or any other earth tilled in the common manner; and I believe no two arable earths in the world do exceed one another in their natural richness twenty times; that is, one cubical foot of the richest is not able to produce an equal quantity of vegetables, *cæteris paribus*, to twenty cubical feet of the poorest; therefore it is not strange that the poorest, when, by pulverizing, it has obtained one hundred times the internal superficies of the rich untilled land, should exceed it in fertility; or, if a foot of the poorest was made to have twenty times the superficies of a foot of such rich land, the poorest might produce an equal quantity of vegetables with the rich. Besides, there is another extraordinary advantage when a soil has a larger internal superficies in a very little compass; for then the roots of plants in it are better supplied with nourishment, being nearer to them on all sides within reach, than it can be when the soil is less fine, as in common tillage; and the roots in the one must extend much farther than in the other; to reach an equal quantity of nourishment, they must range, and fill, perhaps, above twenty times more space, to collect the same quantity of food. But in this fine soil, the most weak and tender roots have free passage to the utmost of their extent, and have also an easy, due, and equal pressure everywhere, as in water.'

"And it is fortunately in our power to prove

that a thorough subsoil-ploughing or trenching is a *permanent* improvement of the soil,—is productive of continued good results for a series of years after the operation has been performed. I have often had occasion to remark this in my own experience; and that how slowly ground which has been once disturbed acquires its original degree of solidity, every railroad contractor or builder can furnish satisfactory evidence. Neither are the good effects of this deep-soil cultivation merely dependent upon the effects of the manure being more deeply placed, or more widely diffused in the soil; the mere loosening and extended pulverization of any soil, is certain to render that soil more productive. It is seldom that any experiments can be carried on to any extent, which will prove this fact more conclusively than those made some years since by Mr. Withers and other planters in Norfolk, with their timber plantations, of which, nearly in his own words the following is the detail. In the year 1811, five acres of poor black sandy land were planted in the parish of Holt; the land had been recently inclosed from the common, and was covered with heath and whins; Scotch fir, and a proper assortment of deciduous trees, were planted in large holes; the fir succeeded pretty well, but the other trees made no progress; and although, he adds, 'I yearly filled up the vacancies occasioned by death and decay, I found, at the end of four or five years, that all the trees but the Scotch fir, with very few exceptions, were either dead or in a dying state. I then had all the ground trenched, and all the vacancies filled up with oak, ash, chestnut, elm, and other trees; and I have kept it regularly hoed, and free from weeds ever since. The consequence has been, that the last-mentioned trees have made such a rapid growth, that I have been enabled to clear away the greater part of the fir, and the remainder must be taken out in a year or two, to give space for the other trees. One mountain-ash, which had escaped the deadly effect of the heath, whins (and iron-bound soil), gave a decided proof of the advantages of trenching and cleaning the land. This tree had barely kept alive, not making more than two or three inches of wood in a season; but in the year following the trenching, it threw out two leading shoots, the smallest of which, when cut off at Michaelmas, measured six feet two inches.' In the spring of 1819, another piece of ground, containing half an acre, adjoining the five acre field, was planted with the same description of trees. 'This land was trenched two feet deep, and has since been kept perfectly clean; and so great is the advantage of preparing the land properly, in the first instance, that the trees in this piece are now much superior to those planted eight years before, although the latter have had the benefit of hoeing for the last nine or ten years.' With regard to field crops, the testimony in favour of subsoiling the same kind of light sandy soil is equally important and unanswerable. Thus, Sir Edward Stracey, the inventor of the Rackheath subsoil-plough, says, 'I have broken up nearly 500 acres of heath land with the plough. My crops have been nearly doubled. The wheat produced on the land so broken up has been fine plump grain, weighing about 63½ lb. to the imperial bushel, has produced the best price in the market, where, before the deep ploughing, the same land scarcely produced the seed. The wheat was so poor and shrivelled, that nobody would look at it; and, as I had no manure to lay upon the ground, I can ascribe the goodness of the crop to nothing but the deep ploughing.' And for heavier soils, the evidence in favour of subsoil-ploughing is nearly equally valuable. In the year 1838, an experiment was made by Sir James Graham, which is important in several respects. It was on a field of about eight acres, of the poorest and wettest land. 'The surface-soil is about five inches deep of black earth, of a peaty quality; the subsoil is a weeping retentive clay, with sand and rusty gravel intermixed; this clay extends to the bottom of the drains, which are of tile, laid thirty inches deep in every furrow. This field was rented by the out-going tenant at 4s. 6d. per acre. It was in pasture of the coarsest description, overrun with rushes and other aquatic plants. After draining on one-half of this field, I used Mr. Smith's subsoil-plough. On the other half I trench-ploughed to the depth of ten inches, by two ploughs following in succession; in the first part, not mixing with the surface any of the subsoil,—in the last part commingling the surface and the subsoil in nearly equal proportions. The whole field was heavily but equally manured, and planted with potatoes; and though the potato crop, even on good land in this neighbourhood (Cumberland), was below an average, yet the crop in this field exceeded an average, and yielded about twelve tons per acre. The field is equally drained in every part. The crop was so equal throughout the field, that I am unable to pronounce positively which part was the best; but I am inclined to give the preference to that portion where Mr. Smith's subsoil-plough was used.'

"It is always refreshing to find the observations of the farmers confirming the experiments of the chemist, as in those which have been made by the Hampshire farmers, who find, in the retentive soils of their stiff clay formations, such as those in the north of that county, that when they are reduced, by dint of ploughing, to a fine mouldy state, so that the atmosphere can freely penetrate through them, that then the surface of the subsoil speedily becomes very moist, and continues so during the warmest weather. The more finely the soil is divided, the more steadily moist the surface of the substratum becomes. The farmers of the chalk formation in the same county also have remarked, in the wheat crops

growing on the edge of chalk-pits, that as the soil near the edge of the pit becomes thus loosened by the removal of the earth, that then the roots of the wheat-plants growing in the immediate neighbourhood of the pits, elongate themselves in a remarkable manner, some of them reaching to a depth of three or four feet, and this, too, in the same chalk, of which the superstratum is principally composed. In this and similar instances, the extension of the roots of the plant in search of nourishment is well worthy of remark, as proving the efforts which a plant thus situated makes to acquire nourishment, which, in such instances, is most likely either moisture or the gases of the atmosphere, since here we find, that the chemical composition of the substratum is very similar to that of the surface-soil. The required ingredient, therefore, could not be chalk or silica; and it is not likely that alumina was needed, from the small proportion in which it exists in plants. Decomposing organic matters must be nearly absent from the iron-bound substratum, so that atmospheric air and water were the only food of plants likely to be found by the roots of the wheat-plant in diving so deeply into the loosened chalk.—Such, I think, are the reasonable advantages derivable from the subsoiling system,—benefits which, on most soils, must be more or less easily within the reach of the cultivator. It possesses, too, the great advantage of improving the land from its own resources. No other district need be impoverished, no expensive artificial fertilizers procured, to enable the farmer to render that portion of his land productive, which he may have hitherto neglected; he has only to avail himself of the advantages which the improved construction of agricultural machinery now offers for his service."

Three things in this long abstract from Mr. Johnson's paper require to be taken with important modifications,—first, subsoil-ploughing, in any case, can produce the effects he ascribes to it only when superinduced on efficient subsoil draining; second, the permanency of its effects is experienced only on some lands, and either somewhat limitedly or scarcely at all on others; and third, the beneficial effects of it, in most cases, do not result properly from a mere stirring of the subsoil, irrespective of the mixing of some of it with the soil, but may be realized also, and even combined with other advantages, by means of deep-ploughing and of trench-ploughing. These points, though with rather undue tendency to the opposite extreme, are well argued in the following extract of the Quarterly Journal's review of Mr. Shaw Lefevre's manifesto of 1836:—"Mr. Smith is naturally favourable to his own contrivance, of which we think he speaks more favourably than it deserves; and, thinking so, we do not admire his subsoil-plough any more than we would adopt his theory, or follow his objectionable practice of taking two white crops in succession. With all his predilection for the subsoil-plough, had this direct question been put to him, If he thought it impossible to improve land to the highest degree of fertility without subsoil-ploughing? he knows farming better than to have answered it in the affirmative; whereas had the same question been put to him in reference to thorough draining, he would at once have given an affirmative answer. He therefore justly deprecates subsoil-ploughing as a mischievous operation, without the preparation of thorough draining. Thus, to the query, 'Have you used your subsoil-plough without any auxiliary permanent drains?' he answers, 'I have, and it is the worst thing possible to deep-plough land without having it first drained; and it is upon that ground that in England, the shallow-ploughing is so much resorted to. The deeper stiff clay is ploughed the worse it is, because there is thereby a greater reservoir formed to hold water.' 'Supposing the instance of a marsh, where you have no fall of water, and you have about eight or nine inches of soil upon the surface that is marl, and underneath you come to a stiff substratum of clay, and it is almost impossible to get water off, the fields are separated by drains, and scarcely any fall for the water, would you then recommend your subsoil-plough?' 'Certainly not: I think it would just make a reservoir for more water to lodge.' Again, in his pamphlet on thorough draining, he intimates, 'I have been often asked if I would recommend subsoil-ploughing of land which had not been drained? To this I answer, certainly not; for until there is an escape for the water through the subsoil, any opening of it but provides a greater space for holding water, and will rather tend to injure than improve the soil.' . . 'So soon as wet lands are thoroughly drained, deep-ploughing may follow with the greater advantage, but not sooner.' Thus, having good authority for believing that without thorough draining, subsoil-ploughing is a mischievous operation, we may also safely believe that with it subsoil-ploughing is a very innocent operation, so innocuous as to do as little good as harm.

"The theory broached by Mr. Smith, and readily adopted by Mr. Shaw Lefevre, that subsoil ploughed with the subsoil plough remains ever after friable, and is so maintained and accelerated by the action of the water and the action of the atmosphere, which is constantly going like a tide into and out of the soil, admits of doubtful acceptance from its improbability. It is a well ascertained physical fact, that water percolating through any state of soil has a tendency to consolidate it, and especially it will most easily consolidate friable soil. Pour water upon loose sand, and observe how firm the sand immediately becomes. Observe how easily a fine barley-seed furrow is consolidated by a shower of rain. Perceive how firm the soil becomes over a deep drain. These being natural effects

produced by natural causes, what is to prevent the consolidation of subsoil by the percolation of water, although it had been loosened by the subsoil plough, especially when placed under a superincumbent weight of earth? Clay soil having a natural affinity for water, its texture does not 'clap' or consolidate so obviously by the action of water as friable soil, though it poaches on the surface much more readily. Air is found in the earth at the lowest depths; but that its action can be so sensible on loosened subsoil, placed under a thick stratum of earth, as to admit of a comparison with those chemical changes which it effects on the surface of the soil in fallow, 'owing to its exposure to the action of the wind and rain,' especially when the essential ameliorating element of light is necessarily excluded from the subsoil, is a proposition to which few scientific minds would give assent.

"Subsoil-ploughing is surely not 'applicable to all qualities of subsoil.' What could it effect on a subsoil of trap, of which there are numerous instances in this country and Ireland? There are subsoils, both alluvial and diluvial, so occupied with erratic blocks, as to render the admission of any kind of plough impracticable. Those in some parts of Kincardine and Aberdeenshires, and the county of Antrim in Ireland, are so full of primitive and trap blocks as to form a sort of causeway under the arable soil. The subsoil of gravelly deposits is frequently full of large and land-fast blocks of stratified rock. From 14 to 16 inches under the surface is the depth recommended by Mr. Smith for subsoil-ploughing, and 6 inches of earth is thought desirable to be between the sole of the plough and the tiles, the depth to the tiles thus being 22 inches; but there are many persons who make their tile drains only 24 inches in depth, in which cases, were they to practise subsoil-ploughing as here recommended, they would inevitably destroy their drains. It would, of course, be foolish to make the attempt; and yet the probability of such attempts being made by inconsiderate persons, shows the imminent danger of recommending the indiscriminate use of the subsoil-plough. Subsoil-ploughing is like an edged tool, which is only safe in the hands of an experienced operator.

"If depth of soil is all that is desired to be obtained by subsoil-ploughing, that object may be more easily and effectively obtained by ploughing a little deeper than usual with the common or with a four-horse plough. This implement is more easily drawn than a subsoil-plough, inasmuch as it chiefly works in the surface soil; and a deep arable soil is more effectually procured by it, in a shorter period of time, inasmuch as it brings some of the subsoil, of whatever quality it may be, 'as in fallow,' to more thorough 'exposure to the action of the wind and rain' and light, than can be done by the subsoil-plough with its once repeated subterranean operation. Some farmers, it is true, object to bringing to the surface any species of subsoil, as being deleterious to vegetation. This objection has no validity in any case where the soil and subsoil have been thorough drained; and it is less valid in cases where the subsoil is nearly similar to the surface soil, as carse clays, black mould, loams, and such like. But however 'tilly' the subsoil is, when mixed in a small proportion at a time, in comparison with the arable soil, after being exposed to the meliorating influence of the light and air, it can never materially injure vegetation. But for our part, we see no necessity for wishing an inordinate depth of workable soil. Six inches form a fair average furrow depth; and if there is as much below it of well dressed soil, plenty of scope will be afforded for the rumination of the roots of the plants usually cultivated. We consider the quality or heart of the soil beyond the depth of the usual plough furrow, of much more importance than its quantity; and, of course, six inches of subsoil is much more easily put in heart than sixteen. We have ploughed deep black mould, resting upon retentive clay, sixteen and ten inches deep, at different parts of the same field, with a four-horse plough, after it had been drained, and we could perceive no advantage on the crops for years after, on the deeper portion. Most of the plants which are cultivated in the fields, being fibrous rooted, do not require great depth of soil to thrive in. We have, indeed, traced the root of broad red clover, six feet in depth, through a fissure in a bank of clay loam, which had been carried away by the irruption of a rapid stream in time of flood; but the plant which sent forth this long foraging root was no larger than its neighbours. We have followed the tap-root of a wheat plant for a foot through the soil, but its produce was not greater than that of others around it. These facts are not marvellous, because, had the energies of those plants which were exerted in the prolongation of root, been directed to the formation of leaves or seeds, their products would have been more valuable. It was the scantiness of food that impelled them to roam abroad in search of it; had they found abundance of food around their roots, like abundantly fed fowls, they would have had no temptation to wander so far from home.

"Whilst expressing our convictions on the inutility of subsoil-ploughing, we have been frequently interrogated, would you not break the pan that is below? Break it up and bring it to the surface by all means, if it is within reach of common ploughing, whether the land has been thorough-drained or not. But all this apprehension of the moorband pan is founded on an erroneous conception of its origin. How does it originate? It is never found in subsoils of pure clay, of black mould, of hazel loams, of sand or gravel. It is quite impossible it should be found in such situations. The pan or crust is a deposition of iron, and can only be deposited on such subsoils as admit of a certain degree of per-

colation of water, but not faster than the water may have time to deposit the iron. Hence the pan or crust is only found on subsoils of clay having gravel embedded in them. It is quite obvious from the nature of the deposition, that were there quick absorption of the water, or, in other words, were the subsoil thorough drained, there would be no deposition of pan. The iron in the pan is in a state of hydrate, is soluble, and of course injurious to vegetation; but when this hydrate becomes dry, by exposure to the action of the air, it is converted into a pure oxide, which is insoluble, therefore innocuous to vegetation, and which generally mixes with, and forms a component part and colouring matter of, the soil. The most rational method, therefore, of getting quit of pan is to render the soil thoroughly dry; and any other method is only a temporary expedient. But after all, the extent of peculiar subsoil which can generate pan must be comparatively small, and is chiefly to be met with under peaty earth in moorland districts.

"It is desirable that farmers, particularly small farmers, should incur no more expense in the purchase of implements than what is absolutely necessary for the right management of their farms. But, independently of this circumstance, many small farmers have not two pairs of horses of sufficient strength to work a subsoil-plough. We know those who have tried it and could not succeed to work it with fewer than three pairs of horses. It is said that the Muirkirk subsoil-plough is more easily worked than Mr. Smith's; but whether it does its work better or not, which is the chief criterion of excellence, we do not pretend to decide. There is another consideration which is not unworthy of notice, in reference to any extraordinarily heavy work to be performed on a farm. We may propound it as an axiom in horse labour, that every kind of work which requires more than the combined efforts of two horses to execute, is injurious to the horses themselves. When more are yoked together, there is so much counteraction in performing work, that the weak and sanguine tempered horse is always in the end sure to suffer. By using the four-horse plough much in bringing in land, trench-ploughing, splitting down old dykes of turf, and tearing up old decayed tree roots, two very powerful horses of our own, both of sanguine temperament, suffered so severely as to superinduce inflammation in the lungs that terminated in helpless broken wind, and so became unfit for ordinary farm work. We afterwards tried to execute much of the roughest part of that kind of work by trenching with the spade, and found it much more cheaply done, taking into account its at once finished effectiveness. Deep-ploughing cannot, of course, be executed, in present circumstances, otherwise than with horses; but it is the easiest kind of hard labour they undertake; and two strong horses will turn over a deep furrow of thorough drained land, and four horses a furrow of sufficient depth for every purpose of culture."

Subsoil-ploughing, whether judged by theory or by the many appeals to experiment which have been reported in the agricultural periodicals, is least suitable in very light lands, as it tends to make them too loose,—and in very strong plastic clay subsoils, as they immediately or speedily run together again; and most suitable in lands with a strong moorband pan between an open soil and a porous subsoil, as it instantly breaks up the pan, and renders the whole mass of earth permanently absorbent,—and in a subsoil of marly clay or in one of mixed rubble and clay, as it produces a permanent openness and porosity,—and in half open or lazily absorbent lands of all kinds in very rainy districts, as it permanently increases their capacity of letting surface water rapidly down to the drains. But in some cases in which proper subsoil-ploughing is useless, trench-ploughing may be beneficial; while in most cases in which it is eminently useful, trench-ploughing may be equally or superiorly beneficial. Mr. Stephens, in his Book of the Farm, makes this out so well by a combined appeal to principle and report and experiment, that we cannot better state the comparative claims of subsoil-ploughing and trench-ploughing than by making ourselves debtors to him for the passage:—"There is a mode of trenching ground," says he, "which is best done with the plough, its object being to imitate the work of the spade by descending deeper than the ordinary depth of furrow, and of commixing part of the subsoil with the surface soil, which has been probably rendered effete by overcropping. Ground can be trenched with the plough in two ways, either with a large sized common plough drawn by 4 horses, or with one plough going before and turning over an ordinary furrow-slice, and another following in the same furrow drawn by 2 or more, usually with 3 horses, or both ploughs drawn by 3 horses each. It is best performed across the ridges. In either of the above ways the same effect is produced in similar soil, breaking up indurated gravel, deepening thin clays, ameliorating stiff clays by exposure to the air, and mixing old and new soils together, the ultimate effect on all being to deepen that portion of the soil which is used by the cultivated crops. In one respect trenching has the same effect as subsoil ploughing, namely, the stirring of the ground to the same depth, the first plough turning over a furrow of 7 inches in depth, and the second going 8 or 9 inches deeper, making in all a furrow of 15 or 16 inches in depth; but in another respect the two operations leave the soil in very different states—the subsoil plough stirs the soil to the depth named, but brings none of it to the surface, whilst the trench-plough does not altogether bring that which was undermost to the surface, but commixes the under and upper soils together.

It has been made a question, which is the better mode, if both are not alike, of making the soil fertile?—the advocates of subsoil-ploughing alleging that it is better to ameliorate the subsoil while under the soil by the admission to it of air and moisture; while those of the trench-plough answer, that if the object of both operations is to ameliorate the subsoil, it will become sooner so by being brought to the surface, in contact with atmospheric air and moisture. But, say the promoters of subsoil-ploughing, there are subsoils of so pernicious a nature, having the salts of iron and of magnesia in them, that the upper soil would be much injured by its admixture with such substances. No doubt, answer the trench-ploughers, if the subsoil that contained these noxious ingredients in a large proportion were brought up in quantity, when compared with the bulk of the upper soil, injury would be done to it for a time, but they say it is not the abuse but the proper use of trench-ploughing which they advocate; and of such a subsoil, they would use the discretion to bring up only a little at a time, which they have it in their power to do, until they accomplish their end, namely, that of ameliorating the whole depth of subsoil. But they maintain, that by far the greatest proportion of subsoils do not contain those noxious ingredients; and, besides, the very best and quickest way of getting rid of even these is to bring them at once to the surface, for any of the acids, or the salts of iron, are easily neutralised by the action of lime, which is always applied to the surface; and those of magnesia are most easily reduced on free exposure to the air. And, moreover, they ask, If subsoils shall be ameliorated by air and moisture when stirred by a subsoil, why should they not also be ameliorated when stirred by a trench-plough? And they urge further, that trenching may be practised more safely without previous thorough-draining, than subsoil-ploughing. I have no hesitation in expressing my preference of trench to subsoil-ploughing; and I cannot see a single instance, with the sole exception of turning up a very bad subsoil in large quantity, there is any advantage attending subsoil, that cannot be enjoyed by trench-ploughing; and for this single drawback of a very bad subsoil, trenching has the advantage of being performed in perfect safety, where subsoil-ploughing could not be, without previous draining. Mr. Melvin, Ratho Mains, mentions an instance of a field containing both damp and dry ground; the dry was trench-ploughed in the autumn of 1836, an inch or two of the sandy gravel being brought up, and 'was decidedly increased in fertility,' both in the turnip and barley crops which followed. I trench-ploughed a field of 25 acres of deep black mould which had been worn out, with a 4-horse plough, taking and clearing a furrow from 14 to 16 inches deep in the solid land, and bringing up almost in every part a portion of the tilly subsoil, which was only drained to the extent of a few roods put in the face of a slope exhibiting spouts of water. The turnips that followed were excellent; the barley yielded upwards of 50 bushels per acre imperial, and the year after a part was measured off and fenced, containing 6 acres, to stand for hay, which yielded of good hay 1,999 stones of 22 lb. Another field, the year after, that was not drained, suffered injury after trench ploughing; but that was in consequence of having been caught with a premature fall of rain in the autumn before the trenched land could be ridged up, and it lay in the trenched furrow all winter. It is stated that Mr. Scott, Craiglockhart, Mid-Lothian, 'trench-ploughed, in the winter of 1833–4, with one common plough following another, a field of 20 acres, every two alternate ridges, and he has never observed on any of the crops the slightest difference.' This is, as I conceive, an unsatisfactory mode of testing the value of any sort of ploughed land, as it is possible that the untrenched ridges derived a certain, and it might be a sufficient, advantage, in regard to drying, from the adjoining trenched ridges.—But whilst giving a preference to trench-ploughing over subsoil, I am of opinion that it should not be generally attempted under any circumstances, however favourable, without previous thorough-draining, any more than subsoil-ploughing; but when so drained there is no mode of management, in my opinion, that will render land so soon amenable to the means of putting it in a high degree of fertility as trench-ploughing. Mr. Smith himself acknowledges the necessity of trench-ploughing land in a rotation or so after the subsoil has been subsoil-ploughed, in order to insure to it the greatest degree of fertility. The experience in trench-ploughing after thorough-draining of the Marquis of Tweeddale at Yester, East Lothian, may with great confidence be adduced in favour of the system. I have seen a field on Yester farm under the operation of draining which did not carry a single useful pasture plant, but which afterwards admitted of the turnips being drilled across the face of inclining ground, and of presenting to sheep in winter as dry a bed as they could desire; and no farther gone than the spring of 1841, after the Swedish turnip seed had been sown, a field was trench-ploughed with 3 powerful horses in each plough, bringing up white and yellow tilly subsoil, as unpromising in appearance as possible. The weather being very dry, this till became so hard, that part of the field had to be rolled four times, before they were reduced to powder, and after all the operations there was apparently no sap left in the ground. White turnips were sown, came away, one half being eaten off by sheep; and when the land was ploughed up in spring 1842, it turned up to appearance a fine rich dark mould, rising in friable clods, and not a particle of till to be seen. No one need be afraid to bring up subsoil of any

kind on thorough-drained land after the experience of Yester."

SUCCISA. See DEVIL'S-BIT.

SUCCORY, or CHICORY,—botanically *Cichorium*. A genus of blue-flowered, herbaceous plants, constituting the type of a suborder of Compositæ. All its florets, both of the disc and of the ray, are hermaphrodite; its involucre is surrounded with scales or smaller leaflets; its receptacle is almost or altogether naked; and its pappus is sessile, scaly, and shorter than the pericarp or seed-vessel. The suborder called Cichoraceæ comprises seven tribes or groups, represented by the genera hieracium, cichorium, leontodon, scorzonera, lactuca, hypochæris, and catananche. See the article COMPOSITÆ. One species of the succory genus grows wild in Britain, four have been introduced from other countries, and two more are known; but only the indigenous species and one of the introduced species possess any economical interest, — and both of these are slightly noticed in the article ENDIVE.

The common or wild succory, *Cichorium intybus*, is an indigen of poor gravelly lands, particularly about the edges of fields, in both England and Scotland. Its roots are rather thick and fleshy,—and, in some of the cultivated varieties, long and bulky; its stems are branching, and naturally about two feet high,—but, in the cultivated varieties, from four to eight feet high, and even more; its leaves are naturally oblong-lanceolate and runcinate,—but, in the cultivated varieties, though generally more or less hairy and runcinate, with lobes hooked back, are diversified in shape and in shades of colour; and its flowers are numerous and sessile, and grow in pairs, and have a blue colour and a dandelion-like form, and bloom from June till August. The varieties are numerous; but few or none seem to possess much permanency when raised from seed; and one of the most distinct is a large-rooted kind which the French grow as a substitute for coffee, and call *Chiccoree à café*.

Succory has long been cultivated in Belgium, France, Germany, Italy, and other parts of Continental Europe as a substitute for coffee. Its roots are used for this purpose; and, when dug up, are cut in pieces, kiln-dried or roasted in revolving iron cylinders, and then ground into powder in mills. About one-fifth of the whole weight is lost by roasting; and about 3 per cent. of butter is commonly added to improve the consistence and flavour. The powder is very extensively used by grocers for mixing with coffee; and not only is it innoxious, but it is even preferred to genuine coffee by persons who have become accustomed to it; so that the use of it by grocers is scarcely an adulteration, beyond the undue price they charge for it; and even the succory powder itself is frequently adulterated with roasted pease, roasted beans, roasted damaged corn, and other similar substances, aided by a little Armenian bole or Venetian red as a colouring agent. Large quantities of the root began about the year 1835 to be imported into England; and so much as about 5,000 tons a-year was supposed to be brought from Belgium alone. —The leaves of succory, particularly when freed from a portion of their bitterness and harshness by blanching, have been much used in various parts of the Continent, and were formerly used, by the Romans, in a culinary way; and they also possessed at one time some medicinal reputation for their action on the stomach and the bowels. —The whole herbage is highly esteemed throughout large tracts of the Continent and in some parts of England, for the purposes of forage; but though frequently and urgently recommended to the attention of British and Irish farmers and cottiers, particularly for the feeding of cattle and swine, it continues to lie under a degree of general neglect in this country which is grossly inconsistent with its merits and altogether unaccountable. The well known Arthur Young brought seed of it from France in 1788, and grew it extensively on his farm, and declared, in the Annals of Agriculture, that "on various sorts of soil, there is no plant to rival it;" and Mr. Gorrie of Annat says, "I have paid some attention to the culture and comparative merits of various agricultural plants,—prickly comfrey and the yellow day-lily among the rest; yet I have found the culture of chicory easiest and cheapest in the outset, and also very decidedly most profitable as a perennial crop,—it yielding nearly double of nutritive matter as green food in summer, from the same breadth of ground, to any other plant with which I am acquainted. * * On waste corners, near large towns, no plant cultivated in this climate will bring the cow-feeder nearly an equal return with chicory. It should also hold a prominent place in the garden of every cottager in the kingdom, whether to be used as coffee by the family, or as green food by the cow or pig. Were its culture general in Ireland, it would soon prove of more substantial advantage to the labouring classes in the Emerald Isle than many of the political panaceas of the day." In the only known instance of its being tried in mixture with clover and ryegrass for artificial pasture precurrently to the full growth of the natural grasses, in Scotland previous to the publication of the "General Report," it vegetated satisfactorily, and was relished by the live stock, and continued to grow vigorously through the third year of the ley; and since it did well in such a way, so far north, it may right cordially commend itself as a general forage plant, on suitable soils, in all districts of the more southerly parts of the kingdom.

The proper cultivation and management of succory for the purposes of forage in Britain, are described as follows by Mr. Lawson:—"It

thrives best on rich soils, and such as are rather light and well drained. It may be sown alone, either in drills or broadcast, and mixed in small quantities, amongst grass, clover, and other seeds for pasture lands. When the drill system is adopted, which in most cases is to be preferred, the rows may be at from 15 to 20 inches distant, to admit of hand and horse-hoeing, and the plants should stand at least 6 inches distant in the rows; sowing may be deferred till the month of May; as, if this be done at an early period of the season, the plants are apt to commence running to seed in the autumn months, whereby they will be materially weakened, and the first crop of the succeeding season considerably lessened. The operation of thinning should be attended to when the plants are very young, and they should be pulled with the hand, in soft weather, in preference to cutting them with a hoe, as the roots are very tenacious of life, and will push out new buds although cut a good deal below the surface. One considerable crop of root-leaves may be obtained in the end of autumn the first season, and three, four, or even more, may be obtained under very favourable circumstances during each of the four or five seasons following, particularly if the first cutting be completed about the time of the plants first showing their flowers, when the average height will be from 3 to 5 feet, and, in many cases, the cutting should not be deferred until the plants arrive at a more advanced state, as the stalks then become hard and the future vigour of the plants impaired. The broadcast system should only be attempted where the soil is previously in a high state of fertility and completely free from root and annual weeds. The period of duration from the time of sowing will be from four to six years, if cut regularly before arriving at full flower, after which they may be ploughed up and the ground fallowed to get clear of the roots. If, however, the seed be allowed to ripen, the plants will lose much of their vigour even after the first crop. When drilled, 4 lb. or 5 lb. will be a sufficient quantity of seed per acre; but 10 lb. or 12 lb. will be necessary for sowing broad cast." In consequence of the plant standing so long in the ground, it cannot take a place in any regular rotation on arable land, except in a similar way to sainfoin, lucern, and a four or five or six years' duration of grass; but it is peculiarly well suited to very steep ground or an out-of-the-way corner, or any other little tract which cannot conveniently or at all be tilled with the plough. Two serious disadvantages have pretty generally been alleged against it, and are sanctioned by so high an authority as that of Von Thaer,—that it occasions great labour and expense by the difficulty of eradicating it, and that it acts very exhaustingly on the soil; but both are altogether imaginary; for, as we shall see in next paragraph, it is currently lifted by an easy method of harvesting in districts where its roots are the main object of cultivating it,—and it sits so mildly on the soil as to require but a moderate pre-enrichment of manure, and then to be capable of occupying the land in two successive sowings for its roots, and being afterwards profitably followed by wheat.

The proper cultivation and management of succory for the sake of its roots in Britain are described to the following effect, and nearly in the following words, by a gentleman in a part of Yorkshire where it is much attended to:—"The soil best adapted to it is deep, rich, and loamy; but it will grow upon any land favourable for turnips or potatoes, or intermediate between cold stiff clay and a poor thin sandy land. Some favourite fields are close upon gravel; others are more of a black peaty moor land. No fallowing is absolutely required; but it is better that the land should be winter-ploughed, and prepared as for turnips; it must be as clean as possible,—and, if of a friable light character, not overmuch wrought or 'loosened' in spring. The quantity of manure will depend on the condition of the land; say about four loads of good short dung (ashes, night-soil, &c.), laid on broadcast, as an average to the acre, when ready for rowing up, which will prevent the ridges being twice turned, as in turnip sowing. The period of sowing will depend upon the season, and the condition of the land; the latter end of April or beginning of May is preferable. The double-drill is in use in this district, and the rows should be from 16 to 18 inches in width,—the drills $3\frac{1}{2}$ inches apart. Very great care must be taken that the drills are kept clean, and not suffered to choke, or much ground may be lost, as it is difficult to tell how far they may have 'missed delivery.' They, and the roller attached to follow, may be worked by a quiet old pony. About three weeks or a month after sowing, it will be requisite to hand-pull and weed. No hoe is ever permitted. If necessary, you may employ the pony and a light scuffler between the rows. Particular care must be paid to the cleaning and weeding; and the frequency of the operation will depend upon circumstances. If the land is clean, 16 or 18 women and children may go over it twice in a season; and an acre may occupy them probably about two days. The plants in the drills should be singled two or three inches apart from each other. Dibbling where seed has failed does not appear to answer. Those plants which 'run to head,' must be watched, and carefully drawn when they show flower; or at the final taking up they will prove woody and worthless, like a radish run to seed. They can be carried home and prepared for sale in the same manner as if drawn at maturity. The proper time for taking up the crop depends on the season;—in November, if considered ripe; but experience alone can enable you to fix the precise time. Those who have much will commence sooner than those who have less to take up. The mode of harvesting

in this district is to let the taking up to a man and his family, or a gang of men, at about £2 per acre (which is considered very 'bad pay,' or 'minimum' allowance). The spades are like dock-drawers, 18 inches long, by 2½ or 3 broad; each plant must be 'lifted' with the spade, and drawn by the hand. The followers pick up the plants, and carefully twist off the tops, or leaves, throwing the roots on heaps; and cattle of all sorts being exceedingly fond of the leaves, it is the practice, after getting the roots away as quickly as possible, to turn a large quantity of sheep into the field to devour the relics, or to cart them away to the pastures whilst they are still pretty fresh. From the field the roots are taken to the most convenient washing-place; a running stream, easy of access, with a good gravelly bottom, is invaluable for this purpose. When washed, they are conveyed to the manufactory and there cut by a machine into pieces or lengths of a ¼ or ½ an inch; these again are riddled to separate the smaller from the larger, the thin from the thick ends, which take more drying. They are then placed on a kiln, in bags, about 16 at a time, until ready for roasting—managed in a similar way to coffee; then ground or crushed with shelling stones, and made up for sale. When cut it must not be allowed to remain in heaps for more than a day. Two cutters are worked by one horse; each has one knife only, and two women to feed it."—The Belgian cultivators sometimes use poppy oil-cakes as manure for it, and always apply the manure in the autumn before sowing; and they sow broadcast, and thin out to final distances of 6 inches, and keep the crop clean by hoeing and hand-weeding. The average crop of roots per acre in Yorkshire is from 3 to 5 tons; but some of the cultivators there who have skill enough to grow the crop, cannot succeed in preparing it for the market.

The endive succory, or simply endive, *Cichorium endivia*, was introduced to Britain from India about the middle of the 16th century. It is a highly esteemed salad plant; and is particularly in request at the seasons when lettuce is scarce; but it requires somewhat nice and careful blanching to make it crisp and completely palatable. Three varieties of it are in cultivation,—the green curled-leaved, the Batavian broad-leaved, and the white curled-leaved. The first is preferable for main crops,—and the second for use in autumn and the early part of winter, but does not well withstand frost; and all may be sown in successions from May till the beginning of August, and afterwards transplanted to distances of 12 or 15 inches. Any which are sown earlier than May run to seed in the course of the summer, without becoming duly available for culinary purposes; yet if a few be wanted for the earliest possible use, a small sowing of the white curled-leaved may be made in March or April. The blanching may be done by tying-up after the manner of lettuce, or by earthing-up after the manner of celery, or by heaping around the plants cones of coal ashes or of dry sand, or by covering them, for protection at the same time from frost, with dry leaves of trees or fronds of ferns, or by covering them with garden pots, or with tiles or pieces of wood. The method of embathing in cones of dry sand is the most generally efficient; but requires to be preceded by a careful and close tying-up of the plants at a time when they are perfectly free from moisture.

SUCCOWIA. A handsome, yellow-flowered, hardy, annual plant, of the cruciferous order. It was introduced to Britain from Minorca about 70 years ago; and it constitutes a genus of itself, and is specifically called the Balearic. It has a height of about 10 inches, and naturally blooms in June and July.

SUCCULENCY. A fleshy juiciness in the root, stem, leaves, or other parts of a plant.

SUCKER. A shoot or young twig from the root-crown or root-side of a plant.

SUDORIFIC. A medicine which excites sweating. It enters the circulation, acts on the subcutaneous vessels, and augments the energy of the cuticular glands which secrete the sweat. No known substance acts safely as a sudorific in the horse; but either a mixture of ipecacuanha and opium, or a mixture of emetic tartar, opium, and ginger, beneficially increases his insensible perspiration. See the article PERSPIRATION.

SUET. The fat situated about the loins and kidneys of sheep, oxen, and some other animals. It is harder and less fusible than the fat of other parts of the same animals, or than that of the same parts of other animals; but it differs from these fats, and even from the softest hog's lard, chiefly in consistency,—and, like them, is composed almost entirely of stearine and elaine, or ultimately of carbon, hydrogen, and oxygen. See the articles OIL and FAT. The suet of sheep and oxen, when melted out of the membranes which envelop it, forms tallow, and is largely used in the manufacture of soap and candles; and when fused, it concretes at a temperature of about 100°. See the articles CANDLE, SOAP, and TALLOW.

SUFFOLK GRASS. See POA.

SUFFRUTICOSE PLANT. A plant of intermediate character between an herb and a shrub. It has not perishable, succulent shoots and herbage like the one, nor hard woody twigs and complete buds like the other; yet it is more shrubby in habit and in general appearance than herbaceous. Common lavender is an example.

SUGAR. The principle in vegetable and animal products which is resolvable by fermentation into alcohol and carbonic acid. It is popularly regarded as the principle of sweetness in all sorts of substances; and has often been scientifically defined as the sweet constituent in organic structures and secretions; but it is totally absent in some very sweet substances, both mineral and organic, such as sugar of lead and manna,—and

it is always the immediate principle whence alcohol is evolved, and is in every case resolvable into alcohol with loss of carbon and oxygen; so that it is far more correctly designated the alcoholizable principle than the principle of sweetness. The elementary transpositions by which it passes into alcohol and carbonic acid are noticed in the article ALCOHOL; the process in which these transpositions take place is described in the article FERMENTATION; the forced or artificial evolution of it from the starch of grain preparatorily to its conversion into alcohol is described in the article MALT; the process of converting it into the alcoholic constituent of malt liquors is noticed in the article BREWING; the natural evolution of it from the starch of seeds as food for nascent plantlets is explained in the article GERMINATION; the part which it plays in the progress of the growth and the maturation of plants is noticed in the article NUTRITION; the purposes which it serves as an ingredient in the food of man and of some of the lower animals are glanced at in the article ALIMENTARY PRINCIPLES; the uses of a coarse and impure form of it in the feeding of cattle are adverted to in the article MOLASSES; the plant from which the chief bulk of the sugar of commerce is manufactured is described in the article SACCHARUM; the making of sugar from beet-root and the sugar-maple is noticed in respectively the articles BEET-SUGAR and MAPLE; and a wide variety of other topics connected with the nature, powers, transmutations, preparation, or uses of sugar, are noticed in the articles BIRCH, CARROT, FRUIT, LIQUORICE, BORASSUS, PALM, MILK, SYRUP, HONEY, and many others.

Sugar, we have said, on being excited by a ferment, becomes alcohol or spirit; and this, by a continued natural operation, and by the aid of another ferment, is convertible into acetic acid or vinegar. But two conditions are essential to these changes,—dilution with water and a certain amount of temperature. Sugar, as it exists naturally in vegetable matter, forms an extremely diluted solution, which, combined with other matters, constitutes the juices of vegetables. In this state, if in contact with its natural ferment, one of the principles of gluten which exists in all fruits and other vegetable products, it will commence the process of alcoholization, which being effected under great agitation and ebullition in the liquid, is termed fermentation. Alcohol itself under this fermentation is formed only in a diluted state, in which, being combined with the other principles also of the fruit, it is termed wine. When the whole of the sugar is converted into alcohol, and the temperature is at the proper point, acetification begins, and the alcohol, by a new kind of fermentation, becomes acetic acid; in a word, the wine is converted into vinegar. Pure dry sugar, separated from every other substance, will not ferment at all, and therefore will not become alcohol; neither will a thick syrup of pure sugar. In its dry and crystallized state, therefore, or in that of syrup, sugar remains unchanged; only in the latter form, as the water evaporates by the operation of heat, time, or any other cause, crystals of sugar will form on the sides of the vessel above the surface of the liquid. And as pure undiluted sugar is not convertible into alcohol, so the pure spirit obtained from the vinous liquid by distillation is not convertible into acetic acid, because, in its concentrated form, alcohol, like sugar, is unchangeable.

There are three distinct kinds of sugar to be found in the products of organized matter. The first contains the greatest quantity of fermentable matter, and therefore yields the most spirit. It is found in the sugar-cane, in beet-root, in the maple, in the carrot, the turnip, the parsnip, in cabbage-stalks, in the stalks of all the gramineous tribes of vegetables, and in the leaves, blossoms, and green stalks of most other plants. It is likewise one of the constituents of honey. This sugar, when purified, and freed from foreign matter, is extremely white and hard, crystallizing into oblique four-sided prisms, that have summits with two sides. It is obtained from the vegetables that possess it, by pressing out and evaporating their juice, which holds it, with other matters, in such a state of diluted solution, that it is ever ready, the moment it is separated from its natural vehicle, to enter into spontaneous vinous fermentation. All the sugars obtained from the sources just mentioned are identical in their properties; but that yielded by the white beet-root has a greater power of cohesive attraction than the produce of any other sugar-bearing plant, not even excepting the sugar-cane; and its crystals, in its purest form, are therefore larger and much harder.—The second kind of sugar does not form regular crystals, but, in its purified state, exhibits a white, hard, concrete body, having the shape of a cauliflower. It is inferior to the former in saccharine or alcoholic principle, because it contains less fermentable matter, the ratio of this inferiority being as six to ten. This description of sugar exists ready formed in all kinds of sub-acid fruits, when ripe, such as grapes, apples, pears, cherries, strawberries, raspberries, oranges, and many other varieties, its vehicle being the juice of the fruit, which holds it in solution,—ready, as stated with reference to the first kind, spontaneously to form wine. Starch is chemically converted into this kind of sugar by being treated with sulphuric acid; and when the saccharification is complete, the acid is separated from the sugar by means of lime, with which it unites. Diastase, a principle extracted from crushed malt by maceration in water, also converts starch into sugar. Gum may likewise be changed into sugar by sulphuric acid,—which will likewise saccharify glue. But the same description of sugar may be derived from still more singular sources, one of which is sawdust. This substance is composed, as every one knows, of

lignin, which is the principle of wood. If, then, sawdust be treated with sulphuric acid, it will be converted into gum, which by further treatment with the same acid, becomes sugar. The sawdust that under this process is perhaps the most speedily convertible into sugar, is that produced from the very hard wood of hornbeam. Hemp and flax, the principal constituent of which is lignin, will both produce the same result as sawdust, under the same chemical agency of sulphuric acid; and this power is so strongly preserved through all the various changes they undergo, that sugar may be obtained from old hempen cloth or from linen rags—or more correctly speaking, the lignin of these substances may be converted into sugar by the agency of sulphuric acid. The sugar of milk is of the kind we are now describing, but is less powerful than that from vegetable sources; and though it exists in smaller proportion in the milk of the cow than in that of many other animals, yet the sugar of cow's milk is separated and granulated upon a large scale, in Switzerland, for pharmaceutical purposes. There is a further peculiarity in this sugar, which is, that its best ferment for the production of alcohol is the union of the other ingredients composing the milk, that is to say, the milk in its unseparated condition, acted upon by a small portion of other milk already under vinous fermentation.—The third kind of sugar is uncrystallizable, but remains in the form of a thick dark syrup. It is still lower in saccharine qualities than the last, its ratio, as compared with the first kind, being no higher than four to ten. This is the kind of sugar formed by germination of grain both natural and artificial. It is likewise found in the sugar-cane, in the beet-root, and in the maple, united with the crystallizable sugar, from which it separates under the form of a black thick syrup, known by the name of molasses and treacle. The sugar obtained from the various palm-trees, especially from the palmyra-tree, or borassus flabelliformis, and known in India by the name of jaggery, is likewise of this description. To this we may add the sugars yielded by many of the boletus or mushroom tribes, and that also found in the liquorice-root.

Sweetness to the taste is certainly one of the attributes of sugar; but, as we have already observed, it is an error to call it the sweet constituent of organic matter, because there are other constituents more lusciously sweet. Pure sugar, obtained for common use through the labours of the refiner, carries with it assuredly, in a given weight, the greatest possible quantity of fermentable matter or alcoholic base; but it has not that intensely sweet and cloying flavour peculiar to brown sugar, to treacle and molasses, and to Spanish juice, neither of which affords anything like the same quantity of alcohol. The Spanish juice yields scarcely any; the molasses and treacle, when wholly free from crystallizable sugar, very little. The sweet, cloying, sickly flavour of manna is universally known; it is sweeter than pure sugar, and yet contains no sugar, and therefore produces no alcohol. The peculiar action upon the palate that produces what is termed a sweet taste, is yet unknown; though the sweetness of pure sugar is always distinguishable from every other kind of sweetness.

To make pure syrup requires twenty-nine ounces of the best refined sugar to a pint of water. If such syrup be diluted with water, a little gluten added, and the whole kept at the temperature of 60 degrees Fahrenheit, it will speedily be converted into wine, the alcohol of which may be extracted by distillation. Thus, when sugar is cheap, moist or unrefined sugar, and even treacle, or sugar and treacle mixed, may be substituted for malt; and by the addition of hops and other flavouring substances to a vinous fermented solution of sugar, a much better liquor may be obtained than that brewed from malt, the sugar from which, being produced partly by germination and partly by chemical conversion in the mash-tub, under the influence of the diastase of the malt, is inferior to and much less rich in alcoholic principle, than that used for ordinary domestic purposes.

If sugar be subjected, in its dry state, or nearly so, to the action of heat, it fuses and assumes the appearance of a dark-coloured syrup, which will harden on cooling. This readily dissolves in water, and also in alcohol, which makes it of use for colouring liquors, and many luxuries of the table. If allowed to burn, it acquires a bitter empyreumatic flavour. Sugar thus fused will not again crystallize. It is termed, in this state, caramel by pastry-cooks, and essentia binia by porter-brewers. Though a very wholesome colouring matter for malt liquor, its use is prohibited by law, in favour of a substance much less innocuous.

Sugar will dissolve in water, in all proportions, but not in alcohol unless heated, and then only in very sparing quantities. It has likewise some chemical properties, which ought to be known to housekeepers. It has a very strong affinity for water, of which, in its pure form, it contains 5·3 parts in every 100 of sugar. This cannot be termed its water of crystallization, because it exists in uncrystallizable sugar, and in the mushroom-shaped concretions already mentioned. This constituent water cannot be separated, except by converting the sugar into a saccharate, the nature of which we will explain. Sugar, though not an acid, has the property of combining with certain metallic oxides, and of producing a specific action upon other metallic oxides, and upon some metallic chlorides. In the first case, it forms saccharates; in the last, it liberates the oxygen or the chlorine from the base. With oxide of lead, sugar has two combinations, forming a saccharate and a bisaccharate, the one insoluble, the other the reverse. The first, produced by digesting oxide of lead in syrup, is a

yellow deliquescent mass, wholly uncrystallizable; the last, obtained by boiling oxide of lead in syrup, is ultimately obtained in the form of thick white flocks, very light, quite tasteless, and insoluble. These flocks will ignite and burn like German tinder. A subsaccharate of lead may be obtained, wholly free from water, by mixing pounded litharge with syrup, and evaporating the mass to dryness by means of the sand-bath.

One of the most useful properties of sugar, in household economy, is its action upon the salts of copper, among which the most common are the oxide of copper, and verdigris or acetate of copper. It completely dissolves and neutralizes these salts, totally destroying their poisonous action upon the animal economy. Orfila states that a quantity of verdigris which in an hour would destroy the life of an adult human being, may be swallowed without danger when mixed with a large quantity of sugar or syrup. When copper vessels are used for making jellies from acid fruits, or for preserving fruits in sugar, the quantity of this latter substance necessarily used counteracts the dangerous properties of the copper. From this it is evident that in all cases of accidental poisoning from the use of copper vessels, or from having taken verdigris into the stomach, the antidote is dissolved sugar or syrup, in as large quantities as the stomach will bear. To this may be added water containing sulphuretted hydrogen, which is always to be obtained at any respectable druggist's. The sugar, however, is effective by itself, and will counteract the poisonous qualities of any of the salts of copper. As capers, from the mode of their preparation, always contain a small portion of verdigris, a little sugar should be added to them when employed to make caper-sauce. In stewpan cookery, likewise, if the stewpan be of copper, even though well tinned, a lump or two of sugar, which always improves the flavour of the savoury preparation, also secures the eater of it against any accidental intrusion of the poisonous salts of copper, which, where proper cleanliness is observed, must, if they exist at all, be very minute. But even should they not exist, it is much better to be secured against them, because the apprehension is often more injurious than the reality of danger.

When sugar in solution is boiled with verdigris, a considerable quantity of the cupreous oxide or protoxide of copper is precipitated. Boiled with nitrate of silver or nitrate of mercury, it precipitates the metal uncombined, as it does also when boiled with the chlorides of gold, silver, and platinum. Sugar, with water, in the form of syrup, has the property of dissolving the alkaline earths, lime, magnesia, baryta, and strontia, which are otherwise insoluble in water. All acids have a remarkable action upon sugar, which, if in contact with it for some time, though the acids be afterwards neutralized and separated from it, they render uncrystallizable. This is the case with citric, tartaric, and oxalic acids, which completely and for ever destroy in sugar its property of crystallization. Nitric acid converts sugar into oxalic acid, or into malic acid, according to the mode of its application. Sulphuric, phosphoric, and the hydro-acids, have all a strong action upon sugar, injurious to its due granulation. Alkaline substances also will prevent the crystallization of sugar, and, when mixed in excess, will reduce the first to the third kind. In the manufacture of sugar, therefore, from the expressed juice of the cane, the beet, or any other sacchariferous plant, the quantity of sugar will be less, and that of molasses greater, whenever too much lime is used in the first purification of the juice. There is a strong electrical action in sugar, by which light is produced when two lumps of pure crystallized sugar are rubbed together in the dark, heat being given out at the same time, but in so small a quantity as to be scarcely sensible.

The sugar of commerce, in Great Britain, the produce of our colonies, is derived from the sugar-cane, or *Saccharum officinarum*, one of the gramineous family. Viewed from a distance, a plantation of sugar-canes has much the appearance of a field of wheat before the ears begin to make their appearance. When ripe, the smooth surface of the cane resembles in colour the skin of a ripe apple, varying in tint from the florid to the pale, according to the variety of the plant. Within the thin, crisp rind of the cane is a whitish porous pith, saturated with saccharine juice. This is expressed by passing the canes through three revolving cylinders, each cane entering first between the bottom and the middle cylinders, and being repassed between the top and the middle cylinders. The mill is turned either by cattle, by a water-wheel, or by steam power. The juice is used immediately, or it would ferment. From the mill it runs into a large boiler, in which, for purification, it is heated, but not boiled, with lime. The use of this alkaline earth has a twofold object,—to neutralize the acetic acid which exists ready formed in the woody part of the cane, and is pressed out by the mill, together with the saccharine juice, and to clear this juice from various foreign matters mingled with it. By the application of gradual heat, these impurities form a cake, with the lime, at the surface of the resinous liquid, which is drawn off clear and conveyed to the first boiler. After going through several successive boilers, in each of which it is boiled to a thicker consistence, it at length becomes a thick dark syrup, when it is put into shallow, flat coolers. In the West Indies, before all the molasses has had time to separate from it, the coarse sugar, containing much dirt and impurity, is pressed into hogsheads by the naked feet of the negroes; in which condition it reaches us in the shape of moist, brown, raw, or muscovado sugar. At the Mauritius, the drier estates of which island produce

the best sugar in the world for the refiner, the muscovado is purified in conical moulds, from the inverted apex of which, the molasses drips out, leaving the sugar crystallized and dry, the upper or broader part of the mould containing the best sugar, the quality decreasing towards the apex. The whole contents of the mould, weighing two or three hundred-weight, are, however, mixed to equalize the quality, and the whole is sent home in bags made of the palm leaf. The molasses, mixed with water and fermented, is employed to manufacture rum. A spirit is likewise drawn from the fermented juice of the cane; those plants attacked by the rats in the field, and already in a state of incipient fermentation, being devoted to this purpose. In very damp districts, the cane yields no crystallizable sugar; the whole of the juice is therefore employed in the production of spirit, termed in the Mauritius arrack, in the West Indies taffia. Both this and rum are exceedingly injurious to the human frame, until they have acquired considerable age; and the cause of the unwholesomeness is this:—The acetic acid in the cane juice is not wholly neutralized by the lime first used to temper this juice, because a portion remains in combination with that part of the saccharine liquid that afterwards forms molasses, in which substance acetic acid may always be detected. Added to this, the attenuation of the wash proceeds so rapidly in tropical climates, that acetification has commenced ere distillation begins. The consequence is that acetic acid rises with the spirit, which therefore comes over, attended with acetic ether and a quantity of free acetic acid, both mixed with the spirit and rendering it exceedingly unwholesome. Time will make the ether evaporate, or nearly so; but the acetic acid will remain. This might be obviated, and these two spirituous preparations rendered less deleterious, by treating the wash with lime, by which the acetic acid might be wholly neutralized in the still. In India there exists a much more primitive mode of making sugar from the cane than the one we have described; but the canes of that generally light and sandy soil yield a sugar very deficient in fermentable qualities, and of little value to the refiner.

Raw sugar brought to England is converted into loaf or white sugar by being deprived of its impurities, which consist of mucilage, gluten, molasses, caramel, and some other matters, to say nothing of absolute filth. The sugar is first made into a pap with hot water, as a diluted solution in water would deteriorate it. This pap is next put into conical forms or moulds, and allowed to drain, which clears it from much of its coarse treacle and other substances. It is then mixed with a small portion of lime-water, some bullock's blood, and a quantity of animal charcoal, and injected with steam admitted through various orifices, by which it is dissolved and incorporated with the albumen of the blood and with the bone charcoal, and these with each other and the blood, into a homogeneous mass. This now undergoes various operations of filtering and separation from the refining ingredients, until the pure sugar remains in the form of a limpid and highly clarified syrup, which is then evaporated to the crystallizing point under great pressure, in what are termed vacuum-pans, and then poured into conical moulds. These, after a few days, are placed in a stove heated to 130 or 140 degrees, where they remain until they are baked hard. The loaves are now taken out of the moulds and covered with blue paper, in which condition they are ready for sale.

SUGAR-CANE. See Saccharum and Sugar.

SUGAR OF LEAD, — chemically, *Acetate of Lead.* A salt composed of lead and acetic acid, and much used in medicine, in surgery, in chemical reagency, and in several of the arts, particularly that of calico-printing. It is made, on a small scale, by dissolving either litharge or carbonate of lead or white oxide of lead in distilled vinegar,—and, on a large scale, by a coarse and operose process with sheet-lead and distilled vinegar. In its pure state, it is inodorous, and has a sweet astringent taste, and forms in irregular masses which look like lumps of sugar, but are aggregations of white, glossy, right oblique-angled prisms terminated by dihedral summits. It has a specific gravity of 2·35, and slowly effloresces by exposure to the air, and dissolves in about four times its weight of water at 60° Fahrenheit. It is a powerful poison in even small quantity; yet, when administered in minute doses. with corrective accompaniments, and under circumstances of due caution, it is employed by the human physician as a mighty astringent and sedative, and as a valuable remedy in various kinds of internal hæmorrhages; and as the principal medicinal ingredient in a lotion, it serves well, in both human and veterinary practice, as a remedy for inflammation of the eyes.

SUGAR PEA. See Pea.

SULPHATES. Salts consisting of sulphuric acid in combination with alkaline and metallic bases. Several exist in a natural state; those of lime and baryta are particularly abundant; and all may be artificially formed by the action of sulphuric acid either on the metals and alkalies themselves, or on the metallic oxides or their carbonates. Six—those of baryta, tin, lead, mercury, antimony, and bismuth—are utterly insoluble; six—those of lime, strontia, silver, cerium, zirconia, and yttria—are sparingly soluble; and all the rest are soluble in water. When any sulphates, except those of soda, potash, lime, lithia, strontia, and baryta, are subjected to a white heat, they suffer decomposition, one portion of their sulphuric acid escaping unchanged, and another portion passing into sulphurous acid and oxygen; and when any sulphates whatever are mixed with carbonaceous matter and ignited, the oxygen both of the acid and of the oxide

combines with carbon, to form carbonic acid, and a metallic sulphuret remains. Five important sulphates are noticed in the articles Gypsum, Epsom Salt, Glauber's Salt, Alum, and Copperas; and both these and some others—particularly those of ammonia, potash, and baryta—perform important offices in animal and vegetable nutrition, in the fertilization of soils, in special manuring, and in medicine and the arts. See the articles Ammonia, Protein, Nutrition, Food of Plants, Manure, and Agricultural Chemistry.

Liebig—after showing that sulphur is a constituent of the protein compounds, and is as truly concerned as nitrogen in building up and maintaining the animal organisms, and becomes available to animals through the medium of the plants or parts of plants which they consume as food—says, "Compounds containing sulphur are present in the seeds of all plants, as well as in the plants themselves; and as they are particularly abundant in cultivated plants employed for animal nutrition, it is quite obvious that a substance containing sulphur is absolutely essential to the development of such compounds, in order to supply to them their proper proportion of this element. It is also obvious, that although all other conditions for the nourishment of plants be present, if the compound containing sulphur be either wholly absent or deficient in quantity, the vegetable constituents containing sulphur will either be not at all formed, or they will be generated only in proportion to the quantity of the above compound. The air cannot contain any substances in which sulphur is present, unless indeed we except minute and scarcely appreciable traces of sulphuretted hydrogen. The soil, therefore, must be the only means of furnishing the sulphur so necessary to the growth of plants; and we are ignorant of any form by which it can be assimilated except that in which it enters the roots. The numerous analyses made of the water of mineral springs, furnish us with a satisfactory explanation of the form in which sulphur occurs in soils. The water of such springs is entirely derived from the rain which falls upon the surface of the earth; the water percolating through the earth, dissolves all soluble materials which it may meet in its course. The substances thus dissolved communicate to the water properties which are not possessed by pure water. Water procured from springs or wells is found to be very rarely deficient in soluble salts of sulphuric acid. The liquid obtained by lixiviating good soil from garden or arable land also contains very appreciable quantities of these salts. These facts leave little doubt as to the source whence plants obtain their sulphur; as far as our knowledge extends, they receive it from the sulphates dissolved in the water absorbed by their roots from the soil. Ammoniacal salts, particularly sulphate of ammonia, are rarely detected in spring water; but this is owing to the constant presence of supercarbonate of lime, which effects their decomposition, and allows the escape of ammonia during the evaporation of the liquid for the purposes of analysis. According to our view, sulphate of ammonia is of all compounds containing sulphur the one most fitted for the assimilation of that element. Sulphate of ammonia contains two elements, both of which are equally necessary for the support of vegetable life; these are sulphur and nitrogen, and they form constituents also of vegetable albumen, fibrin, and casein. But what is still more worthy of observation, sulphate of ammonia, viewing it according to the proportion of its elements, or what is termed its empirical formula (O^3, H^3, S, N,), may be considered as a compound of water with equal equivalents of sulphur and nitrogen. Thus, by the simple removal of the elements of water from this compound, its sulphur and nitrogen might be enabled to pass over into the composition of the plants. The ingredients of plants containing sulphur are so composed that one equivalent of sulphur exists for every 25 equivalents of nitrogen. Hence it is obvious that much more ammonia must be offered to plants than that contained in the form of sulphate of ammonia, if all the sulphur of the latter is to become a constituent of the organic ingredients alluded to. This bears a complete analogy to the assimilation of the carbon and nitrogen furnished to plants in the form of carbonate of ammonia. This salt may contain two equivalents of carbon to one equivalent of nitrogen. Hence it is necessary that the carbon of six equivalents of carbonic acid must at the same time be taken up, and enter into combination with the nitrogen, in order to produce the principal nitrogenous constituents which contain one equivalent of nitrogen to eight equivalents of carbon.

"The passage of sulphur derived from a sulphate into the composition of vegetable matter, necessarily indicates that the sulphate has been exposed to the action of the same causes as those by which the decomposition of carbonic acid was effected in the plant; and, therefore, that the sulphuric acid has been decomposed into sulphur and oxygen, the former of which is assimilated, whilst the latter is separated. If we suppose the sulphuric acid to be presented in the form of sulphate of potash or soda, the basis of these salts must be set at liberty after the decomposition of their acid. Now we actually find these bases in all cultivated and even in most wild plants. They are found either united to organic acids, or, what is still more remarkable, they are found in union with the vegetable compounds containing sulphur. The vegetable casein of pease, beans, and other leguminous plants, is itself insoluble in water; but it is very soluble in the form in which it occurs in the plant. This solubility is due to the soda and potash with which it is united. In like manner, the albumen

contained in the juices of plants is combined with an alkali; and we must even suppose that vegetable fibrin, the insoluble ingredient of cereal plants, must have originally been soluble, and have attained its position in the seeds by the agency of alkalies. The potash and soda of the alkaline sulphates which furnish to plants their sulphur, remain, therefore, either in combination with the ingredients containing that element, or they enter into some new state of combination, or, finally, they are returned to the soil. Gypsum (sulphate of lime) is the most generally diffused sulphate; and, being soluble, it may either pass directly into the plant, or it may be decomposed by the carbonate of ammonia existing in rain water, and pass into the plant in the form of sulphate of ammonia. A solution of gypsum containing common salt or chloride of potassium, such as sea water, and the water of most springs, may be viewed as a mixture of an alkaline sulphate with chloride of calcium. From this it must be obvious, that when we furnish to a plant at the same time both gypsum and common salt (chloride of sodium), we actually furnish by such a solution the same materials that we would do if we supplied a mixture of sulphate of soda and chloride of calcium. In order to form the constituents containing sulphur, that element and the alkali must be retained by the plant, while the chlorine and calcium will be expelled by the roots. We know that this process actually does take place in the case of marine plants. The soda or potash is obtained from common salt or chloride of potassium, which suffers decomposition by the presence of sulphate of lime or sulphate of magnesia. It is necessary to suppose that this process also occurs with the cereal and all other plants destitute of lime. Thus we are enabled to explain the use of common salt as a manure; it enables the plant, for which this manure is useful, to extract its sulphur from the soil in which it existed in the form of sulphate of lime."

SULPHUR. An elementary substance, of a combustible and non-metallic nature. It occurs as a native mineral in the vicinity of volcanoes, in the veins of primitive rocks, and in mixture with ores of iron, copper, antimony, lead, and silver; it is obtained, for commercial purposes, from excavated sulphur pits and from the roasting of pyrites; and it is commonly cast into cylindrical moulds forming roll-sulphur, and into cones about two feet high forming loaf-sulphur, —and is afterwards purified for medicinal or other nice purposes by a process of sublimation, and is then termed sublimed sulphur or flowers of sulphur. Roll sulphur is a crystallized, brittle, solid body, of a greenish-yellow colour, and has very little taste, and emits a peculiar odour when rubbed or heated, and breaks from the heat of the hand when held in it for a short time; but it is always more or less impure, and in some instances contains an admixture of six or seven per cent. of orpiment. Sublimed sulphur is an impalpable powder, of a very bright yellow colour; and contains a minute portion of sulphuric acid, from which it can be separated by washing with water. Sulphur has a specific gravity of 1·99; and is a non-conductor of electricity; and is very volatile, within a very great range of temperature, from comparatively low to very high; and, when volatilized, condenses again unchanged in close vessels. It fuses at a temperature of 216° Fahrenheit; attains a maximum fluidity between 230° and 280°, and is then of amber colour; begins to become thick and viscid at 320°,—and if then poured into water, assumes a red colour, and has a ductility like wax, and may be kneaded into a state of eminent fitness for receiving the impressions of seals and medals; becomes so tenacious between 428° and 482° that the vessel containing it may be inverted without causing it to change its place; and from 482° to its boiling point, becomes an elastic fluid. It tends to crystallize in cooling; and generally exhibits a perceptible crystalline arrangement in the centre of the rolls; and sometimes displays an elaborate and very beautiful system of crystals in an open vessel where it has slowly cooled. It inflames in the open air at 300°, burns with a pale blue flame, and emits pungent, suffocating vapours of sulphurous acid. It is insoluble in water; but unites with it, under favourable circumstances, to form the white hydrate of sulphur, popularly called milk of sulphur. It dissolves readily in boiling turpentine,—sparingly in many oils,—and freely in a volatilized state with vaporous alcohol; and it combines with oxygen, with hydrogen, with the alkalies, and with many of the earths and metallic substances. It so obstinately retains a minute portion of hydrogen as to resist separation from it by either fusion or sublimation; and it was supposed by Sir Humphrey Davy to be, not an elementary substance, but a triple compound of oxygen, hydrogen, and a peculiar base, —and has been conjectured by other chemists to hold a similar relation to oxygen which charcoal does to carbon; but it is still regarded by the great body of chemists as truly an elementary substance, comprising a minute proportion of hydrogen in the way of an impurity.

Sulphur is an important ingredient in the nutritional principles of both animals and plants. See the articles PROTEIN and SULPHATES. It is extensively used in the arts for making sulphuric acid, manufacturing sulphates, some kinds of bleaching, and other purposes. It is used in medicine, both for internal administration by itself, and as a chief ingredient in ointments, and as a constituent of various compounds. In internal use, it is a laxative and a stimulating diaphoretic, and acts with eminent serviceableness in hæmorrhoidal affections; and in combined internal use and external application, it is a specific in scabies and some other diseases of the

skin. In veterinary medicine, it is the grand remedy for mange; and, when combined with nitre and antimony, is an excellent alterative in grease, hidebound, surfeit, and other similar diseases of the horse; and serves also as an efficient ingredient in balls for cough and fever.

SULPHURIC ACID. A compound of one equivalent of sulphur and three equivalents of oxygen. It was discovered by Basil Valentine toward the close of the 15th century; and is often though very improperly called, in popular phraseology, oil of vitriol. It naturally occurs in small quantities, concretely in the cavities of some volcanic mountains, and fluidly in some mineral waters; and it is manufactured on a large scale, for the purposes of medicine and the arts, either by subjecting protosulphate of iron to destructive distillation in close vessels, or by burning a mixture of eight parts by weight of sulphur and one of nitrate of potash in a peculiarly constructed furnace, connected with a large, leaden-walled, water-supplied, condensing chamber. The former method is the oldest, and continues to be practised in several places on the Continent, and yields a dense, oily-looking, brownish liquid, which emits copious white vapours when exposed to the air, and is commonly called fuming sulphuric acid, and has a specific gravity of from 1·896 to 1·9, and consists of two equivalents of anhydrous acid and one equivalent of water; and the latter method is practised in Britain and in most parts of the Continent, and yields a liquid which generally contains about three or four per cent. of sulphate of potash and sulphate of lead, and requires to be freed from these impurities by a process of precipitation and distillation, and is then a dense, oily-looking, colourless fluid, having a specific gravity of from 1·847 to 1·85, and consisting of about 81·54 parts of anhydrous acid and 18·46 of water. Sulphuric acid as it occurs in commerce, therefore, is always more or less hydrous; and, as it has a very powerful affinity for water, and unites with it in all proportions, it suffers the utmost possible facility of adulterating dilution; so that persons purchasing it, in any considerable quantity or for any nice purpose, require to look well to its strength; and this may, in every case, be readily ascertained by saturating a specimen with subcarbonate of soda,—every 100 grains of that salt having the power to neutralize 92 grains of the concentrated acid of specific gravity 1·848.

Sulphuric acid is one of the strongest acids known; and is terribly corrosive. It has a furiously sour taste, and exhibits in an energetic manner all the reactions characteristic of powerful acids. It combines with all alkaline substances, abstracts alkaline bases from their combination with all other acids, and carbonizes all animal and vegetable substances, with formation of water. It acquires a brown colour from the mixture of any vegetable matter,—a brown, green, or blue tint from the addition to it of a small quantity of sulphur,—a green colour from selenium,—a crimson one from tellurium,—and successively a pink and a dark reddish brown one from a minute quantity of charcoal. It freezes at 15° into six-sided prismatic crystals, bevelled at both extremities; but when diluted with water down to the specific gravity of 1·78, it freezes at 45°, or 13 degrees above the freezing-point of water,—so that at all seasons, except summer and the warmer parts of spring and autumn, it is liable, in this diluted state, to burst the bottles in which it is kept. The combination of sulphuric acid and water always evolves sudden and intense heat, and requires to be conducted with caution; for when four parts by weight of the cold acid are instantly mixed with one part of cold water, the mixture suddenly attains a temperature of 300° Fahrenheit. Sulphuric acid absorbs water so greedily and rapidly from the atmosphere as to increase its weight one-third in 24 hours, and to double its weight in a month; so that it needs to be kept in vessels with air-tight stoppers. In consequence of its powerful affinity for water, it causes the sudden liquefaction of snow, and is employed in the process of freezing water by its own evaporation, and, when mixed in due proportion with snow, generates intense cold; and probably it is the action of the same fearfully fierce affinity which constitutes its power of destroying the skin, forming ethers, and decomposing animal and vegetable substances.

Sulphuric acid has many uses in the arts,—chiefly, however, in connexion with the sulphates; and it has of late years come into extensive and important use upon the farm, in connexion with the economical preparation of bone-manure. See the article BONE-MANURE. Diluted sulphuric acid may also be employed as a means of increasing the fertility of all calcareous soils in the growth of whatever crops are benefited by the action of gypsum; for an application to such soils of a mixture of 100 parts of concentrated sulphuric acid and from 800 to 1,000 parts of water is equivalent to the application of 176 parts of gypsum. See the article GYPSUM.

SULPHURWORT,—botanically *Peucedanum*. A genus of herbaceous plants, of the umbelliferous order. The medicinal species, or hog's fennel, *Peucedanum officinale*, is a perennial-rooted indigen of the salt marshes of some parts of England. Its root comprises many strong fibres, which run deep into the ground; its stem is cylindrical, solid, striated, branching, leafy, and about 6 feet high; its leaves are repeatedly compound, and have very narrow, entire, acute leaflets; its umbels are large, and comprise numerous smooth rays; its flowers are yellow, and bloom from May till July; and its fruit is at first reddish, and afterwards assumes a tawny brown colour. This plant takes its names of sulphurwort and

peucedanum—the latter signifying "a parched pike"—from its strong, fetid, resinous smell; and its roots were formerly in request for old coughs, difficulty of breathing, deep-seated pulmonary complaints, jaundice, and obstructions of the liver, but have now lost their medicinal reputation.—Nearly twenty species, principally hardy, perennial-rooted, and yellow-flowered, have been introduced to British botanical collections from Continental Europe, Northern Asia, and other regions; but they possess little interest.

SUMACH,—botanically *Rhus*. A large and diversified genus of exotic ligneous plants, of the terebinth order. A few species have been introduced to Britain from Southern Europe and Eastern Asia; and nearly eighty from various parts of Africa and America. Three or four are creepers or climbers, a good many are upright deciduous shrubs or trees, and the rest are upright evergreen shrubs or trees; nearly twenty are hardy, seven or eight are tropical, and the rest are suited to the greenhouse or the conservatory; several are very poisonous or highly medicinal, three or four possess great or peculiar economical value, some are elegantly beautiful, and nearly all are more or less ornamental; the greater number love a soil of peaty loam, and some are propagated from seeds, some from layers, and most from cuttings. The gum-copal species has been noticed in the article Copal; and some of the most interesting of the other species may be briefly noticed here.

The poison-oak sumach, *Rhus toxicodendron*, is a poisonous and powerfully medicinal plant, and has a place in all the British pharmacopœias. It is a native of North America, and was introduced to Britain in 1640. It is a hardy, many-stemmed, decumbent, deciduous shrub, of seldom more than three feet in height. Its stems divide into slender, woody branches, and are covered with a brownish bark; its leaves are alternate, and stand on long footstalks, and comprise each three oval leaflets, angularly indented, deep shining green above, hoary below, about 3 inches long and 1½ inch broad; its male flowers rise from the sides of the stalks in close short spikes, and have a herbaceous colour, and bloom in June and July; the female flowers are larger than the male, and come out in loose panicles; and the fruit are striated berries. The leaves are the parts used in medicine. They are inodorous, and have a mawkish, subacrid taste, and yield some of their virtues to alcohol and all to water, and possess stimulating and narcotic properties, and have been used as a remedy for cramp in the stomach, herpetic eruptions, and paralysis. The infusion of them excites a sensation of heat and pricking, and causes irregular twitchings in the affected limbs of a paralytic, and is proved by its action to contain a narcotic principle, and by chemical tests to contain gum, gallic acid, resin, and tannin. An acrimonious vapour, combined with carburetted hydrogen, exhales from a growing plant of the poison-oak sumach during the night, and can be collected in a jar, and is capable of inflaming and blistering the skin of persons of excitable constitution who plunge their arms into it. A yellowish milky juice exudes from a wound or fracture in the stems of the plant; and acts as a strong poison on some persons, but produces little or no effect on others; and becomes black on exposure to the atmosphere, and then forms one of the best kinds of indelible ink for marking linen, and is used by the Japanese as a varnish. The poisonous power of the poison-oak sumach is possessed in a slight degree by most of the other sumachs, and in an eminent degree by *R. pumila*, *R. vernix*, *R. radicans*, and *R. typhina;* and both the inky and the varnishing powers are also possessed by a number of other species. Several varieties of the poison-oak sumach occur, some with hairy leaves, some with very downy leaves, and some of fine erect habit,—but all of strictly one specific character as to both structure and properties.

The tanner's sumach, *Rhus coriaria*, is a native of the Levant and of Southern Europe, and was introduced to Britain toward the close of the 16th century. It is a deciduous shrub, of commonly between 10 and 15 feet in height. Its branches are covered with a brownish hairy bark; its leaves are alternate and pinnate, and comprise each 7 or 8 pairs of leaflets, and a terminating odd one, and have a grand appearance; its leaflets are ovate, obtuse, serrated, rough or scabrous above, and villous or downy below; and its flowers come out at the ends of the branches, in large compound spikes or clusters, and have a whitish green colour, and bloom in July. The bark of this shrub is said to be as tanniniferous as that of the British oak, and to be the chief substance used in the tanning of Turkey leather; and the young shoots, ground to a coarse powder by a mill, constitute the well-known sumach of dyers,—a substance which, when used alone, imparts to wool and woollen cloth a fawn colour inclining to green, and, when used for cotton stuffs which have been previously impregnated with acetate of alumina as a mordaunt, imparts a very durable yellow. The plant is extensively cultivated in Spain and Portugal in a similar way in which osiers are cultivated in Britain, and yields a yearly harvest of young shoots to be bruised or ground for economical use; and, as it is quite hardy enough to withstand the winter in most ordinary situations in our climate, it probably would well repay somewhat extensive cultivation in our own country.

The smooth sumach, *Rhus glabra*, is a native of North America, and was introduced to Britain in 1726. It in a few years overruns lands laid down to grass in some parts of America, in the same way as furze does in Britain. It is a hardy deciduous shrub, comprising several well-marked varieties, and differing in ordinary height from 8 to 16 feet according to the variety

and the soil.—The New England smooth sumach generally attains a height of about 14 feet, and sends forth from its root and its sides many strong shoots, covered with a smooth downy bark. Its radical shoots of only one summer's growth are often an inch in diameter; its lateral shoots or young branches also are large, and have in winter a light brown colour; its leaves are larger than those of the other varieties, and comprise each ten or more proportionally large leaflets and a terminating odd one; and its flowers come out in large loose panicles at the ends of the branches, and have a greenish yellow colour, and bloom in June.—The Carolina or elegant or scarlet-flowered smooth sumach generally attains a height of upwards of 10 feet. Its branches are smooth, and have a fine purplish colour, and are dusted over with a whitish powder; and its flowers grow in panicles at the ends of the branches, and have a fine scarlet colour, and bloom in July, and are succeeded by bunches of seeds which in autumn exhibit a very beautiful red colour.—The Canada smooth sumach generally attains a height of about 10 feet. Its branches are purplish and dusted like those of the preceding; its leaflets are small on both surfaces, but are shining green above and hoary below; and its flowers grow in large panicles at the ends of the branches, and have a red colour, and appear as if a whitish powder had been dusted in among them, and bloom in July.—The berries of the smooth sumach dye a red colour, and, when boiled with the young wood, afford also a black ink-like colour; but they do not come to maturity on plants grown in Britain.

The fever or Virginian sumach, *Rhus typhina*, is a native of Virginia, and was introduced to Britain in the former part of the 17th century. It is hardy and deciduous, and comprises several varieties, which so differ in height and habit as to render it both a shrub and a tree.—The common stag's horn variety generally attains a height of about 10 feet. Its younger branches much resemble stag's horns, and are covered with a hairy down of a velvety appearance; its older branches have in some places a greyish colour, but are properly clothed with a smooth brownish bark; its leaves are pinnated and large and of noble aspect, and comprise each about seven pairs of leaflets and a terminating odd one; its leaflets are oblong, and larger than those of the tanner's sumach; its flowers come out in large tufts at the ends of the branches, and have a herbaceous colour and an inconspicuous appearance, and bloom in June; and its seeds, after the fall of the foliage at the end of the autumn, are left in large tufts at the ends of the branches, and have a scarlet colour, and make an uncommon show.—The dwarf Virginian sumach differs from the preceding only in the dwarfishness of its stature; and it seldom rises higher than 3 feet.—The large Virginian sumach shoots more strongly than the common stag's horn variety, and has a more reddish colour and a less velvety surface in its young shoots, and generally attains a height of 16 or 18 feet.—The arborescent variety commonly rises as high as 25 feet, and blooms in July and August.—The fever sumach, in at least its principal varieties, is economically valuable.

The varnish sumach, or varnish-tree, or poison-ash, *Rhus vernix*, is a native of North America and of Japan, and was introduced to Britain in the early part of the 18th century. It is hardy and deciduous, and has commonly a height of from 8 to 15 feet. It takes the epithets of poison and varnish from the properties of its milky juice, and its epithet of ash from the form and appearance of its foliage. Its branches are not very numerous; its bark is smooth, and has a light brown colour tinged with red; its leaves are pinnated, and comprise each three or four pairs of leaflets and a terminating odd one, and change in autumn to colours varying from red to purple, and make then a gorgeous show; its leaflets are oblong, pointed, entire, and, till autumn, of a fine green colour; and its flowers come out on the wings of the branches, and have a whitish herbaceous colour and an inconspicuous appearance, and bloom in summer.

Six other hardy deciduous species are the rooting, *R. radicans*, a low decumbent shrub, from North America, of similar habit and appearance to the poison-oak sumach, carrying herbaceous-coloured flowers in June and July, and comprising two varieties, the one with small fruit and the other of a twining habit; the aromatic and the sweet-smelling, *R. aromatica*, and *R. suaveolens* from North America, respectively 8 and 6 feet high, and both carrying yellow flowers in May; the wild olive, *R. cotinus*, from the South of Europe, 6 feet high, and carrying herbaceous-coloured flowers in June and July; and the hawthorn and the hawthorn-like, *R. oxyacantha* and *R. oxyacanthoides*, both from Barbary, 6 feet high, and herbaceous-colour-flowered. The greenhouse and conservatory species are chiefly upright evergreens of from 2 to 10 feet in height, and mostly from the Cape of Good Hope; and, with scarcely an exception, may be described as generally ornamental. Two of the most interesting of the hothouse species, both evergreens, are the Javanese, *R. javanica*, 10 feet high, white-flowered, and blooming in July,—and the lineated-leaved, *R. lineatifolia*, from Cuba, 2 feet high, cream-colour-flowered, and blooming from July till September.

SUMMER. The season of general inflorescence,—the warmest and sunniest of the four,—that which comprises the anti-hybernal solstice and the longest days. "There is a pleasure peculiar to spring," says Dr. Duncan, "in the contemplation of Nature rising, as it were, from the tomb, and bursting into life, and light, and joy; but that which belongs to summer is not less intense, although of a different kind. The de-

light of this season arises from the view of the full development or successful progress of the powers and processes which in Spring began to operate. The plants, which had just pierced the earth in the commencement of that season, have now shot forth their stalks, and expanded their blades, and opened their beautiful flowers to the sun; the trees rejoice in their leafy pride; the fields luxuriate in the abundance of their vegetable stores; and animated nature is instinct with life and enjoyment. The whole scene is full of delight; but it is only when it is associated with religious feelings, and when it raises the mind to a Father Being, who called all this loveliness into existence, and whose unseen presence and mysterious energies cheer and bless the world He has made, that it can be enjoyed with its highest and most appropriate relish. It is this pious sentiment which gives such sublime beauty to the 'Hymn on the Seasons;' and perhaps there is no part of that hymn which more successfully expresses the tenderness and devout admiration of a rightly constituted mind, in contemplating the wonders of Nature, than that which refers to Summer:—

'Then comes thy beauty in the summer months
With light and heat refulgent. Then thy sun
Shoots full perfection through the swelling year;
And oft thy voice in dreadful thunder speaks;
And oft, at dawn, deep noon, or falling eve,
By brooks, and groves, and hollow whispering gales.
* * * * *
Soft roll your incense, herbs, and fruits, and flowers,
In mingled clouds to Him, whose sun exalts,
Whose breath perfumes you, and whose pencil paints.'"

SUMMER FALLOW. See Fallow.

SUNDEW,—botanically *Drosera*. A genus of thalamiflorous aquatic plants, constituting the type of the natural order Droseraceæ. The species inhabit marshes or inundated lands in all the temperate regions of the world; and are remarkable for combined beauty and singularity of structure. All parts of their foliage have an abundance of glandular hairs; and their young leaves are always rolled up in the circinnate manner which is so generally and beautifully exemplified in ferns. They possess very little medicinal virtue, but in many instances have the power of coagulating milk. Five or six greenhouse species, and a dozen or upwards of hardy species, occur in British collections, and belong to five genera.

The true sundews, or plants of the genus drosera, strongly exhibit the interesting characteristics of the order, and discharge from the ends of their red glandular hairs drops of viscid acrid juice of similar appearance to dew, and possess so curious an irritability that their hairs when touched by insects contract upon them and imprison them. Three occur wild in Britain, six or seven have been introduced from North America, Southern Africa, and New Holland, and upwards of twenty more are known. The three indigenous ones are the English, the round-leaved, and the long-leaved,—the first occurring only in England and the other two both in England and in Scotland; and all three, as well as all the introduced kinds, have a height of only a few inches, and thrive only on boggy ground, and are propagated from seeds. The leaves are simple, and either undivided or lobed; and the flowers are terminal and racemose, rarely solitary, and have either a white or a purple or a white and red colour, and bloom for the most part in July and August.

SUNFLOWER,—botanically *Helianthus*. A genus of ornamental, herbaceous, exotic plants, constituting the type of a suborder of compositæ. Its involucrum is imbricated and spreads horizontally; its receptacle is flat and chaffy; and its fruit-crown has two leaf-like appendages. The suborder which it represents bears the name of Heliantheæ, and is the largest of the compositæ, and comprises about ninety genera,—among the most conspicuous, or beautiful, or best-known of which are georgina, calendula, helianthus, zinnia, sanvitalia, coreopsis, and calliopsis. Five annual species of true sunflowers, and nearly thirty perennial-rooted species, all hardy, and nearly all yellow-flowered, have been introduced to Britain; and several more are known. Most thrive in any common soil,—and the rest in a soil of peaty loam; and the annual kinds are propagated from seeds, and the perennial kinds, with one exception, by radical division. A tuberous rooted species, constituting that exception, and extensively cultivated for the sake of its esculent tubers, is noticed in the article Artichoke (Jerusalem). The name sunflower alludes either to the sun-like disc of the flowers, or to the popular but erroneous notion that they always turn toward the sun.

The common annual sunflower, *Helianthus annuus*, shares with the Jerusalem artichoke the main interest of the genus, both popular and economical. It is a native of South America, and was introduced to Britain toward the close of the 16th century, and has long been generally known and admired as a showy and staring ornament of the front of shrubberies and the back-row of broad flower-borders. Its stem is thick, strong, and branched, and usually attains a height of from 4 to 7 feet; its leaves are cordate, rough, and three-nerved; its flowers stand on strong foot-stalks, and have various shades of yellow from sulphur-colour to semi-orange, and bloom from June till October; and its heads are large and nodding, and look conspicuously both near and distant, and produce a comparatively vast quantity of seeds. Small sowings for ornamental purposes may be made in beds, at different periods, so as to obtain a long succession; the young plants, as soon as they come fairly up, should be thinned to proper distances, and kept free from weeds; and, when they attain a height of about 6 inches, they should be taken up, with

balls of earth round their roots, and planted in their final situation, and there watered till they become completely established. But the plant is eminently suited for important economical purposes, and may, in some instances, be profitably cultivated in the field. The stems form good fuel, and yield a considerable quantity of potash; and, when not wanted for these purposes, they may be either burned for manure-ashes or rotted in the dung-heap. The leaves, in either a green or a dried state, are said by some French writers to be excellent food for cows, and to be greedily eaten by them. In Portugal, the seeds are made into bread and into a kind of meal; in America, they are roasted, and used as a substitute for coffee; in all countries, they are highly relished by birds, both great and small, both wild and domestic; in various countries, they are esteemed for the expression of an oil, which is well adapted for burning in lamps, and is nearly as good as that of the olive for domestic purposes and for making soap; and in Great Britain and Ireland, they might be remuneratingly produced for the sake both of yielding the oil and of feeding poultry,—and they are said to possess the peculiar recommendations for this latter purpose of being cheap food, and of rendering hens prolific. The produce per acre will widely vary according to soil, situation, and culture, but has been found to average about 50 bushels of seed,—equal to 50 gallons of oil and about 1,500 lbs. of oil-cake; and the stems of the crop, if burnt for alkali, will yield about 10 per cent. of potash, while the leaves may be dried and pulverized and mixed with bran for fodder. The crop, however, has a very scourging effect on land, and particularly robs it of potash, and is peculiarly unsuitable for going before potatoes in a rotation. The soil most suitable is light, friable, and richly alkaline; and does admirably well to be manured with fresh sea-weed; and if loamy or clayey, may be advantageously prepared by commixations of shell sand, limestone gravel, or any other opening, calcareous substance; and, in any case, must be well tilled and finely pulverized. The situation most suitable is a moderately shady one, with sufficient exposure to enjoy free and constant circulation of the air. The sowing may be done, in a dry season, in the latter part of January,—in a wet season, about the middle of February,—in any season, in the latter part of February or at any time in March,—and in circumstances where the earliest possible crop is desired, in moderately dry weather, in October. The manner of sowing and of transplanting may be very varied; but the following has been particularly recommended: —"Let drills be drawn with a hoe or otherwise, about an inch deep, and about 18 inches asunder; sow the seed therein thinly, and cover it over an inch thick; or it may be sown by dibbling in, which is the better plan. When the fourth leaf of the young plants has sprouted, and the fifth is ready to sprout, let them all but one be removed from each place and planted elsewhere, in rows 12 or 18 inches apart, and at a distance of 10 inches in the row. Water the plants as they are put down if the weather be dry, and dry weather is essential to the success of the crop. Especial care should be directed to remove all weeds for about a month or 6 weeks, and occasionally to mould up the earth around each plant." When the heads are quite or nearly ripe, the plants should be cut down at about an inch from the ground, and removed to a shed or some other place of complete shelter from rain, and there left till they become dry; and either then or afterwards, they may be freed from the seed; but they must not, in any case, be left on the ground, as they have a great capacity for moisture, and would be very likely to attract it and to become filled with insects.

The dwarf Indian sunflower, *Helianthus indicus*, possesses similar properties to the common annual sunflower, and may be cultivated for the same purposes, and in a similar way. It is also an annual, and blooms throughout the same period; but it is less branched, and smaller in all its parts, and has only about half the height, and is of a lighter yellow colour in its flowers. It was introduced from Egypt in 1785.—The tube-formed sunflower, *Helianthus tubæformis*, is an annual of rather less height than the common sunflower, and blooms during a much shorter period. It was introduced from Mexico in 1799. —The showy sunflower, *Helianthus speciosus*, is an annual of about the same height as the preceding, and carries red-coloured flowers from September till November. It was introduced from Mexico in 1833.—The perennial fibrous-rooted sunflowers vary in height from 2 to 10 feet; and all have yellow flowers, and are natives of North America.

SUN-ROSE, — botanically *Helianthemum*. A genus of ornamental plants of the cistus family. They are very nearly allied to the true cistuses in botanical characters, and closely resemble them in eminent adaptation to the covering of rock-work. The great majority have a golden or sun-like colour of flowers, varying from pale yellow to copper-colour; and they derive from this circumstance both the popular name sun-rose and the botanical name helianthemum or 'sunflower.' Seven species grow wild in Britain, and considerably upwards of one hundred have been introduced from other countries. About a dozen are hardy annuals; a few are hardy herbaceous perennials; a large number are hardy, evergreen, trailing or procumbent undershrubs; a few are hardy, evergreen, erect undershrubs; and most of the remainder are frame, evergreen, erect undershrubs and shrubs. The annual and herbaceous kinds are propagated from seeds, and the ligneous kinds from cuttings. The great majority of the species, of whatever kind, love a soil of sandy peat, and bloom in June and July.—One subgenus comprises about sixteen erect, evergreen

shrubs of from 1 foot to 6 feet in height, all exotic, one or two of them hardy, and the rest somewhat tender; and its sepals generally amount to three, but sometimes to five,—its petals are very often spotted at the base,—and its stigmas are capitate and subtrilobed. The umbel-flowered species, *H. umbellatum*, belonging to this group, is particularly handsome, and has white flowers. It was introduced from the South of Europe in 1731; it comprises two varieties,—the erect and the subdecumbent; and it has a height of about 2 feet, and blooms from June till August.—Another subgenus comprises three hardy herbaceous perennials, one hardy evergreen undershrub, and three more or less tender evergreen undershrubs,—and almost all about 10 or 12 inches in height; its sepals, as also those of all the remaining subgenera, amount to five,—its outer sepals are linear,—its stigmas are large and capitate,—and its capsules are smooth, three-valved, and three-celled.—A third subgenus comprises five hardy annuals, one hardy undershrub, and three herbaceous perennials,—almost all about 6 or 8 inches in height; and its outer sepals are variable in size,—its petals are often spotted at the base,—its styles are scarcely perceptible,—and its stigmas are capitate. The spotted-flowered sun-rose, *H. guttatum*, a species belonging to this group, is an annual indigen of the sandy pastures of some parts of England.—A fourth subgenus comprises seven or eight hardy annuals, varying in height from 3 to 14 inches; and its outer sepals are very small,—its petals are small and often spotted at the base,—its stigmas are simple,—and its capsules are triquetrous. The ledum-leaved species, *H. ledifolium*, belonging to this group, is an indigen of the sandy pastures of some parts of England, and has a height of about 6 inches.—A fifth subgenus comprises four or five exotic evergreen undershrubs, principally about a foot in height, and most of them erect; and its sepals have a silky exterior,—its outer sepals are very small,—its styles are twisted at the base,—and its capsules are pilose or woolly.—A sixth subgenus comprises about a dozen erect, exotic, evergreen undershrubs, of from 6 to 25 inches in height; and its calyx, in the early stages of development, is twisted,—its outer sepals are small,—and its stigmas are capitate and trilobate.—A seventh subgenus, so similar to the true rock-roses as to be called pseudocistus, comprises eight or nine trailing evergreen undershrubs, and about the same number of erect ones,—most of the former hardy, and most of the latter somewhat tender; and its outer sepals are very small,—its petals also are small,—its styles are twisted at the base,—and its stigmas are capitate and trilobed. The marum-leaved species, *H. marifolium*, a hardy, evergreen trailer belonging to this group, is a native of the rocky portions of some of the lofty mountains of Britain.—An eighth subgenus, so eminently exhibiting the proper characteristics of the sun-roses as to be called euhelianthemum, comprises all the rest of the genus except one anomalous species, and is therefore much the largest subgenus, and consists in a main degree of hardy trailing evergreen undershrubs,—most of which have a height of from 4 to 10 inches; and its outer sepals are small,—its stigmas are simple,—and its capsules are three-valved and one-celled. The common sun-rose, *H. vulgare*, belonging to this group, is an indigen of the grassy banks and calcareous hills of many parts of Britain, and is one of the best known species even in gardens, and may be regarded as a good and fair specimen of the whole genus. Its stems are slender and leafy, and extend trailingly to the distance of nearly a foot in various directions; its leaves are small, oblong, dark green above, and greyish below; its flowers come out at the end of the stems in loose spikes, and have a deep yellow colour, and spread open during the day, but shut close in the evening, and bloom from May till September; and its capsules are roundish, and enclose many angular seeds. Double-flowered varieties occur in gardens, with respectively common yellow flowers, dark yellow flowers, large dark yellow flowers, blood-coloured flowers, and variegated leaves. Three other indigenous species belong to the same group,—the tomentose, *H. tomentosum*, a trailer of the Scottish Highlands, with larger stems than the common sun-rose, carrying yellow flowers in July and August; the polium-leaved, *H. polifolium*, a trailer of the downs of England, with stems about 6 or 8 inches long, carrying white flowers from May till July; and the Surrey, *H. surrejanum*, a trailer of the chalk hills of the south of England, with stems nearly a foot long, carrying yellow flowers from July till October.

SUPPURATION. The process of forming purulent matter under certain kinds of inflammatory action. See the articles PURULENT MATTER and INFLAMMATION.

SURBATING. Inflammation of the horse's foot. See the article FOOT.

SURFACE DRAINING. See DRAINING.

SURFEIT. A disease of the horse's skin, consisting in the eruption of scabs or small pustules, notwithstanding all due attention to cleanliness and grooming. It seems to arise from a diseased state of the stomach and the intestines; and in every ordinary case, it ought to be attacked with alternately a mild purgative and an alterative, accompanied by the use of warm clothing,—and in a very bad or stubborn case, it should be further treated with bleeding and aloetic physic,—and, if it do not give way to these remedies, it may be regarded as the precursor or covering of a worse malady. See the article MANGE.

SURVEYING. See LAND-SURVEYING.

SUTHERLANDIA. An ornamental, evergreen, Cape-of-Good-Hope shrub, of the lotus division of the leguminous order. It constitutes a genus of

itself, and is specifically called the frutescent; but it is nearly allied to the bladder-sennas, and was ranked as such by Linnæus. It was introduced to Britain so long ago as the latter part of the 17th century; and it is but slightly tender. It has a height of about 3 feet, and carries scarlet flowers in June and July; and it loves a soil of sandy loam, and is propagated from seeds.

SUWARROW NUT. See Butter Nut.

SWAD. A pod or legume. The word is provincial.

SWAINSONIA. A genus of ornamental, evergreen, small, Australian shrubs, of the lotus division of the leguminous order. Two species with purple flowers, and two varieties of another species with respectively red and white flowers, all about 2 feet high, and blooming in July and August, have been introduced to British gardens. They love a soil of sandy peat, and are propagated from seeds.

SWALLOW,—scientifically *Hirundo*. A genus of birds of the fissirostrous family of passerinæ. In a large sense, it comprises all the diurnal species of that family; and in even a smaller sense, it comprises not only the common swallow, but also the martin, the sand martin, and the salanganes. The bill of all, in common with that of other fissirostres, is short, broad, horizontally flattened, slightly hooked, and unemarginate, and has an extended commissure, so that the opening of the mouth is very large, and possesses eminent adaptation to the catching and swallowing of insects while the birds are on the wing.

The common or country or chimney swallow, *Hirundo rustica*, is a well-known, regular, very numerous, and very useful visitor of Britain, and of many other lands. Its total length is 8½ inches; its outside tail-feathers are very elongated, and measure nearly 5 inches; its general plumage is slate blue and dull black; its forehead, eyebrows, and throat are red or chestnut; and some parts below are pure white. It feeds entirely on winged insects, and hunts them through the air during the greater portion of the day, and has such power of flight as to pursue its prey for hours in succession without any apparent fatigue. It builds in chimneys and similar places, and forms its nest of moistened earth or clay mixed with bent and straw, and lined with feathers. Its eggs amount to four or six, and have a white colour speckled with ash and dark red, and measure 9½ lines in length and 6½ in breadth.

Swallows are controlled in the period of migration by the temperature of the season and the state of the wind; but, on the average, they arrive in Britain about the 10th of April, and depart about the middle or latter part of October. They come gradually or in small and successive numbers, but go away in vast flocks, leaving only a few stragglers behind. On the coast between Orfordness and Yarmouth, they assemble in swarms in October, covering the church-leads and the naked branches of trees; and they are then preparing to depart from the tract of coast whence emigration is easiest to their winter-retreats, and they are evidently wind-bound, for they abide in their gathering-place till the wind veers to the north-west or some other favourable point,—and if this happen in the night, they so suddenly and entirely disappear that not a swallow can be seen in the morning.

Swallows are a very useful race of birds, and relieve us from innumerable noxious insects which infest our atmosphere and prey upon our crops. "Whoever contemplates the myriads of insects that sport in the sunbeams of a summer evening will soon be convinced to what a degree our atmosphere would be choked by them, were it not for the friendly interposition of the swallow tribe. Such would-be marksmen as shoot at swallows should recollect that these birds are seen only during the breeding months in summer, and that by shooting the old ones the nestlings in consequence perish. Minute observers calculate that one of these birds destroys daily hundreds of gnats, flies, moths, and other insects, parents of the swarms of gnats and caterpillars which strip our gardens, and commit such waste upon vegetation in general. These birds, therefore, should be considered as little messengers of Providence, and as instruments without whose assistance the plough and the spade would often be ineffectually employed. In almost every village in America, they are held in the same sort of veneration as the Egyptians show to the ibis of the Nile; the villagers place small square boxes,—some of them prettily adorned and painted,—to induce these strangers to sojourn and peaceably enjoy their months of incubation. The late Dr. Franklin used to say,

"Be kind to the swallow,
And profit will follow."

SWALLOW-WORT,—botanically *Asclepias*. A genus of ornamental exotic plants, constituting the type of the natural order Asclepiadeæ. This order is noticed in the article Asclepias. The calyx of the swallow-wort genus is five-cleft, small, and persistent; the corolla is monopetalous, flat or reflexed, with a five-leaved crown, and a process on the inside; the pollen-masses are fixed by a fine end; and the stigma is depressed and blunt. About 40 species have been introduced to Britain from other countries,—principally North and South America; about 30 more are known; and a good many which formerly belonged to it, and have been introduced to Britain, are now assigned to nine other genera. The swallow-worts are remarkable for curious beauty; and several are economical and medicinal. Most of those in British collections are erect, perennial-rooted, annual-stemmed herbs; but a few are either tuberous-rooted or evergreen herbs or twiners. The majority are hardy; and the rest belong variously to the greenhouse and the hothouse. All, with a few exceptions,

have either purple, red, or white flowers; and the greater number are most readily propagated by radical division.

The Syrian swallow-wort, Virginian swallow-wort, or Virginian silk, *Asclepias syriaca*, is a native of North America, and was introduced to Britain in 1629. Its roots are creeping and perennial; its stems are annual, erect, unbranched, and from 4 to 6 feet high; its leaves are opposite, oval, thick, and downy below; its flowers come out in nodding umbels from the junctions of the leaves and stem, and have a purple or dull reddish colour, and bloom in July and August; and its pods are long and nearly upright, and have a rough coriaceous skin, and contain thin membranous-edged seeds, thickly covered and profusely enveloped with a white down of similar appearance to cotton. The flowers are highly fragrant, especially in the morning and the evening, and are gathered in their native country while the dew is on them for the purpose of making sugar; the young shoots, in spring, are a very good substitute for asparagus; the down of the pods serves well for stuffing pillows and cushions, for making thread and cloth, and for some other purposes; and the fibrous matter of the stems is abundant in quantity, and excellent in flax-like quality, and is used and highly appreciated in some parts of North America for making thread, cordage, fishing-nets, and cloth. The plant accommodates itself to a great variety of soils and situations, and has been successfully experimented with as an agricultural plant in France, and may probably be well worthy of field cultivation in some parts of Britain. It may be propagated by either sowing seeds or transplanting roots in rows about two feet apart; it must, of course, be kept clean from weeds; it gradually fills the intervals between the rows by the creeping of its roots, and arrives at full maturity in the third year after sowing; it might be combined in culture, during the first and second year, with some annual crops which should occupy the vacant spaces previous to its maturation, and it will continue in full vigour and maintain entire occupancy of the soil during a considerable number of years. The soil most suitable for it is rather moist, of medium texture, and of medium fertility.

The principal medicinal swallow-worts are the curassoa, *A. curassavica*, a tropical, perennial-rooted, annual-stemmed herb, of about 3 feet in height, carrying scarlet flowers from June till September, but comprising also a white-flowered variety, and introduced from South America toward the end of the 17th century; the asthmatic, *A. asthmatica*, a tropical twiner of about 8 feet in height, carrying white flowers in July and August, and introduced from Ceylon in 1810; the antidotal, *A. alexiaca*, a tropical twiner, of about the same height as the preceding, with herbaceous-coloured flowers, introduced from Ceylon in 1816; and the decumbent, *A. decumbens*, a hardy tuberous-rooted herb, of about 2 feet in height, carrying orange-coloured flowers in July and August, and introduced from North America in 1731. Their chief medicinal properties are emetic and sudorific. See the article Ipecacuan.

Among the most ornamental species are the pleasing, *A. amœna*, fibrous-rooted, purple-flowered, and about 3 feet high; the variegated, *A. variegata*, fibrous-rooted, white-flowered, and about 4 feet high; the whorl-leaved, *A. verticillata*, fibrous-rooted, white and green flowered, and about 3 feet high; the acuminate, *A. acuminata*, fibrous-rooted, red and white flowered, and about 2 feet high; the tuberous, *A. tuberosa*, tuberous-rooted, orange-flowered, and about 2 feet high; the roseate, *A. rosea*, herbaceously evergreen, red-flowered, and about 1 foot high; and the flax-leaved, *A. linifolia*, herbaceously evergreen, white-flowered, and about 3 feet high;—all from North America, most blooming in July and August, the first five hardy, and the other two suited to the greenhouse.

SWAMP. Moist and soft land akin in character to a marsh or a bog, but differing from both in producing shrubs and trees. See the articles Marsh and Bog.

SWAN,—scientifically *Cygnus*. A group or subgenus of the duck tribe of lamellirostrous palmipedes. They are the largest birds of the tribe; and are distinguished internally by comparatively long intestines and cæca, and externally by a very long neck, and by a bill of equal length throughout, higher at its base than it is wide, with the nostrils about the middle of its length.

The tame or domestic or red-billed swan, *Cygnus olor*, is the species which, when domesticated, forms the finest living ornament of our ponds and water-scenery. It is larger than the wild swan, and may readily be distinguished from it by its bill,—which has a red colour, edged with black, and surmounted at the base by a black rounded protuberance or callous knob. The general plumage of the bird is snow-white. A cygnet or young swan of its species, however, has a lead-coloured bill and grey plumage. The domestic swan figures nobly before every eye, and is admired alike by the rustic and the poet, by the child and the philosopher; and, in joint virtue of the elegance of its form, the gentleness of its motions, and the brilliant whiteness of its plumage, it is a fit emblem of beauty and innocence. It feeds indifferently on vegetables and fish, eats alike bread, seeds, and succulent parts of plants, is capable of such familiar domestication as to feed from the hand, and requires artificial supplies of food, and also artificial assistance in the breaking of ice and the keeping of ponds open, during the severe parts of winter. It flies at a great elevation, and with considerable rapidity; and it swims swiftly, and employs its wings both as sails for moving before the wind, and as pow-

erful weapons for striking down any enemy by whom it is attacked. The female breeds only once a-year, and lays in summer from five to six eggs. She prefers an islet as her breeding-place for sake of its quiet; and forms her nest by a simple surface deposition of a little straw; and sits about a month if the weather be fine, and longer if it be coarse. The young ones remain with her nearly a year; but are driven away by the old cob or male bird at the approach of the next breeding season; and they do not attain their full plumage till the third year. The cob is larger and bolder than the female; and two pairs seldom live peaceably or profitably together on the same pond or lakelet. The old birds often take a fancy to fly away at the fall of the year; and when not very perfectly domesticated, they require to be kept from roving by having the first joint of one wing removed. The domestic swan hisses when angry, and has a peculiar kind of snort, but no voice; and is therefore sometimes called the mute swan.

The wild or whistling or black-billed swan, called by Linnæus *Anas cygnus*, comprises several varieties or subvarieties, some one or more of which have frequently been mistaken for distinct species. It has a length of about 5 feet, and a breadth of about 7 feet, and weighs from 14 to 17 pounds. Its bill is three inches long, and has a yellowish-white colour from the base to the middle, and a black colour from the middle to the end; its legs are black; its skin is clothed beneath the plumage with a thick fine down; and its general plumage, in the case of every full-grown individual, is either a perfectly pure white or a white tinged with yellowish-grey. It is externally very similar to the tame swan, but internally very different,—for its trachea bends over and penetrates to a considerable extent in a cavity of the keel of the sternum; and it owes to this configuration the power of uttering a wild shrill note when flying or calling; but it performs no melody,—and the old story of its singing on the approach of death is a fable. "Wild swans," we are told, "are inhabitants of the northern regions, never appearing in England but in hard winters, when troops of five or six are now and then seen. Martin says, that in October, swans come to Lingay, one of the Western Isles, in great numbers, and continue there till March. A few stay in Mainland, one of the Orkneys, and breed in the little islands of the fresh water lochs; but the principal part of them retire at the approach of spring, and are considered the countryman's almanack, the inhabitants expecting a mild spring, when their departure is early. In countries where they may be considered as natives, they generally keep together in small flocks, except in the pairing season, or at the setting in of winter; at the latter period they assemble in immense throngs, particularly in the extensive rivers and lakes of the thinly inhabited northern part of Europe, Asia, and America. At the commencement of frost the wild swans are said to associate in prodigious multitudes, and, thus united, to use every effort to prevent the water from freezing, by constantly dashing it with their extended wings; and by this means are enabled to remain in some favourite part of a lake or river which abounds with food, so long as it suits their convenience; but when the severity of the weather threatens to become insupportable, high in air, in divided and diminished numbers, they shape their course in search of milder climates; and in such seasons they are most commonly seen in various parts of the British Isles, and in other more southern countries of Europe. In their flight the swans follow so closely that the bill of the one lies upon the tail of the other. The great bodies of them are, however, met with in the large waters near Hudson's Bay, and those of Kamtschatka, Lapland, and Iceland. They are said to return to the latter place in flocks of about a hundred at a time in the spring; and also to visit that island from the north in nearly the same manner, on their way southward in the autumn. In Iceland these birds are objects of chase, losing their feathers in August, so as to be unable to fly. The natives at that season come provided with dogs, and active horses, capable of passing nimbly over the boggy soil and marshes, where they most resort. The swans will puzzle a tolerably quick horse to overtake them; but the greater numbers are caught by the dogs, that are taught to seize them by the neck, which causes them to lose their balance, when they become an easy prey. Many are likewise shot and killed with clubs. The Icelanders compare the voice or cry of the swan to the notes of a violin; they hear it at the termination of their long and gloomy winter, when the return of the swan announces the return of summer; every note, therefore, must be melodious which presages a speedy thaw, and the release from their tedious confinement. The flesh is highly esteemed by the Icelanders (especially that of the young birds), insomuch that, summer or winter, no entertainment is deemed complete without a swan. Their eggs, of which they lay four, and hatch them in July, are also considered delicious food. The Icelanders, as well as the Kamtschatdales, and other natives of the northern world, dress their skins with the down on, sew them together, and make them into garments of various kinds; and the covering of the legs taken off whole is used for purses, and appears not unlike shagrin. The northern American Indians employ the skins in similar uses, and sometimes weave the down as barbers weave the cauls for wigs, and thus manufacture it into ornamental dresses for the principal women of rank, while the larger feathers are formed into caps and plumes, to decorate the heads of their chiefs and warriors. They also gather the feathers and down in large quantities, and barter

them with the traders of more civilized nations. The swan is with propriety termed 'the peaceful monarch of the lake.' Conscious of his superior strength, he suffers not even the eagle to molest him. His vigorous wing is as a shield against all attacks; and the blows from it are said to be so powerful as to stun or kill the fiercest of his foes. The wolf or the fox may surprise him in the dark; but in the day their efforts are fruitless. His food, like that of the tame swan, consists of the grasses and weeds, and the seeds and roots of plants which grow on the margins of the water,—of the myriads of insects which skim over, float upon, or are found beneath its surface,—of frogs, and, it is said, occasionally (but this wants confirmation) of the inhabitants within its bosom. Swans are certainly detrimental to fish from their dung, when the water upon which they are kept is shallow, and no stream runs into, to freshen it; and they are with some reason believed to destroy the spawn of trout, by stirring up the gravel, and of other fishes by rooting up the weeds on which many kinds deposit their ova; but of their directly preying on the spawn, or the small fry lately excluded from it, there is no positive evidence."

SWANWORT. See Cycnoches.

SWARD. The surface of grass land. It widely varies in thickness, texture, and luxuriance according to soil, situation, management, and the kinds of the herbage; but, in a general view, the sward of Britain is finer and greener and more velvety than that of any other European country, not even excepting Ireland, and may be regarded as a grand and beautiful characteristic of British landscape, and as owing its superiority, not alone to the peculiar nature of our climate, but in some degree also to the comparatively enlightened and assiduous attention which Britons give to lawns and pasturage. See the article Grass Lands.

SWARM. See Bee.

SWARTH. See Swath.

SWARTZIA. A genus of ornamental, evergreen, exotic shrubs, constituting, with the genus baphia, the small non-papilionaceous suborder of curvembrious leguminosæ. See the article Leguminosæ. Three species, all about 6 feet high, all loving a soil of peaty loam and propagable from cuttings, two of them white-flowered and the other yellow-flowered, have been introduced to British gardens from the West Indies; and about a dozen more are known.

SWATH, or Swarth. A layer of mown grass or other mown crop deposited by the scythe. See the article Mowing.

SWEALING. The singeing of hair, or burning of it off, as is done in the case of hogs.

SWEAT. See Perspiration.

SWEDE, or Swedish Turnip. See Turnip.

SWEET ACORN. See Acorn and Oak.

SWEET BAY. See Laurel.

SWEET BREAD. See Pancreas.

SWEET BRIAR. See Briar (Sweet).

SWEET FLAG. See Acorus.

SWEET GALE. See Candleberry Myrtle.

SWEET GRASS. See Glyceria.

SWEET GUM. See Liquidambar.

SWEETIA. A genus of ornamental, twining, evergreen, purple-flowered, tropical plants, of the kidney-bean division of the leguminous order. Three species, the woody, the long-leaved, and the thread-shaped, varying in height from 3 to 6 feet, have been introduced to British collections from South America and the West Indies; and they love a soil of sandy peat, and are propagated from cuttings.

SWEET LEAF. See Symplocos.

SWEET MARJORAM. See Marjoram.

SWEET MAUDLIN. See Milfoil.

SWEET PEA. See Lathyrus.

SWEET POTATO. See Battatas.

SWEET-SCENTED VERNAL GRASS. See Anthoxanthum.

SWEET SULTAN. See Centaurea.

SWEET WILLIAM, — botanically *Dianthus Barbatus*. A well-known, hardy, ornamental, evergreen, herbaceous plant, of the pink genus and carnation family. It was introduced to Britain from Germany in 1573, and has long been one of the most generally diffused and universally admired beauties of the British parterre. It is often so carelessly and exhaustingly cultivated in the flower-plots of the poor and the ignorant as to have a decumbent habit and a slender and sickly appearance; but, in its proper character, and with ordinarily good treatment, and when not in extreme old age, it has a bold stem, and stands firmly erect, and has a height of from 12 to 20 inches, and shows a great profusion of the most brilliantly tinted flowers. It comprises multitudes of varieties, which differ from one another in the height of the stem, the breadth and form and colour of the leaves, the nature or aggregation of the inflorescence, the form and singleness or doubleness of the flowers, and especially the ground-colour and variegations and markings of the petals; and it commonly brings out very many of these varieties, or exhibits great and beauteous sportiveness of character, from a single sowing of even one specimen of seeds. The narrow-leaved kinds were formerly called Sweet Johns, and only the broad-leaved kinds Sweet Williams; but the two groups were soon found to be interchangeable with one another from sowings, and the distinction between them was abandoned. Some of the single flowers have very rich colours, and often vary from one another in the same bunch; and some are most lusciously variegated or exquisitely traced and marked with minute tintings; while others, popularly called painted ladies, have a soft red centre and a delicately white border. Very fine kinds may, in some degree, be perpetuated as well as endlessly diversified and sometimes improved, by completely clearing them from the vicinity of all inferior sorts, so that they may be im-

pregnated only by one another's own pollen. The single kinds are propagated from seeds, and the double kinds from layers. Seeds must be saved from select plants in August, and sown on a bed of light earth about the end of March or beginning of April; the seedlings must be planted out, in June, into prepared beds, at distances of about 6 inches; and the young plants should be transplanted in October to their final situation, where they will bloom in the following June and July. The layers of the double kinds are managed in the same way as those of carnations. A method of propagating sweet williams by slipping their roots at Christmas is often practised; but it is coarse and very degenerating, and nearly as troublesome as the proper methods.

SWELLED LEGS. Acute inflammation of the cellular substance of the legs of horses, accompanied with the effusion of fluid into the cellular membrane. It is very varied in symptom, and still more varied in cause; and occurs oftener in working horses than in saddle ones, and oftener in the hind legs than in the fore legs. It sometimes appears as a sudden and violent and enormous swelling from the hock to the fetlock, accompanied with heat, tenderness, considerable feverishness, and a very peculiar lameness; and in this form, it attacks principally young horses who have been pampered with food and not duly exercised,—and must be treated with fomentations and physicking, and, if necessary, with moderate bleeding. It sometimes appears as a sudden and prodigious swelling, with little or no accompanying lameness, or as a vast gorging of the limbs, with very great accompanying pain and stiffness, or as a kind of simple chronic swelling, tending to abscess and eventually to grease; and in these forms, it is often troublesome and refractory, and must be treated with purgatives and diuretics, and, if the animal be in high condition, with also moderate bleeding. But the disease sometimes has different characters from these, and arises from widely different and even totally contrasted causes,—such as fitfully irregular work, alternations of violent exercise and none, difficulty in the seasonal moulting of the coat, and even downright starvation; and in all these cases, it must be treated with means of renovation and strengthening, such as mild diuretics, tonics, cordials, and hand-rubbing,—varied and modified in adaptation to the special causes and symptoms.

SWERTIA. See Felwort.

SWIETENIA. See Mahogany.

SWIFT. Birds of the martin or martinet group. See the article Martin.

SWINE. See Hog.

SWINE-CRUE. A hog's sty.

SWINE'S CRESS. See Wart Cress.

SWINE'S SUCCORY,—botanically *Hyoseris*. A genus of hardy, yellow-flowered, exotic, herbaceous plants, of the succory division of the composite order. Two annual species, and two perennial-rooted ones, all about a span high, thriving in any common soil, and blooming in the latter part of summer, have been introduced to Britain from the sea-boards of the Mediterranean; but they possess little interest.

SWINGLE-TREE. See Plough.

SWING-PLOUGH. See Plough.

SWITCHING. Lopping off the salient branches, protruding twigs, and exuberant points of a hedge, so as to clear it of all straggling growth, and reduce it to regular dimensions. The implement with which this operation is performed is called a switching-bill; and has a curved blade of about 9 inches in length and 1½ inch in breadth, fixed elongatedly on a haft of about 2¼ feet in length; and is used with a stroke directed upward and inclined backward. See the article Hedge.

SYCAMORE. See Maple.

SYMPHORIA. See Saint Peter's Wort.

SYMPHYTUM. See Comfrey.

SYMPLOCOS. A genus of ornamental, evergreen, corolliflorous, exotic shrubs, constituting the small natural order Symplocineæ. It is nearly allied to the epacris and the storax orders. The leaves of all the species are serrated and become yellow in drying,—and those of most are astringent; and the flowers of all are white or yellow, and of small size,—and those of some are fragrant. The dyer's or laurel-leaved species, *S. tinctoria*, is a native of Carolina, and was introduced to Britain in 1780. It has a height of about 3 feet, and carries yellow flowers, and is propagated by layering. Its foliage, under the name of sweet leaf, is used by the Americans for yielding a yellow dye.—The Chinese species, *S. sinica*, was introduced from China in 1822; and it has a similar height to the preceding, and carries white flowers in May, and is propagated from cuttings.—Both species love a soil of peaty loam.

SYNAPTAS. A peculiar nitrogenous substance which cannot be preserved when dissolved in water. The solution of it speedily becomes turbid, and deposits a white precipitate, and acquires an offensive putrid smell.

SYNGENESIA. See Botany.

SYNNOTIA. A small genus of ornamental, bulbous-rooted, Cape-of-Good-Hope plants, of the iris order. Three species, the variegated, the two-coloured, and the helmeted, the first and second about 6 inches high, the third about a foot high, and all blooming in spring, have been introduced to the greenhouses of Britain. They are akin to the ixias and the gladioli; and they love a mixed soil of sand and peat and loam.

SYNOVIA. The mucilaginous secretion which lubricates the joints of animals, and is popularly but erroneously called joint-oil. It has a consistency similar to the fluid white of an egg, and seems to be secreted by the vessels of the capsular ligaments, and, when secreted in excess, constitutes capsular dropsy. See the article Rheumatism.

SYRINGA. See Lilac and Philadelphus.

SYRUP. A saturated solution of sugar. It may be either simple, as a mere form or variety of sugar itself; or flavoured with essential oils or fragrant vegetable substances, as a liquid confection; or impregnated with any one or more drugs capable of thoroughly combining with it, as a compound medicine. Many syrups figure in the pharmacopœias; but, with a few exceptions, they might be very advantageously substituted by infusions, decoctions, tinctures, or some other ordinary forms of exhibition. Sugar can serve at best as only a means of modifying the nauseousness of drugs combined with it,—and to some palates it rather heightens that nauseousness than decreases it, while to few or none can it conceal it so well as some other plain and common accompaniments would do. All syrups should be clarified by means of a little white of egg beat into a froth, and should have a specific gravity of 1·385 when cold; but, however carefully and exactly made, they are liable to ferment and become asescent in a temperature above 60° Fahrenheit,—and if they be not well boiled and have not enough of sugar, they will ferment in almost any ordinary circumstances,—while, if they contain an excess of sugar, they will speedily undergo crystallization of part of it and spoiling of the rest.

T

TABACUM. See Tobacco.

TABERNÆMONTANA. A genus of ornamental, evergreen, ligneous, tropical plants, of the dog's-bane tribe. Upwards of a dozen species, varying in height from 4 to 45 feet, mostly carrying either white, yellow, or cream-coloured flowers, and all loving a soil of rich mould and propagable from cuttings, have been introduced to the botanical collections of Britain; and upwards of twenty more are known. See the article Nerium.

TABES. A morbid wasting of live trees. It is indicated by sickliness of colour, diminution of foliage, and the gradual consuming of the branches; and it is caused sometimes by parasitical plants, and sometimes by spontaneous bleeding or great loss of sap. When it is caused by ivy, it may be arrested by an early and prompt eradication and removal of the parasite; when by mosses and lichens, it may be mitigated by topical applications of caustic lime water; and when by bleeding, it may sometimes but not often be arrested by dressing wounds, closing apertures, and promoting by every possible means the healthiness of the branches and the luxuriance of the foliage. But all trees ought to be protected from choking attacks of parasites by timely thinning and pruning, and by the free admission of air and light; and full-grown timber trees, especially elms, attacked by tabes from loss of sap, may most profitably be cut down at once, and used for timber, without incurring the risk of further progress of the disease.

TACAMAHACA. See Balsam-Poplar.

TACCA. A genus of curious-looking, herbaceous, tropical plants, of the order aroideæ. The pinnatifid species, *T. pinnatifida*, is a native of India and other eastern countries, and was introduced to British collections in 1793. It has a height of about 2 feet. Its root is bulbous; and is used as an esculent in China, Cochin-China, Banda, India, and some parts of Polynesia. It possesses a considerable degree of acrimony, and requires to be frequently washed in cold water before being dressed. In some places, it is eaten in substance with some agreeable acid or other condiment to subdue its natural pungency; and in others, it is ground into meal, and baked into a sort of gelatinous bread, similar to that made from salep. Four other bulbous-rooted species, chiefly about the same height as the pinnatifid, and all carrying brown flowers in July and August, have been introduced from India and Mauritius; and all the five species love a soil of loamy peat, and are propagated by division of the root.

TACSONIA. A genus of ornamental, exotic plants, of the passion-flower family. They are nearly allied to the true passion-flowers, yet may readily be distinguished from them by the long tube of their corolla. See the article Passion-Flower. They are well adapted to the conservative walls of gardens; and may be made to produce there a succession of their magnificent flowers from July or August till the commencement of frost.—The softest species, *T. mollissima*, is a climbing shrub of considerable height, with downy stems and stalks, serrated, trilobate leaves, ovate-lanceolate leaf-lobes, and axillary, solitary, downily-peduncled flowers,—each flower comprising a long green tube and five calycine and five petaline segments, forming together ten nearly equal divisions, all of a lively rose colour.

TADPOLE. The young produced from the

eggs of the frog, which is extremely unlike the animal in its perfect state, seeming to consist only of a head and tail. The head is large, black, and roundish, the tail slender, and margined with a broad, transparent fin. Its motions are very lively. Its food consists of small water plants and different animalculæ. The mouth has very minute teeth. About five or six weeks after it is hatched, the first change takes place. The hind legs first appear, and gradually increasing in length and size, are succeeded, in about two weeks, by the fore legs, which are formed at an earlier period beneath the skin. The tail now decreases, so that, in a day or two, it is quite obliterated. After this change the animal leaves the water, and covers the shores in myriads. The sudden appearance of such multitudes of young frogs has probably induced the popular but groundless belief of their having fallen from the clouds in showers. It has now become a perfect frog. Tadpoles, just after they are hatched, are perfectly transparent; and, when placed before the double microscope, the pulsation of the heart may be easily seen, and the blood protruded thence may be observed in its passage through the whole body.

TÆNIA. See Worms (Intestinal).

TAG. A sheep of the first year.

TAGETES. A genus of hardy, ornamental, exotic, annual plants, of the jacobea division of the composite order. Fourteen species have been introduced to Britain from Mexico and South America; and all thrive in any common soil, and are propagated in the ordinary manner of hardy annuals. One, *T. lucida*, has entire leaves, and all the others have pinnate or bipinnate leaves; one, *T. patula*, has variegated flowers of yellow, orange, and blood-colour, and all the others have yellow flowers; two, *T. lucida* and *T. corymbosa*, have a height of less than 20 inches, and most of the others have, or may have, a height of about 2 or 3 feet; two, *T. patula* and *T. erecta*, are among the most common and most highly admired beauties of the annual flower-border, and have been described, under their popular names, in the articles African Marigold and French Marigold, and most of the others are more or less worthy of abundant diffusion. The slender-leaved, in particular, *T. tenuifolia*, may be selected as well deserving to compete with the two old favourites. It was introduced from Peru in 1797; and is noticed as follows in one of the florist periodicals of 1845:—"It is one of the best annuals for bedding out with which we are acquainted. The plant forms a dense compact mass of small twiggy branches, having numerous, slender, pinnatifid leaves, and a profusion of moderate-sized orange-yellow, marigold-shaped flowers. The leaves are curiously marked with a row of what appear to be minute orange-coloured dots, but which are in reality minute glands, the secretions of which give the plant a very agreeable balsamic fragrance, — very agreeable indeed when but slightly experienced, but if in too large a quantity, partaking of what is regarded as the disagreeable odour of the common marigold. The flowers are composed of five roundish florets, which have a deep notch at the end. This plant is an incessant flowerer. If sown in the spring with other annuals, and kept in pots till the time of planting out, it blooms from the earlier part of the summer quite up to the time of frosts, when all flowers of a kindred nature are cut off. One quality of it which can hardly be sufficiently admired is, that it never appears littery from the decay of the old flowers. At the end of every small lateral shoot, a blossom is produced; this opens in due time, and continues in beauty its allotted period; and then, ere it fades and becomes unsightly, the fresh lateral shoots rise and spread just above it, producing more flowers; these again are followed in the same way, and so on without intermission; so that the plant always looks as if robed in its holiday suit."

TAIL. The free, projecting, flexible prolongation of the vertebral column in most species of vertebrated animals. It sustains a terminal fin in fishes, a fan or rudder of large feathers in birds, and a brush or mop or whip of long hairs in quadrupeds; and it serves the first for regulating motion through the water, the second for balancing flight through the air, and the third for protecting and defending the body from the attacks of insects and from other nuisances. The tail of a horse usually comprises thirteen bones, and comprises a museum of the most beautiful contrivances for combining gracefulness of appearance with whip-like utility. A fracture of it sometimes occurs from entanglement or violence, and is perceptible generally by the eye and always by the fingers, and must be rectified by either amputation or resetting,—the latter effected by means of a cord with a small weight attached to it passed over a pulley. The tail of a well-bred horse is set on high, and neither seems to be merged between the hips, nor appears to spring saliently from the back-bone, but projects and descends in a graceful curvature. Two cruel usages in the treatment of horses' tails are noticed in the articles Docking and Nicking.

TAIL-SLIP. An imaginary disease in cattle. See the article Palsy.

TALAUMA. A genus of ornamental, evergreen, fragrant, tropical plants, of the magnolia family. Its plants are nearly allied to the true magnolias, but require hothouse treatment. Several species, with respectively white, cream-coloured, and striped flowers, have been introduced to Britain since 1828; and they love a soil of peaty loam, and are propagated from layers.

TALC. A well-known and widely diffused species of mineral. It is rarely seen under a distinctly crystalline form. Its primary form is believed to be a right rhombic prism of 120° and 60°. It is sometimes seen in minute hexagonal

plates, and in a figure resembling the frustra of two cones, applied base to base. Cleavage highly perfect; fracture not observable; lustre pearly upon the faces of crystallization and of cleavage; colour various shades of green, as blackish-green, leek-green, celandine-green, and apple-green; streak similar to the colour; semi-transparent to translucent. It exhibits different colours, sometimes in different directions; sectile in a high degree: thin laminæ are easily flexible. It is one of the softest of all solid minerals. The massive kinds present a great variety of structure. The composition varies from imperfect columnar to granular and impalpable. The individuals are sometimes strongly coherent with each other, or flat, so as to give rise to an imperfect slaty structure. The species talc has been subdivided into a great number of varieties or sub-species, the most of which depend upon colours, composition, and foreign admixtures. The varieties of dark-green (leek-green and celandine-green) colours, inclining to brown, constitute the *chlorite*, which has been subdivided into *common*, *slaty*, and *earthy* chlorite. The first of these contains the granular or crystalline varieties; the second embraces those in which the individuals can scarcely be traced, and which exhibit a slaty texture; the earthy chlorite consists of such as are but loosely coherent, or already in a state of loose, scaly particles. Immediately with those varieties of chlorite whose composition is impalpable, the *green earth* is connected. The species talc comprehends the varieties of pale-green, particularly apple-green, grey, and white varieties, and is divided, in popular language, into *common*, *earthy*, and *indurated* talc. Simple varieties are common talc; also such compound ones in which cleavage is transformed into slaty structure, or such as consist of columnar particles of composition; earthy talc, or *nacrite*, consists of loose particles, or such as are but slightly cohering; and indurated talc refers to imperfect and coarse slaty varieties, in which this kind of structure is more the effect of composition than of imperfect cleavage. If this structure be sufficiently imperfect to become coarse and indistinctly granular, *potstone*, *soapstone*, *lapis ollaris*, or *steatite*, is formed, which, possessing the united properties of softness and tenacity, may be easily turned, and wrought into vessels. Four varieties of the present species, foliated talc, analyzed by Vauquelin, slaty chlorite, analyzed by Gruner, green earth, analyzed also by Vauquelin, and steatite by Klaproth, have yielded

Silex,	62·00	29·50	52·00	59·50
Magnesia,	27·00	21·39	6·00	30·50
Oxide of iron,	3·50	23·39	23·00	2·50
Alumine,	1·50	15·62	7·00	0·00
Water,	6·00	7·37	4·00	5·50
Potash,	0·00	0·00	7 50	0·00
Lime,	0·00	1·50	0·00	0·00

These analyses, as well as those of several other varieties of the species, show that our information respecting its chemical constitution is still very defective. Before the blow-pipe, some of them lose their colour, and are fused with difficulty; others are changed into a black scoria; still others are infusible. Common talc, indurated talc, steatite, potstone, and slaty chlorite, constitute beds of themselves in primitive mountains. The latter often contains imbedded crystals of magnetic iron. Common chlorite is found in beds in rocks consisting chiefly of ores of iron and calcareous spar with augite. Other varieties, and among them the small scaly crystals of chlorite and earthy chlorite, occur in veins of various descriptions, and in the crystal caves of the Alps. Green earth occurs in amygdaloidal rocks, lining vesicular cavities. Tyrol, Salzburg, Switzerland, Sweden, Norway, Scotland, and New England abound in those varieties which by themselves form mountain masses. The soapstone of Cornwall is impalpable in its composition, nearly white, or sometimes mottled with green and purple: when first raised, it is so soft as to allow of being kneaded like dough; but, by exposure, loses a part of its moisture, and is then translucent on the edges, yields to the nail, and possesses an unctuous feel. A similar variety is met with in Wales. It is included in serpentine, and sometimes embraces veins of amianthus. The white varieties of steatite, or those that become so by calcination, are employed in the manufactory of the finest porcelain; other varieties are said to be used in fulling. The Arabs, according to Shaw, use steatite in their baths, instead of soap; and it is confidently asserted that the inhabitants of New Caledonia either eat it alone, or mingle it with their food. Humboldt says, that the Itomaques, a savage race, inhabiting the banks of the Orinoco, are almost entirely supported, during three months of the year, by eating this variety of talc, which they first slightly bake, and then moisten with water. The varieties known under the name of potstone have been in use for the construction of a variety of utensils from time immemorial. It is particularly valuable as a fire-stone in furnaces, and is worked into plates in the fabrication of stoves.

TALINUM. A genus of ornamental exotic plants of the purslane family. Nearly a dozen species, variously annual, biennial, herbaceous perennial, and subshrubby evergreen, mostly about a foot in height, and carrying purple, red, pink, or yellow flowers in the end of summer or early part of autumn, have been introduced to Britain: and about as many more are known. Most love a soil of peaty loam, and require to be propagated from seeds.

TALLOW. The fat of suet freed from all membranous matter by melting and straining. It consists principally of stearin and elain, and yields by distillation a large portion of oleic and margaritic acids. Its ultimate constituents, according to Chevreul, are 78·996 per cent. of carbon, 11·708 of hydrogen, and 0·304 of oxygen.

See the articles Suet, Fat, and Oil. Tallow is used in medicine as an emollient and a demulcent; in pharmacy, to give consistency to plasters and ointments; and in the arts, for dressing leather, for making candles and soap, and for other purposes. Pure tallow is white and tasteless, and differs little from pure lard except in greater density; but the tallow of commerce is very diversified in colour, consistency, sapidity, and odour,—and is commonly classified, according to its degrees of whiteness and purity, into white candle tallow, yellow candle tallow, and soap tallow. A very large quantity is imported into Britain from various parts of the Continent, and particularly from the Russian ports of the Baltic.

TALLOW (Piney). A solid vegetable fat, of somewhat similar appearance and properties to true tallow. It is obtained by boiling the fruit of the *Vateria indica* in water; and is skimmed off in a melted state, and cooled into the form of a solid cake. It has generally a white but sometimes a yellow colour; it is greasy to the touch, with some degree of waxiness; it is almost tasteless, and has an agreeable odour; and it melts at a temperature of 97½° Fahrenheit, and therefore remains solid in the ordinary climates of even some parts of the tropics. It consists, according to Dr. Babington, of 77 per cent. of carbon, 12½ of hydrogen, and 10½ of oxygen. The tree which yields it abounds throughout the western coast of Hindostan, at least as far north as the confines of Canara, and could no doubt afford a sufficient supply to render it of some commercial importance; and it at the same time exudes a resin of the nature of copal, viscous and of a dirty white colour when taken from the tree, but afterwards solid, brittle, and pulverulent, soluble in turpentine, and making as good a varnish as the copal of America. Substances similar to tallow and wax are obtained from several other ligneous plants. See the articles Wax and Stillingia.

TALLOW-TREE. See Tallow (Piney).

TAMARIND,—botanically *Tamarindus*. A small genus of tropical evergreen trees, of the dalbergia division of the leguminous order. The Indian species, *T. indica*, is a native of the East and West Indies, of Arabia, and of Egypt, and was introduced to the botanical collections of Britain in the former part of the 17th century. It is naturally a large, spreading, beautiful tree, of about 60 feet in height. Its leaves are abruptly pinnate, and comprise each sixteen or eighteen pairs of leaflets, and are bright green and downy; its leaflets are sessile, entire, oblong, obtuse, half-an-inch long, and one-sixth of an inch broad; its flowers come out in loose bunches of five or six from the sides of the branches, and have a straw-coloured calyx and yellowish petals, beautifully veined with red, and bloom in June and July; and its pods are thick, compressed, of a dull brown colour, and from two to ten inches long, and contain each from two to seven flat, angular, shining seeds, lodged in a dark-coloured pulp. The prepared pods are medicinal and condimental, and constitute the well-known tamarinds of commerce. They are gathered when fully ripe, freed from all shelly fragments, deposited in layers in a cask, and—in the West Indies at least—saturated with syrup; and they require to be preserved in air-tight and closely-covered vessels. They have an agreeable, acid, sweetish taste; and contain, independently of the sugar with which they are preserved, citric acid, tartaric acid, malic acid, fecula, gum, vegetable jelly, and bitartrate of potash; and owe their acid taste mainly to their citric acid. They possess cooling and gently laxative properties; and, when infused in hot water and strained, they make a very grateful and refreshing beverage for persons in fever.—The western species, *T. occidentalis*, is very similar to the Indian, but not so tall, white-flowered, and much earlier in bloom.—Both species love a soil of rich mould, and are propagated from seeds.

TAMARISK,—botanically *Tamarix*. A genus of calyciflorous plants, principally shrubs, with small, entire, scale-like leaves, and small, white, pink, or flesh-coloured, spicate or racemose flowers, constituting the small natural order Tamariscineæ. The plants occur in all the three great divisions of the old world,—in both cold countries and hot; and they are somewhat nearly allied on the one hand to Onagrariæ, and on the other to Lythrarieæ, but differ from both in some very distinct botanical characters of the flowers. One species grows wild in Britain; two hardy deciduous and three tropical evergreen species have been introduced from other countries; and about a dozen other species are known.

The French tamarisk, *T. gallica*, occurs naturally in some parts of the southern coasts of England, and is also a native of France, Spain, and Italy. It is a deciduous shrub, and commonly attains a height of about 12 or 14 feet. Its branches are few, and spread irregularly abroad, and are variously upright, horizontal, and pendulous; its bark is smooth, and has a purplish or deep red colour toward the sun and a pale brown colour on the opposite side; its leaves are very narrow and very finely scaly, and have a rather pale green colour and a very beautiful appearance; and its flowers have a pale red colour, and grow in seemingly very large panicles, and bloom from May till October,—but they really grow in spikes, and are produced near the extremities of the branches on the slender twigs all around, and not only are they individually very minute, but each of the spikes taken separately is rather small. This plant is highly elegant, and well deserves a place in shrubberies. It thrives in any ordinary soil or situation, and is easily propagated from cuttings planted in the open ground in spring or autumn. Sheep feed greedily upon it for the sake of its salt taste.

The German tamarisk, *T. germanica*, was intro-

duced to Britain from Germany in the latter part of the 16th century. It is a more regular deciduous shrub than the French tamarisk, but has commonly a height of only 8 or 9 feet. Its branches all grow more or less upright, and are odorous and very brittle; its bark is smooth and yellowish; its leaves stand much closer than those of the French tamarisk, and have a scaly appearance, an exceedingly light green colour, and a highly ornamental character; and its flowers come out in long loose spikes at the end of the branches, and are individually small and of a pink colour, and bloom from June till September. The spikes attract the attention and excite the admiration of all observers; and besides having a noble appearance during the period of bloom, they continue to be beautiful till the period of the ripening of the seeds, and then seem to dissolve into shattered down and scales. This species loves a light moist soil, and is propagated in the same manner as the preceding.

TAMETOMO. See Lily.

TAMONIA. A small genus of ornamental, herbaceous, tropical plants, of the verbena family. Two species, both biennial, blue-flowered, blooming in July and August, and about a foot high, have been introduced to the hothouses of Britain from Guiana and the West Indies.

TAMUS. See Bryony (Black).

TAN. Oak-bark which has been chopped and ground into a coarse powder for the use of tanners, and which has been employed in the process of tanning leather, and afterwards thrown out and dried. See the articles Leather and Tannin. Tan is much used in horticulture,—both in a fresh state to produce heat by its fermentation, and in a well-rotted state as manure for all kinds of cold stiff soil. See the articles Bark-Bed, Hotbed, and Manure. Tan is also used, in various ways and after widely different methods of preparation, as both an incorporated manure and a top-dressing in agriculture. Fresh tan, when laid on grass-land in autumn, so as to be retarded in fermentation by frosts and washed into the ground by the winter's rains, greatly improves the grass; but when laid on in spring, especially if a tract of dry weather should follow, it may evolve such strong heat by fermentation as will scorch and burn the grass. Tan ferments sturdily and very prolongedly, and resists putrefaction, and though very absorbent and retentive of moisture, cannot be penetrated by the roots of plants; so that it does exceedingly ill to be employed in a fresh or merely half-fermented state as an incorporated manure. Yet it is very rich in the principles which nourish cultivated field-plants; and may be made thoroughly available for their nutrition either by complete preparatory rotting, or more economically by reduction with solvents; and was reckoned by the old gardeners to be, in a well-rotted state, worth more than twice its weight of rotted farm-yard manure. Stable dung has been used as a solvent, but caustic lime acts more rapidly, more powerfully, and with less waste by gaseous dissipation; and after it has effected a destruction of the fibre, earths and dung may be added to bring the whole mass into a soluble and perfectly putrescent state; and the mixture thus prepared has a finely divided and even comminuted texture, and may be used, either in the field or in the garden, for any purpose of either top-dressing or incorporated manuring.

TANACETUM. See Tansy.

TANGHINIA. See Cerbera.

TANGIER PEA. See Lathyrus.

TANK. An excavational structure, cistern, or reservoir for collecting and preserving in places where it is scarce, or for receiving and accumulating large quantities of any useful liquid.

A water-tank is an essential appendage to a dwelling-house, a farmery, or a garden in every district where a sufficiency of water for routine use can be obtained only by preserving supplies from rain or by accumulating them from meagre or uncertain springs. Some water-tanks are formed for collecting water, as well as for preserving it; some with open surface to receive rain as it falls, and others with only minute apertures to admit a rill and to give off supplies; some with entirely sunk space, of the nature of ponds or subterranean reservoirs, and others with more or less elevated space, of the nature of above-ground cisterns; some with walls of stone or timber in masonry or wood-work, and others with enclosure or frame of metal in the manner of plumbing or cast-iron work; some with ventilating and filtering appliances for adapting the water to the nicest uses of the kitchen or the table, and others with merely the coarse and ordinary appliances of a garden reservoir or a cattle drinking-pond. The constructions of them, therefore, in adaptation to different sites, circumstances, purposes, sizes, and materials, are so endlessly varied, as to be irreducible to any small number of rules or directions, and must be determined in each case by the judgment of the proprietor and his mechanics. We shall only say that a sufficiently good large one for the coarsest uses of the farmery may be constructed on the principles mentioned in the article Pond; and that every prime or even tolerably good one for the finest uses of the dwelling-house ought to comprise appliances both for filtering either by ascension or otherwise, and for sweetening and purifying by constant currents of air.

Tanks for the receiving and accumulating of liquid manure possess great importance in the economy of farming; and as they require to be of large capacity, and must be excavated a little beneath the level of the farmery in whatever kind of ground occurs in its vicinity, they always involve nicety, and sometimes considerable difficulty, in their construction. But Mr. Kinninmonth of Invertiel, in a Prize Essay in a recent number of the Transactions of the Highland So-

ciety, discusses the principles of them so well, that we cannot do better than copy a considerable portion of his paper. "Experience," says he, "led to enquiry as to the best means of constructing large tanks; and here it appeared, in the first place, that failures had occurred in consequence of projectors of tanks having adopted methods that promised great economy in the construction, but which eventually proved failures. In some cases the defects had arisen from the tank being incapable of retaining the liquid collected therein, while, in others, it arose from an opposite cause—the incapacity of preventing the circumjacent water from entering the tank and too much diluting the manure; hence, in place of an economical result, such tanks were rendered useless, unless a double expense was incurred to reconstruct them. It appeared also that some of those failures had been, in some measure, the result of neglecting, on the part of the constructor, the laws of hydrostatics. Thus, in the case of tanks being formed like wells—that is, their depth being considerable—in which case the counteraction necessary to resist the hydrostatic pressure becomes greatly more difficult, whether from the liquid within or from the circumjacent water pressing from without. For this reason alone it became a fixed point, in the views of the writer, that, in all cases, there is safety in avoiding the construction of deep wells to serve as tanks.—Still further consideration of the subject led to the inquiry as to the best form of a tank, and this was found to involve another question—the nature of the ground and substrata in which the tank is to be formed. It is, in the first place, evident, from the case of well-tanks already stated, and from due consideration of the effects of hydrostatic pressure, that the difficulties and even the expense of construction, especially as regards tightness, will always be diminished in proportion to the decrease in depth of the tank; and in no case should the depth exceed eight or nine feet. In most cases it will be advisable to limit this to six or seven feet, or even less, where the ground may be unfavourable. It being essential also that tanks should be closely covered, both for safety and preserving the ammonia, it follows that arching with stone or brick, as being more durable than timber, should in all cases be resorted to; but since arching becomes more expensive as the extent of the span increases, it becomes necessary again, with a view to economy, that the width of the tank be limited to six or eight feet, and from this it follows that *capacity* must be always obtained, principally by extending the length; or, when circumstances require that a tank must be limited in its length, *capacity* may be obtained by extending the width to two or even three times the limit here prescribed, and then subdividing it into three chambers or vaults, by division walls, in which requisite openings are formed to give the effect of one reservoir. Upon these and the boundary walls, two or three arches, as the case may be, are to be thrown, covering in the whole area. This last form of tank, while it may appear more expensive, will, in fact, be rather less so than the single one.

"The actual construction of tanks will always be, in some degree, modified by the strata in which they are placed, and, from the different nature of the strata, may be divided into three kinds, viz., clay, rock, and gravel, but in each of these there will be varieties. Tanks formed on the first kind of strata, especially on the mountain or boulder clay, will be done with little difficulty, such clay being generally highly impervious, and will require only the requisite excavation, and lining the same with walls of rubble masonry to carry the arched covering. In the alluvial clays, in which pervious strata sometimes occur, it may be necessary to treat the construction in the same manner as will be required in the more pervious gravels and rocks, that is, by careful puddling; but there are many localities where this variety of clay is quite impervious, and hence nothing but excavation and building are necessary. In the second kind—rocks—the same variety of circumstances may occur; they may be perfectly dry, or they may contain springs of water. In the first case nothing more is necessary than to excavate and build; but, in the second, every precaution is required, both to prevent entrance of spring water and the escape of the manure. To puddle only, in such a situation, would be endless; for, whenever the tank might be emptied of the manure, the circumjacent water would press upward against the bottom puddle, which, if not pervious, would be broken up, and so admit water, and in either case the destruction of the tank must follow. To secure a tank in such a position, the certain method is to carry a drain from the lowest point of the excavation to the nearest outlet—this being done, all danger of pressure from without is removed, and the tank may be completed with a layer of puddle all over the bottom and sides, upon and against which the rubble walls are built, with the certainty of a successful result. In the class of gravels, artificial drainage will seldom if ever be required, there being seldom any danger of hydrostatic pressure from circumjacent water—the construction of a tank here will therefore proceed, as last described, by puddling and building. But, should it so happen that water is found to stand in the excavation, then draining must be resorted to; for it is incompatible with the nature of such a structure that it can both hold in and hold out water; for, though the sides might stand, the bottom would ultimately be forced upward, unless recourse is had to the expensive alternative of an inverted arch of stone or brick, laid over the bottom puddle. Localities may indeed occur where such an expedient might be advisable, but such a case must be the exception and not the rule. In the construction

of tanks it should be kept steadily in view, that where puddling is required it becomes the essential means of rendering the work perfect; and, therefore, the greatest care should be bestowed upon it. The kind of puddling required for the purpose is what may be named dry puddle. It is well tempered pure clay brought to such a firm consistence as will just allow of any two pieces, on being pressed together, to unite into a solid mass. It is made up into irregular balls or lumps and thrown with force into its place. A succession of such balls are laid all over the bottom of the excavation to the depth of at least one foot, they are thrown down, pressed, and beaten firmly together till the whole forms one solid mass. When the stratum of bottom puddle has been sufficiently consolidated, the side walls are founded upon the puddle with broad flat stones. The bottom puddle must extend to at least one foot in breadth beyond the foundation of the walls, and upon this extension the wall puddle is founded, being first well incorporated with that of the bottom, and afterwards carried up regularly with the stone walls. The walls and arch may be built in rubble masonry as already stated, or of brick-work. Towards each end of the arch a hatchway or manhole should be formed, for the purpose of gaining access to the tank, and for ventilation when required; but these are usually closed with a cover, and a third opening is required for the pump. The floor of a tank, puddled as here described, must be paved with rough flagstones regularly jointed, or with brick laid on edge, to prevent the waste of the puddle. It is necessary also that the floor have a small declivity towards the point where the pump is to stand. There remains to be noticed that, in choosing a site for a tank, it should be so placed that the surface of the liquid in the tank, when full, shall be sufficiently below the level of all the sources of supply, as to give a free current from them through the drains or conduits to the tank. It is advisable also that the conduits should be water-tight, for which purpose burnt-clay pipes, of three to four inches bore, properly jointed, are the most eligible; and, to prevent choking of the conduits, their eyes should be defended by a grating, besides having a water-trap or cess-pool immediately under it, to intercept any grosser substances that might enter, and which in time tend to close up the conduits. It is also worthy of notice that, on some farms, the position of the steading, if on sloping ground, may allow of the tank being so placed as to admit of its contents being drawn off by a pipe and stop-cock, and thus delivered into the manure-cart without the intervention of a pump." See the articles LIQUID MANURE and LIQUID MANURE CART.

TANNER'S-BARK. See TAN, BARK, and TANNIN.

TANNIC ACID. The peculiar vegetable principle which combines with the gelatine of skins and converts them into leather. See the article LEATHER. It can be separated from the vegetable substances which most abundantly contain it, and especially from gall-nuts, by any one of several chemical processes; and, when separated and purified and dried, it is a white, odourless, fiercely astringent, uncrystallizable powder, very soluble in water and alcohol. A solution of it reddens litmus paper; and, when exposed to the air, becomes yellow, yellowish-brown, and dark-brown; and when evaporated to the consistence of an extract, is rendered partially insoluble. It destroys the acidity of acids, or completely swallows it up in its own astringency; and is decomposed by nitric acid and by chlorine in a very obscure or complicated manner; and is precipitated by the carbonates of potash and ammonia, by alumina, by the alkaline earths, and by many of the oxides of the common metals. It forms with the peroxide of iron, or still better with a mixture of the peroxide and the protoxide, a black-coloured compound which, together with gallate of iron, constitutes the basis of writing ink and of the black dyes; and it combines with gelatine in solution to form a yellowish flocculent precipitate which is insoluble in water, and powerfully resists putrefaction, and becomes hard and tough when dry. This precipitate bears the name of tannogelatine, and is the essential basis of leather, and is always formed and deposited within the substance of skins when they are macerated in an infusion of bark. The ultimate composition of tannic acid, according to Berzelius, is 52·69 per cent. of carbon, 43·45 of oxygen, and 3·86 of hydrogen.

TANNIN. Impure tannic acid. Yet the names tannin and tannic acid are very often used as strictly synonymous, by the former being put instead of the latter. Tannin occurs in the bark of most trees, in the excrescences or gall-nuts of several species of oak, in some inspissated juices, such as kino and catechu, in the leaves of such plants as tea, sumach, and whortleberry, and in general in all astringent parts of all astringent plants. It is in fact the chief principle of vegetable astringency; but it varies somewhat in character in different plants, somewhat in quantity at different seasons in the same plant, and very greatly in proportion or relative amount in the corresponding parts of different plants. For example, the tannin of some plants strikes a green colour with salts of iron, while that of most strikes a black or a bluish-black colour; the tannin of any tree is generally more abundant in the inner cortical layers of the bark than in other parts, and much larger in quantity at the budding period of spring than in any period of autumn and especially of winter; and the percentage of tannin in a few of the principal substances which contain it is as follows,—2·2 in willow bark, 2·7 in elm bark, 4 in the inner coloured bark of the oak, 4·3 in chestnut bark, 6·3 in ordinary oak bark, 8·5 in green tea, 10 in

souchong tea, 10·4 in Malaga sumach, 15 in the inner white bark of old oak, 15·2 in the inner white bark of Indian chestnut, 16 in the inner white bark of young oak, 16·2 in Sicilian sumach, 27·4 in nut-galls, 48·1 in Bengal catechu, and 54·3 in Bombay catechu. It is naturally accompanied with gallic acid in tea, gall-nuts, and most kinds of bark; but is not so accompanied in kino, catechu, and cinchona bark.

Artificial tannin can readily be made by digesting charcoal in diluted nitric acid, in the proportion of 100 grains of charcoal, one ounce of nitric acid of density 1·4, and two ounces of water, by exposing the mixture to a gentle heat till all the charcoal is dissolved, and by evaporating the solution to dryness, using care toward the close of the process so to regulate the heat as not to effect decomposition. It may be made also by the action of nitric acid on animal charcoal, on pit-coal, on asphaltum, on indigo, or on various resinous substances; and by the action first of sulphuric acid and next of alcohol on camphor, common resin, balsams, asafœtida, and similar substances. It is brown, astringent, fusible, of resinous fracture, and soluble in cold water and in alcohol, and acts precisely in the same way on a salt of iron and on gelatine as natural tannin does, but is not decomposed by the action of strong nitric acid.

TANNING. See Leather.

TANNO-GELATINE. See Tannic Acid.

TANSY,—botanically *Tanacetum*. A genus of herbs and shrubs, of the chamomile division of the composite order. One species grows wild in Britain, and is cultivated in kitchen gardens; upwards of a dozen species—four of them greenhouse evergreen shrubs, and most of the others hardy, perennial-rooted, annual-stemmed herbs—have been introduced from other countries, but possess little interest; and a number of other species are known. Most of the introduced species, as well as the indigenous one, are yellow-flowered and have a height of about two feet.

The common tansy, *Tanacetum vulgare*, grows wild on road sides and similar situations in various parts of Britain. Its roots are perennial; its stems are annual, solid, smooth, unbranched, and about two feet high; its leaves are doubly pinnatifid, deeply serrated, and of a dark green colour; and its flowers grow in dense terminal corymbs, and are numerous, and have a golden yellow colour, and bloom in July and August. The whole plant emits a strong but not unpleasant odour, and has a bitter taste, and is alleged to possess tonic, cordial, and anthelmintic properties, and has long figured in horticultural catalogues as an aromatic herb for making tansy pudding and for other kitchen uses; but it does not agree with every stomach, and has quite lost a large portion of its culinary reputation. Two varieties of it occur in gardens,—the double or curled and the variegated or striped-leaved; and the former is cultivated for culinary purposes on account of being milder and more grateful than the wild sort, while the latter possesses some little claim to a place in the flower-garden. Tansy is propagated from slips or offsets of the root, planted in spring or autumn, at distances of 12 or 18 inches.

TAPEWORM. See Worms (Intestinal).

TAPIOCA. See Cassava.

TAP-ROOT. A root which penetrates perpendicularly and deeply into the ground, without dividing into branches, or sending off many lateral fibres. A simple tap-root is generally spindle-shaped, and therefore is designated fusiform; and, in many instances, as in those of the carrot and the parsnip, it is fleshy and juicy, and is therefore termed succulent. But the tap-root of a tree or of any other plant which takes wide and complex anchorage within the ground, is merely the main-trunk of a root descending perpendicularly, just as the top or leading shoot of the stem ascends vertically.

TAR. A viscid, dark-brown, resinous semi-fluid, obtained from the wood of the Scotch pine, the long-leaved pine, and other resiniferous trees of the pine and fir tribe. A conical cavity is dug in the ground, commonly in the side of a bank, or on the slope of a hill, within or near a forest; billets of the roots and branches of pine are filled into the cavity and piled above it till they form a large stack; a covering of turf is placed over the whole, and beat firmly down; the stack is kindled, and allowed to burn with a slow smothered combustion; the tar is formed, during the burning, by the decomposition of the resinous juice of the wood; a cast-iron pan at the bottom of the cavity receives the tar as it descends, and delivers it by a projecting spout through the bank or other base of the cavity into barrels placed to receive it; and the barrels, immediately on being filled, are closed with bungs, and are then ready for exportation. Most of the tar used in Britain is brought from Russia, Sweden, and Denmark; but a considerable quantity also is brought from the United States.

Tar is a very compound substance, and contains modified resin, oil of turpentine, empyreumatic oil, acetic acid, charcoal, and water; and when inspissated by boiling, it is converted into pitch. It is extensively used in the cordage, caulking, and sheathing of ships to preserve them from decay; and is of great service in many of the arts and medicinal usages connected with agriculture. It serves well as a paint to coarse kinds of boarding and paling, but is improved, in this use, by being mixed with tallow or other coarse fat. It is highly useful in various details of sheep management, as in some kinds of topical shelter, and as an application to cuts from clipping and to parts affected by the fly. It serves, either alone or in combination with some fatty substance, to defend the sore or diseased feet of cattle from being further injured by wet or abrasion; and, when spread upon coarse cloth, it is a

prime covering for broken horns, and makes an excellent application to various kinds of wounds and punctures in cattle. Tar in substance is sometimes administered internally to horses as a remedy for cough. A mixture of equal parts of tar and some solid fatty substance is the common stopping used by farriers for diseased feet; a mixture of equal parts of tar and oil is an excellent and extensively-used dressing for hoofs; and a liniment composed of two parts of tar, two of cocoa-nut oil, and one of yellow wax, is a good dressing for mange and an efficient detergent in most kinds of scabby, eruptive, cutaneous affections in the horse, but requires to be rubbed in with a piece of hair-cloth or with a rather stiff brush. The rectified oil of tar, popularly called the spirit of tar, is sometimes used alone for mange, though not always with effect; and a mixture of it with twice its bulk of fish oil, when well-rubbed with a brush every night on both crust and sole, is an eminently good application for hardness and brittleness in the horse's feet.

TARAXACUM. See DANDELION.

TARCHONANTHUS. A genus of ornamental exotic plants, of the chamomile division of the composite order. The camphor-scented species, or African fleabane, *T. camphoratus*, is a native of the Cape of Good Hope, and was introduced to British gardens near the end of the 17th century. It is an evergreen shrub of from 10 to 14 feet in height, and sends out many leafy branches at the top, and may be trained up to a regular head. Its leaves are shaped like those of the broad-leaved sallow, and have a downy surface like those of sage, and emit an odour like those of rosemary when bruised; and its flowers are produced in spikes at the extremity of the shoots, and have a dull purple colour and an inconspicuous appearance, and bloom from June till October. This plant helps to adorn the greenhouse or the conservatory in winter; and it loves a soil of peaty loam, and is propagated from cuttings. Another and smaller species has been introduced; and several more are known.

TARE. The common cultivated vetch,—*Vicia sativa*. See the article VETCH.

TARE,—botanically *Ervum*. A genus of annual-rooted, herbaceous, climbing plants, of the vetch division of the leguminous order. Two species grow wild as weeds in the corn-fields, hedges, and thickets of Britain; eight species, all hardy, most about a foot high, and two of them subjects of field and garden cultivation, have been introduced from other countries; and eight more are known.

The smooth or four-seeded tare, *Ervum tetraspermum*, is a troublesome British weed, particularly on rather moist, arable soils. Its root is small and tapering; its stem is weak, quadrangular, leafy, and branched all the way up, and climbs to the height of from 1½ to 3 feet; its herbage, particularly that of the flower-stalks and the calyx is beset with fine soft hairs; its flowers are small, drooping, and of a pale grey colour, and are streaked on the standard and tipped on the keel with a deep blue, and generally come out in pairs, and bloom in June; and its pods are pendulous, oblong, bluntish, and smooth, and commonly contain each four seeds.

The hairy tare, *Ervum hirsutum*, is also a weed of the arable soils of Britain. It somewhat closely resembles the preceding in habit and general appearance, but in general is some inches taller. Its flowers grow in clusters of five or seven, and are very small, and have a very pale blue or almost white colour, with two dark spots on the keel, and bloom in June and July; and its pods are short, and beset with hairs, and of a dark brown colour, and contain each two large prominent seeds.

The lentil tare, or common lentil, *Ervum lens*, is noticed in the article LENTIL. It is generally called dill in those parts of England where it has been tried as a field plant; and though highly esteemed in quality—as green food for suckling ewes, as haulm-fodder for all kinds of cattle, and as ground seed in mixture with barley or potatoes for fattening pigs—it has been found so comparatively poor in quantity that, except on land which does not suit vetches, it has ceased to be cultivated by even such English farmers as have most strongly liked it. Every plant, on the average, has a close branching habit of growth, and produces from 100 to 150 pods, or even a greater number.—The small variety of it is the kind most commonly grown for green food in France. It is rather taller and later than any of the other three varieties; its flowers are reddish; its pods are often two-seeded; and its seeds have each a diameter of little more than one-eighth of an inch.—The large variety is the most productive, but is regarded on the Continent as inferior to the yellow in quality. Its height is from 12 to 15 inches; its flowers are very small and whitish, and stand commonly two but sometimes three on a footstalk; its pods are flattened, about three-fourths of an inch long and one-half broad, and generally one-seeded; and its seeds are round, compressed, of a whitish or cream colour, and each about three-eighths of an inch broad and one-eighth thick.—The yellow or common variety is the kind most esteemed in Paris. It is about as early as the large, and differs from it principally in the smaller size and better quality of its seeds.—The red variety is about as early as the large and the yellow. Its flowers have a light red colour; and its seeds are reddish-brown, and of smaller size than those of the large.

The one-flowered tare, or one-flowered lentil, or jointed vetch, *Ervum monanthos*, was introduced to Britain about 50 years ago from the South of Europe. Its stems are 12 or 15 inches high; its flowers are purple-coloured and bloom in June and July; its pods are subinflated, oblong, linear, and generally three or four-seeded; and its seeds are globular, of a dunnish-brown

colour, often slightly wrinkled, and from one-eighth to two-eighths of an inch in diameter. This plant is much less esteemed than any of the varieties of the common lentil, yet is cultivated, for the sake of both its herbage and its seeds, in some parts of France and of other Continental countries.

The tare-lentil or vetch-tare, *Ervum ervilia*, was introduced to Britain from the South of Europe toward the close of the 16th century. It closely resembles the preceding in height, habit, flower, and pod, and is also cultivated.—The slender and the pubescent tares, *E. gracile* and *E. pubescens*, the former pale blue flowered, the latter purple flowered, and both similar to the two preceding in height, habit, and pod, were introduced within the last 30 years from the South of Europe.

The small lentil tare, *Ervum lenticula*, was introduced in 1820 from Carinthia. It has a general resemblance, especially in pod, to the common lentil; but is regarded by some botanists as a chick-pea. Its flowers are blue.—The blackish tare, *E. nigricans*, was introduced from Tauria in 1817. It still more closely resembles the common lentil; but has purple-coloured flowers. —The two-seeded tare, *E. dispermum*, was introduced from India in 1802. It is somewhat lentil-like, and has a height of about 20 inches, and carries purple-coloured flowers.

TARTAR. See Teeth.

TARTAR (Cream of). See Cream of Tartar.

TARTAR EMETIC. See Antimony.

TARTARIC ACID. This acid, as it exists in vegetables, is usually combined with potash, forming a salt with an excess of acid—the super-tartrate or bi-tartrate of potash. This salt is deposited in considerable quantity from the juice of the grape during its conversion into wine, or rather from the wine during the slow fermentation which it suffers in the cask. It does not appear to be a product of the fermentative process, but exists before this in the juice of the grape, and is merely separated. It also exists in other fruits, particularly in the tamarind, of which it forms a considerable part. As deposited from wine, it is impure, having mingled with it colouring matter and tartrate of lime. In this state, it forms the crude tartar of commerce, named *white* or *red tartar*, according to its colour. It is purified by boiling it in water, with the addition of a small quantity of fine clay, which attracts the colouring matter. By evaporation, it is obtained crystallized, forming the purified tartar, crystals, or cream of tartar of the shops. From this salt the tartaric acid is obtained, by adding to a solution of the super-tartrate of potash in boiling water, carbonate of lime in powder, as long as any effervescence is excited: the tartrate of lime which is formed and precipitated, being well washed, is decomposed by adding sulphuric acid equal in weight to the chalk that had been employed, previously diluted with half its weight of water, digesting them with a moderate heat: the sulphuric acid combines with the lime and forms the sulphate, which, being of sparing solubility, is separated, while the tartaric acid is dissolved by the water, and, by evaporation, is obtained in a crystallized form. The crystals are tables or prisms, white, and nearly transparent. Their taste is sour, and they deeply redden vegetable blues. They are very soluble in water, and form a solution so concentrated as to have an oily appearance. By the action of very strong nitric acid, tartaric acid is converted into oxalic acid. The crystals are composed of acid 66 and water 9 in 75 parts. The acid appears to be composed of

Hydrogen,	4·48
Carbon,	35·82
Oxygen,	59·70
	100·00

Tartaric acid is decomposed by heat, affording, among other products, a white sublimate, which is a peculiar acid, named, from its origin, *pyro-tartaric acid*, which has been regarded by some as acetic acid disguised by the addition of a little oily matter. Tartaric acid combines with the alkalies and earths, forming salts named *tartrates*. The acid appears to have a peculiar tendency to enter into combination with more than one base, and to form ternary salts. It has also a tendency to form salts with an excess of acid, in uniting with those bases, with which it forms soluble compounds. Tartrate of potash is usually formed by neutralizing the excess of acid in the bi-tartrate, by the addition of carbonate of potash. From its affinity to water, it is not easily crystallized, but, by a slow evaporation, affords four-sided prisms. It is deliquescent in a humid atmosphere, and very soluble in water, whence its name, also, of *soluble tartar*. Tartrate of soda is soluble and crystallizable. A triple salt, the tartrate of potash and soda, or *Rochelle salt*, is formed by neutralizing the excess of acid in the super-tartrate of potash, by adding carbonate of soda. See the article Rochelle Salt. Tartaric acid acts on some of the metals, and it may be combined with the oxides of all of them by double affinity. By employing the bi-tartrate of potash to act on these oxides, ternary compounds are obtained. The most important of these is that formed with the oxide of antimony,—long known in medical practice under the name of *tartar emetic*, as one of the mildest and most manageable of the antimonial preparations. See the article Antimony.

TARTONRAIRA. See Daphne.

TARUGA. See Alpaca.

TAUSCHERIA. A small genus of hardy, ornamental, exotic, annual plants, of the cruciferous order. Two species, the naked-podded and the hairy-podded, both about 6 inches high, white-flowered, and blooming in June and July, were

introduced to Britain within the last 30 years from Siberia.

TAXES denote that portion of their property which the government of a state exacts, for the supply of the public necessities, from its subjects, or other persons residing in the country and partaking of its advantages. Hence they form a part of the state-revenues. Another part is formed by the revenues from the domains, and from the royal prerogatives, so far as the last afford only official gains, and are not used at the same time as means to exact or to raise taxes.

In most states, particularly in those of ancient times, the public expenditures were supplied from the revenues of domains and royalties, which were considered, the former as the property, the latter as privileges, of the sovereigns. As the expenses of the state continually increased, or the rulers, from bad economy, found the above-mentioned sources of revenue insufficient, they began to demand contributions from the members of the community, and imposed upon them taxes or imposts. They usually, however, met with great difficulties, since the nobles would not suffer themselves to be taxed, under pretext of forming a state within themselves, and maintained that such contributions could be raised only with their consent. What could be obtained from them voluntarily, was very little. They, however, acknowledged the necessity of increasing the revenue of the state; but the sovereigns were afraid to constrain them to contribute, and inclined to grant them exemption from taxes, if they would only consent that the rest of the nation, which did not belong to their privileged order, should be subjected to imposts. The nobles, fearing that if no other source of revenue were left open to the sovereign, the burden of taxes would finally fall on themselves, willingly allowed him the right of taxing the rest of the nation, which, from want of union and power, was obliged to yield. Thus the taxes, for a long time, were laid almost everywhere on the commons only, the higher and more powerful orders, the clergy and nobility, being exempt. Enlightened governments, however, early perceived that, in order to render taxes a permanent source of revenue, means must be left to the subjects, of gaining, every year, so much as to be able to subsist, and to have a sufficient sum remaining to pay the taxes. Hence they were induced to refrain from exhausting their property. But a long time elapsed before the principles of equitable taxation were well understood. It was not till a late period, since government has become an object of profound reflection and a more perfect system of political economy has arisen, that a theory of taxation has been formed, which can be used as a solid basis of revenue. According to this theory, taxes are the portions of the property of individuals, which each has to contribute to the public treasury, to defray the public expenses. From this definition it follows,—

1. That no one should be exempted from taxes, who possesses property or income, and is protected in his person and estate, and that, in consequence, absolute freedom from taxes in any individual, so situated, is unjust towards those members of the community who are charged with them.

2. That the taxes ought to be assessed according to the net income of each individual.

3. That the taxes must never be suffered to injure the sources of income.

4. That the ratio of taxes to income ought to be as small as possible, in order that the revenue of the nation, as well as of the individual, may be allowed to increase.

The greatest difficulty in effecting a just distribution of taxes, is to find the clear income of every individual. In the mode of taxation formerly practised, this difficulty was but little considered. Financiers were satisfied with laying taxes where they observed property or income, without caring much whether they were taken from the gross or net income, from the capital, or from the interest and profits. The rudest mode was to assess the taxes according to the number of heads. On the supposition that every one receives enough to pay something, they demanded from every head such a sum as, it was presumed, even the poorest could afford: the rich and the poor paid the same amount; and, therefore, the greatest inequality prevailed. Real property was early taken as a standard in distributing the taxes, as cultivated land, in civilized countries, appeared to be the safest and most substantial property. As this afforded to its proprietors or cultivators a certain income, the annual produce of the lands of those who were declared subject to taxation was estimated, and, after this ratio, the tax was distributed on real property. Thus arose the land tax, in which, however, the gross and net produce of the lands were seldom accurately distinguished; and where it was done, little dependence was to be put upon the estimate itself, and still less on the maintenance of this principle through the changes of income.

As the land tax was insufficient to furnish the necessary revenue, other means were sought for, and the closest attention was paid, particularly as the circulation of money increased in civil society, to all those quarters where money appeared. Wherever money changed hands, as in sales, exchanges, inheritances, taxes were laid. Whoever desired to obtain any favour from the public officers, was obliged to purchase it with money. When property was acquired, something must be relinquished. Hence the long series of taxes on acquisition and industry. As the income of the members of the community did not yield so much as the state required, the attention of governments was directed to expenditures; and people were made to pay, wherever their expenses could be estimated. Thus taxes on

consumption of every description were established. When taxes began to be treated scientifically, which was not till a long time after the different kinds had been invented and introduced, attempts were made to bring the whole mass of the existing taxes under a general system.

All taxes may be arranged under the following classes: taxes on the *possession*, on the *acquisition*, or on the *enjoyment of property*. In order to judge whether they are rightly distributed, it must first be considered, whether they can be paid regularly and continually from the net income or not. There may be a possession which brings no gain at all, as a library, a collection of pictures, &c. If an annual tax is laid upon such property, it would, sooner or later, consume the property if it were to be paid from it, and, consequently, would contradict the principles above laid down, that property should be taxed only so far as it affords a regular income. In like way, acquisitions can be taxed, according to the principles of political economy, only when they are a permanent source of gain. If, therefore, any one acquires an estate or a capital by purchase, exchange, &c., and taxes are laid upon such an acquisition, the tax is taken from the capital, that is, from the means destined to produce profit. As far as this happens or is in danger of happening, the system of taxation is defective. If, in fine, a tax is laid on enjoyment, or the value of things enjoyed, this can be justified only so far as he who purchases or enjoys such things can afford the expense, from an income which furnishes more than enough for his subsistence, and the source of which is not necessarily diminished by the tax. If we seek, therefore, for the principle of the distribution of taxes, which ought to serve at the same time as a rule for judging of the propriety of the distribution, this can be no other than the *net income* of the persons, or the *net produce* of the property.

Net income or net profit is that part of income or profit which remains after the portion necessary for the maintenance of the person, or the continuance of the property which produced the income or the profit, has been subtracted. An income and profit are produced either, 1. from land; 2. from capital; 3. from labour. All taxes will be just and useful only so far as they are a part of the net produce from these sources, and are imposed and distributed after this principle. But as it is difficult, and in many cases impossible, in practice, to ascertain the net revenue of every one, the politician must take different ways to find the just proportion. The first way is direct—to determine, from the statement of the parties concerned, or from official estimation, the net income of the persons, or the net produce of the land, and to assess the taxes according to the result. This kind of taxes is called *direct*. But as this mode leaves a large portion of net incomes doubtful, their amount is sought for in an indirect way. It is supposed that he who receives more than the amount at which he has rated his income, will consume and enjoy more than this sum will warrant, and, in particular, that he will enjoy certain articles which the man of smaller income consumes not at all, or not in equal quantity. If, now, the expense for articles of consumption is taxed, an additional sum can be generally drawn from all those who pay already a direct tax on income, not sufficient, however, to cover the expenses of the state. This sum they can pay from their net income, if their affairs are properly arranged. In this way, something more is obtained from the net income of those who have concealed a part, than they would have contributed if they had been taxed merely according to their own statement. These taxes are termed *indirect*, as they are calculated like the others on the net income, but only in an indirect way. The art of reaching this net income by taxes on consumption, or other indirect taxes, still remains very imperfect. Its perfection is, however, necessary, if the system of taxation is to be established according to just principles.

Another signification is usually attached to the division of taxes into direct and indirect. The mode in which they are raised is made the principle of denomination. By direct taxes are understood such as are laid immediately on the consumers; by indirect taxes, such as are assessed on others in advance, who are left to remunerate themselves from the rest of the community. But this principle does not afford a logically correct division; for the same tax can be raised at one time directly, at another indirectly. Thus all taxes of consumption may be raised as well from those who consume the articles, as from the tradesmen who deal in them. In like manner, many articles of luxury are taxed directly. Nevertheless, the taxes remain indirect, because the net income only is taxed according to the extravagance of individuals. Taxes imposed on goods at the time of their importation, are denominated *customs*, *duties*, or *imposts*. Adam Smith mentions one objection to this mode of raising revenue, as the importing merchant must enhance the price of his goods, not only by the amount of the duty advanced by him, but also for interest, profit, and guarantee of that amount, so that the consumer must, in fact, pay more than the tax. This objection is avoided by an excise tax, which is levied on the goods in the hands of the person who uses them, or at the time of their coming into his hands. An annual excise is sometimes levied upon articles of a durable nature, such as carriages, watches, &c.; and the principle on which this is apportioned, is to graduate it according to the supposed expenditure of the persons paying the tax, assuming that this will, as a general rule, be in some near proportion to their income. In respect to imported articles, the excise is either a substitute

for customs, or an addition to them. Considered as a substitute, the excise avoids the objection pointed out by Adam Smith; but then it is an expensive tax to collect, and it necessarily gives rise to an irksome inquiry into the private concerns and habits of people, so that, as far as imported goods are the subject of taxation, the customs are the most convenient, and, on the whole, the most productive tax; and this mode of taxing is almost universally adopted.

It cannot be made a question, among a free people, to whom the right of taxation belongs. In England the principle has long been acknowledged, that taxes are a voluntary donation from the people to the government. On the European continent, where, in the course of time, nearly all national representation has been lost, the physical power of the government is the sufficient argument, as in so many other instances, by which all discussion on the right of taxation is made useless. The theory of taxes has been but very lately illustrated and perfected. Adam Smith laid the first foundation of a complete theory. Before him prevailed the physiocratical system, which, however, has no solid foundations.

Exemption from Taxes.—The privilege of exemption from taxes is granted to some orders of society, to individuals, or to particular kinds of property. The reasons for which it is usually allowed are, 1. the identity of the person exempted with the state; 2. to reward services rendered to the state; 3. as a means of paying debts due from the state; 4. the incompatibility of the public burdens with the office or character of the individual exempted; 5. because an equivalent is received in some other way; 6. poverty; 7. ancient privileges. As to the first reason, it is applicable only to the person of the sovereign; for it would be absurd to load the sovereign with taxes, whilst the taxes are only established in order to afford the sovereign the means of promoting the public welfare. It follows, then, that the revenues of the state must be free from taxes, or that the state itself, considered as a person, must be free from every tax. But whether the individual, likewise, who is invested with the sovereignty, should be entirely exempt from taxes, is a very different question; for, in the revenue of such an individual, there are always two things to be distinguished, namely, *a.* that which is employed by him in the exercise of his public functions, and, *b.* that which serves to defray his private expenses; for it cannot be contended that all which the sovereign expends is devoted to the accomplishment of public objects. In addition to his public capacity, he stands in the condition of a private person, who has his individual wishes and wants to gratify. Now, if the revenue of the ruler is so large as not only to supply that expenditure which is required for maintaining the dignity of the reigning family, but also to suffice for the private gratification of the ruler, the latter part is undoubtedly to be considered like the net income of a private person. In this point of view, there is no sufficient reason why the income of the prince should be free from taxes. It appears rather, for several reasons, advisable to subject it to taxation, like other private property; 1. because in this way the prince feels, proportionally, the burden of the tax in his private capacity, being obliged, like every other man, to restrict his personal expenditure; 2. because the participation of the prince in the public burdens, affords an encouraging example to his subjects, and serves to check the claim of exemption in any other class of society. In those states where the sovereignty is vested in a numerous body, the distinction between that which belongs to the members of the sovereign body, in their public and in their private capacity, is yet more evident. The members of a council who share in the sovereignty, or of the sovereign senate itself, can be as little entitled to exemption from taxes as the members of a sovereign assembly of the nation in a democracy; and the right of a prince to freedom from taxes on that portion of his income which is devoted to his private gratification, is no better founded. If the state would reward an individual for public services by exempting him from taxes, this can reasonably be done only by a personal exemption for his lifetime. To declare his estates free from taxes, is to make him a donation of a sum equal to the tax from which his estates are exempted. But to make this exemption perpetual, would be to make a grant of an indefinite value, and must be regarded as an instance of blind extravagance. In general, this species of reward is one of the most objectionable; for the reward of public services should be drawn from the public revenue, to which all classes contribute in equal proportion. But the remission of a certain kind of taxes usually imposes new burdens on some particular class of subjects. Another objection to this kind of reward is, that it makes exemption from taxes appear an honour, when it is for the interest of the state that a citizen should consider himself the more important the more he contributes to the support of the public burdens. Nearly the same reasons, in particular the last, may be urged against the use of this exemption as a means of paying the salaries of public officers. The privilege too often operates unequally in the case of different officers, one deriving from it a much greater advantage than another. Taxes paid in money are incompatible with no rank in society and no kind of occupation. Other public burdens, personal service, maintenance of soldiers, &c., may, indeed, be inconsistent with one or the other. On that account, it would be better that such burdens should be borne by individuals who are paid at a fixed rate for undertaking them. That the poor pay no taxes, is the natural consequence of a good system of taxation, which charges only the net income. It follows from what has been

said, that a personal right to exemption from taxes cannot be properly granted, and should be abolished where it exists; sufficient indemnification being provided for those who suffer by the measure. These exemptions had their origin in a time of limited views.

As to the exemption from taxes of particular kinds of property, the most remarkable is that which is granted to certain landed estates. This privilege is usually justified by the following reasons: 1. that one estate has undertaken to pay the tax of another. In this way the nobility have often endeavoured to defend the exemption of their estates, by pretending that their ancestors had ceded part of their lands to the peasants, on condition that the latter, in addition to some labour on the lord's estate, should pay the taxes of the same, from the produce of their farms. Such a contract might have been legally made, and might stand good if it had been concluded for a fixed proportion of taxes, and the agreement could be clearly proved; but no compact can be acknowledged as binding, by which one side undertakes to relieve the other from the burden of all future taxes, since no one can know what their amount may become, and whether the land granted would be a proper equivalent; for, in every contract, the nature of the obligation should be definite. But in addition to the fact that such contracts are mere fictions, the state should allow them no validity, because they give to taxes the appearance of an ignominious burden—an idea which no government should favour. 2. Governments have sometimes allowed individuals, and even whole nations, to redeem themselves from a certain tax, for a gross sum; as, for instance, in England, in the case of the land tax. Such contracts must be kept; but no individual, still less a whole class or nation, can purchase an entire exemption from taxes, because the amount of future taxes cannot be estimated, and, consequently, their value cannot be settled. This would be to sell the very means of the state's existence. To sell an improper tax in order to establish a better, as was done with the land tax in England, may be advisable, and certain objects may thus for a time be exempted from taxes; but this is no reason for releasing the income which they afford, for all future times, from taxes. 3. Finally, the privilege of exemption never can be considered as absolutely irrevocable, but is subject to be judged on the general principle of utility, like all other positive laws and institutions; and if found inapplicable, injurious, and oppressive to other classes of citizens, such laws must be amended or abolished. And as the state ought never to persist in old errors at the expense of its citizens, so, on the other hand, those who are to lose the privilege of exemption from taxes, should be indemnified for it according to equitable principles.

TAZETTA. See Narcissus.

TEA,—botanically *Thea*. A genus of economical, evergreen shrubs, of the camellia order. The plants of it furnish most of the well-known tea of commerce; but are the subjects of great uncertainty as to their specific characters and arrangement. Two kinds, the black and the green, *Thea bohea* and *Thea viridis*, both white-flowered and commonly from 4 to 6 feet high, the former blooming from August till December, and the latter from February till November, were introduced from China to the greenhouses and conservatories of Britain in 1768; and they are regarded by some botanists as two distinct species, by others as only varieties of one species, and by many persons as mere specimens of a considerable number of different forms into which one wild plant has been wrought by very long and assiduous cultivation. The Chinese themselves, even including most or all of them who take part in tea cultivation, probably could not come to any harmony of opinion respecting the specific characters of the varieties; for they call the wild kind which grows on the mountains of Ho-nan *tchow-tcha* or bastard tea, and designate any variety which yields the largest and best produce for the market the true tea; and were they to study botany and plant-culture after the European style, they would very likely pronounce their cultivated tea-plants to stand related to their wild tea-plant in nearly the same way as our orchard apple-trees do to our wild crab, or as our cultivated cabbages and coleworts and borecoles and cauliflowers do to our wild cabbage. In their practice of preparing different kinds and qualities of tea for the market, too, they are dependent far less on different varieties of plant, than on different stages of growth, different seasons of the year, and different methods of drying and flavouring; and they manufacture black tea and green tea, not from the leaves of two species or two varieties corresponding to the *Thea bohea* and the *Thea viridis* of our greenhouses, but from different growths or kinds of the leaves of one plant, or by different methods of drying even the same growth of leaves.

The stem of the tea-plant is somewhat rigid, of an ashy colour in the lower parts, and more reddish toward the top; the branches are alternate, yet shoot out irregularly; the leaves are elliptic, indented at the top, entire near the base, smooth, firm, glossy, shining, and of a bright green colour; the buds are enclosed in a husk, which drops off; the flowers come out singly from the axils of the leaves, and have a small calyx, generally six white round petals, and upwards of two hundred stamens; the capsules have three round cells, opening longitudinally on only one side; and the seeds are single, globose, and about the size of filberts, and have an oily and disagreeably bitter kernel. The leaves in their fresh or unprepared state are said to possess an intoxicating property; but they lose it on being exposed to

the fire and kept during a twelvemonth. All the varieties of the tea of commerce are prepared for the market by more or less application of artificial heat; and some are highly or repeatedly torrefied. The bohea derives its name from Vo-vyee, the country in which it grows; congo or cong-foo, signifying "great trouble," from the operose method in which its leaves are gathered; pekoe or pe-how, signifying "white leaf," from its consisting only of the leaves of the tenderest of the trees of three years' growth, gathered just after they have bloomed; and souchong or seou-chong, signifying "small good thing," from its being the scarce produce of trees of three years' growth on particular kinds of soil. The leaves which are gathered earliest in the spring afford the strongest and most valuable varieties; those which are gathered late in the year afford the inferior varieties; and those of any season can be made into the green or hyson varieties by peculiar and abundant torrefaction. All the leaves naturally possess an unctuous quality; and they lose almost all of it in the process of drying.

Many adulterations of tea, by admixture of the leaves of old stock, of exhausted specimens, or of totally different plants, are practised both in China and in Britain. The Chinese mix the waste unmarketable teas of former years with the new crop, in order to increase its bulk, and mix other substances with many or most or all of the varieties in order to increase their weight, to modify their colour, or to give them a peculiar flavour; and if they were not checked and controlled by searching inspection at Canton, they would practise such vast and multifarious deception as would speedily throw the whole tea-trade into a state of chaos. They systematically use the leaves of the *Olea fragrans*, in particular, for imparting a special scent to some varieties, and those of the *Camellia sasanqua*, for modifying the appearance and the quality of both good and bad varieties, and those of *Azalea indica*, for producing the small silvery-looking intermixture which characterises pekoe. Among the tricks of adulteration played at home are the intermixing of the scalded and dried leaves of the white-thorn and the common ash, and of the re-dried waste tea-leaves of hotels and taverns.

The tea-plant is indigenous in eastern parts of China and in Japan, and is held in the highest esteem by the natives, both as an article of diet and as a means of national wealth. It has been used by the Chinese from time immemorial, some say from the time of Confucius, as both an invigorating beverage and a medicinal condiment, peculiarly salutary to the human constitution. It has for ages been the theme of their poets, the idol of their husbandmen, and the highest favourite of their emperor and his government; and it is discussed at great length, and with reference to all its history and treatment, in a series of twenty-four native treatises which began to be composed about the seventh century. The consumption of it throughout the vast Chinese empire is so great that, in the opinion of Sir George Staunton, it would not be materially lowered in price to the native consumer if the whole trade in it to Europe were abandoned. It seems to have been first introduced into Europe, about the middle of the 17th century, by the Dutch,—and into England from Holland, in 1666, by Lords Arlington and Ossay. It was originally sold in this country for sixty shillings per pound, and was treated as a rare and high and dangerous luxury; and though strenuously denounced and vigorously opposed, it year after year got into increasingly extensive use,—and, at about the beginning of the 18th century, it became generally established as a culinary necessary of British life. It subsequently continued to be a vast and rapidly increasing department of the East India Company's imports to Britain; and, in recent times, it rose to a great and permanent augmentation by the opening of the Indo-Chinese ports to general commerce. The experimental cultivation of it was tried in Bengal so early as 1793,—and on a greater and more vigorous scale in 1835; the actual and extensive cultivation of it has for a considerable period been carried on in Assam and Cochin-China,—and promises to acquire great consequence in several of the Anglo-Indian provinces; and the amateur cultivation of it in the open ground, with the view of testing its possible adaptations to routine culture, has been tried in several parts of England, and in several countries of Continental Europe. The plant proves quite capable of withstanding the winter in the open ground in Britain, with the aid of a little protection when young; and it may admit of a very easy and extensive naturalization throughout the milder regions of Southern Europe; nor does it seem to possess any particular fastidiousness as to soil or situation or cultorial treatment; yet—on the mere ground of the far greater cheapness of labour in China than in Europe, combined with the fact of the extensive hereditary experience which the Chinese possess both in the department of cultivating the plant and in that of drying and otherwise preparing its leaves—it probably can nowhere be so grown in Europe as to yield marketable produce at as low a price as the tea imported from China.

Tea is cultivated, not in every part of China, but chiefly in a tract on the east side, called the tea country, situated between the 28th and 35th degrees of north latitude, and more particularly between the 30th and 33d, and possessing a mean temperature in November of 56° Fahrenheit at sunrise and 62° at noon. But in Japan, it is cultivated, not in any particular district, or in lands specially devoted to it, but in all parts of the country, around the border of corn and rice fields. The mode of cultivation in the two countries is very much the same. The plant thrives best on light stony soil; and is commonly sown in the month of February, in rows 4 or 5

feet asunder. From six to twelve seeds are deposited in each hole; for in consequence of their oiliness, they are apt to become rancid, so that a considerable proportion do not germinate. The plants require to be carefully weeded while very young; but are otherwise easily reared. Their leaves are not available for gathering till the third year after sowing; but they are then good and abundant. At seven years from sowing, the plants attain their full height, but they then have thinner and less valuable leaves than in the third and three following years; and at that time, they are generally cut over near the ground, so that they send forth an exuberance of new shoots, and may yield as strong, well-flavoured, and plentiful leaves as before; and, by this practice of cutting over, repeated at suitable intervals, they can be rendered fairly or fully productive during an indefinite number of years. The leaves are gathered either singly or in sprigs; and can be collected by a diligent worker, sometimes to the amount of ten or even fifteen pounds in a day, and on the average, to the amount of from four to six. The leaves are gathered at different seasons or upon different methods, according to the several varieties of the tea; and are torrefied in buildings adapted for the purpose, having a number of small furnaces, each about three feet high, with a large flat iron pan at the top.

Bohea is gathered first from about the middle till the end of April, next from about the middle of June till about the middle of July, and next from the beginning of August till the end of September; and if the demand be great, a fourth gathering is made later in the year, though at the serious risk of impoverishing next year's crop. The leaves are put into large baskets to dry, elevated to receive currents of air, or exposed to the sun, if not too intense, for a few hours, when they begin to impregnate the air; then they are what is called *tatched*, which is done by throwing each time about half a catty of leaves into a flat pan of cast iron, which is hot, and stirring them with the hand. They are then taken out and again put into the baskets, and rubbed with men's hands to roll them, after which they are again tatched in larger quantities, and over a slower fire; which being accomplished they are further fired in baskets over charcoal. This being completed, the tea is laid upon a table, and the useless or bad selected from it; but being a common tea, it is not so carefully examined as the other sorts. The best is of a small blackish leaf, and dusty, of a somewhat brackish taste; and it should be crisp. Reject what smells faint and disagreeable.

Congou requires great care in the making. The London dealers know three sorts of Congou teas, viz. Congou, Campoi Congou, and Ankay Congou. The first is a superior kind of bohea, larger leaf and less dusty. It should be chosen of a fresh smell, the taste less strong than bohea, to feel crisp, and easily crumbled. Those congous which run broken and dusty, of a heated smell, and faint unpleasant taste, should be rejected. Campoi congou is a superior kind of congou, but much resembling it, but fresher and of a cleaner flavour, not unlike souchong. Ankay congou receives its name from Ankay where it is propagated. The leaf is small and wiry, and of a burnt smell. At Canton it has a high flavour, which is lost in the course of the voyage. This tea is little esteemed in London.

Souchong, or Se-ow-chong, is made from the leaves of trees three years old, and where the soil is very good, of older leaves; but of the true souchong very little is produced. What is sold to Europeans for souchong is only the first sort of congou; and the congou is only the first sort of bohea. Upon a hill planted with tea-trees, one only may produce leaves good enough to be called souchong, and of these only the best and youngest are taken; the others make congous and boheas. The London dealers distinguish three species of souchong. Souchong, or what is commonly called so, should be crisp and dry, of a pleasant fragrant smell, and as free from dust as possible. When tried in water, the more reddish brown the leaves are the better, and the water of a lightish brown. It is sometimes of a high colour, and sometimes pale; but the tea, if good in other respects, should not be rejected on account of the colour. Avoid such as is broken, dusty, or foul, or that smells old and musty. Caper souchong takes its name from being rolled up something like a caper. The leaves of this should be chosen of a fine black gloss, heavy, of a fresh good smell, taste full flavoured and high. On being infused in water, it tinges of a bright reddish brown colour. Reject that which is dusty and broken, and of a faint smell. Padre souchong, or Pow-chong, is a very superior kind of souchong, having a finer taste, smell, and flavour. The leaves are larger and of a yellowish hue, not so strongly twisted. This tea is scarce, and difficult to be procured genuine. That which is small and broken should be rejected.

Pekoe, or Pé-how, is made from the leaves of trees three years old, and from the tenderest of them, gathered just after they have been in bloom, when the small leaves that grow between the two first that have appeared, and which altogether make a sprig, are downy and white, and resemble young hair or down. This tea is esteemed superior to souchong. It should be chosen with small white leaves, or flowers at the ends of the leaves; the more flower it has, the more it is esteemed. It has a peculiar flavour; and it greatly improves souchong on being mixed with it. That which is old, small, and broken, with little flavour, should be rejected.

Green teas are cured in the following manner:—When the leaves are gathered, they are directly tatched, and then very much rubbed by men's hands to roll them, after which they are

spread, to divide them, for the leaves in rolling are apt to stick together. They are then tatched very dry, and afterwards spread on tables to be picked; then they are tatched again, and tossed in flat baskets, to clear them from dust; they are then again spread upon tables, and picked, and then tatched for a fourth time, and laid in parcels, which parcels are again tatched by ten catties at a time, and when done, put hot into baskets for the purpose, where they are kept till it suits the owner to pack them in chests or tubs; before which the tea is again tatched, and then put hot into the chests or tubs, and pressed into them by the hand. When the tea is hot, it does not break, which it is apt to do when it is cold. Singlo tea being more dusty than hyson tea, is twice tossed in baskets; hyson only once. It appears that it is necessary to tatch these teas whenever they contract any moisture; so that if the seller is obliged to keep his tea any time, especially in damp weather, he must tatch it to give it a crispness, before he can sell it. It is a common opinion that the verdure on green teas is occasioned by their being dried on copper; but this seems entirely a mistake. The London dealers classify green teas into several species; and the first of these is Singlo.

There are two gatherings of Singlo tea, the first in April and May, the second in June; and each gathering is divided into three or more sorts. The first picking contains the largest and finest leaves, and is of course the best. Singlo is of a flattish leaf. It should be chosen of a fresh strong flavour; be of a light green colour when chewed; should feel crisp and brittle; and on infusion have none of the leaves turn brown or dark coloured. That which is yellow, of a large loose leaf, and dusty, should be rejected.

Twankay, or Tunkey, is a superior kind of singlo. It grows near the Hyson country, and is oftener tatched and picked than the common singlo. Twankay, like other singlo tea, is made into two or three sorts; and the best is sometimes sold for hyson of an inferior growth. It should be chosen with the leaves well twisted or curled; it ought also to have a burnt smell, not too strong but pleasant; and on infusion it should yield a paler colour than singlo. That which is yellow, and has a smell inclining to sulphur, should be rejected.

Hyson skin, or bloom tea, has its name from being compared to the peel or skin of the hyson tea, a sort of cover to it, consequently not so good. It consists of the largest, unhandsome, bad coloured, and uncurled leaves, that are picked out from the hyson tea. Hyson skin is a superior kind of green tea, of a round, knobby, brightish leaf; but great part of what is imported is of an inferior quality, of a yellowish open leaf, somewhat resembling singlo, and in consequence varies greatly in price. It should be chosen of a fresh smell, on infusion yield a pale yellowish green colour, and of a delicate taste, though somewhat of a burnt flavour. The more it approaches to hyson, the more it is esteemed.

Superior hyson skin intervenes between the common hyson skin and the hyson. It is said to be hyson tea a year or more old, which, after undergoing the process of tatching repeatedly, is brought to market a second time. Its appearance is much darker than hyson, with less bloom on it. Its smell is somewhat musty, and the taste has more of the brassy flavour peculiar to green teas, without any of the delicate aromatic taste of good hyson. On infusion, the water is darker coloured, and with less fragrance than hyson.

Hyson, or He-tchune, is the first crop of this tea. There are two gatherings of it; and each gathering is distinguished into two or more sorts. Hyson tea should be chosen of a full sized grain, of a fine blooming appearance, very dry, and so crisp, that with a slight pressure it will crumble to dust. When infused in water, the leaf should open clear and smooth, without being broken or appearing shrivelled,—which is one of the indications of old tea. It should give the water a light green tinge. The water should also have an aromatic smell, with a strong pungent taste. Those leaves which appear of a dyed yellowish green, or give the water a similar tinge, or rather a brownish hue, should be rejected; likewise that which appears highly glazed, which occasions it to yield a darker colour to water.

Gunpowder is a superior kind of hyson. This tea should be chosen round, resembling small shot, with a beautiful bloom upon it, which will not bear the breath. It should appear of a greenish hue, and a fragrant pungent taste. The chest of gunpowder is of the same dimensions as that of hyson; and the heavier it weighs, the better the tea is considered. Gunpowder tea is sometimes adulterated. An inferior kind of tea is dyed and glazed, to bear the appearance of the finest tea, but which, on infusion, is very inferior in every respect. This should be carefully avoided; likewise that of which the leaf is open and loose, the face of a darker hue or bloom, and that has a brassy unpleasant taste.

Chulan hyson is a peculiar kind of hyson-leaf, having the berries of a small plant, called by the Chinese chulan, mixed with it, which gives it a cowslip flavour, on which account it is sometimes called cowslip tea. It should be chosen of a yellowish leaf, a fragrant and perfumed smell, and when infused in water, of a strong cowslip flavour.

Ball tea is so called from the form into which it is made, being round, and nearly the size of a nutmeg, composed of the leaves of black tea, generally of the best kind, gummed together.

Brush tea is so called from the leaves being twisted into small cords, like pack-thread, about $1\frac{1}{2}$ to 2 inches long. Usually three of these are tied together at the ends by different coloured silks. They are made both of green and black tea.

The latest analysis of tea is that of Mulder; and is as follows:—

	Chinese.		Javanese.	
	Hyson.	Congou.	Hyson.	Congou.
Volatile Oil	0·79	0·60	0·98	0·65

	98·78	98·30	100·42	97·70
Salts included in the above	5·56	5·24	4·76	5·36

"According to this analysis," remarks Dr. Pereira, "green tea contains more tannin than black tea. This accords with every-day experience, as well as with the experiments of Mr. Brande; but it is opposed to the results obtained by Sir H. Davy and Frank, both of whom state that black tea is the most astringent. It is probable, therefore, that the amount of tannin in different teas is subject to variation.

"The substance called theine, or theina, is a crystalline salifiable base, discovered some years since by Oudry, and since found to be identical with caffeine, obtained from coffee. Its formula is $C_8\ H_5\ N_2\ O_2$. It exists in tea in combination with tannic acid. Hot water extracts the tannate of theina as well as free tannic acid; but by cooling, both of these substances almost entirely precipitate. According to Mulder, theina is not to be regarded as the principle which confers on tea its peculiar or characteristic properties. Its action on the system is not very obvious. He gave half a grain to a rabbit; the animal ate but little the next day, and aborted the day after. Liebig has suggested that it may contribute to the formation of bile. Without entering minutely into the medicinal action of caffeine (theine) he observes, it will surely appear a most striking fact, even if we were to deny its influence on the process of secretion, that this substance, with the addition of oxygen and the elements of water, can yield taurine, the nitrogenised compound peculiar to bile:—

1 atom Caffeine or Theine	=	$C_8\ N_2\ H_5\ O_2$
9 atoms Water	=	$H_9\ O_9$
9 atoms Oxygen	=	O_9
= 2 atoms Taurine	=	$2\ (C_4\ N\ H_7\ O_{10})$
		$C_8\ N_2\ H_{14} O_{20}$

The same authority adds that $2\frac{8}{10}$ths grains of caffeine (theine) can give to an ounce of bile the nitrogen it contains in the form of taurine. If an infusion of tea contain no more than the $\frac{1}{10}$th of a grain of caffeine (theine), still if it contribute in point of fact to the formation of bile, the action even of such a quantity cannot be looked upon as a nullity. Neither can it be denied, that in the case of an excess of non-azotised food, and a deficiency of motion, which is required to cause the change of matter in the tissues, and thus to yield the nitrogenised product which enters into the composition of bile, that in such a condition the health may be benefitted by the use of compounds which are capable of supplying the place of the nitrogenised product produced in the healthy state of the body, and essential to the production of an important element of respiration. In a chemical sense—and it is this alone which the preceding remarks are intended to show—caffeine or theine, asparagine, and theobromine, are, in virtue of their composition, better adapted to this purpose than all other nitrogenised vegetable products. The action of these substances, in ordinary circumstances, is not obvious; but it unquestionably exists. These views, though quite hypothetical, are highly ingenious and interesting.

"The peculiar flavour of tea depends on the volatile oil, which is lighter than water, and has a lemon-yellow colour, and the taste and smell of tea. Alone, it acts as a narcotic; but in combination with tannin, as a diuretic and diaphoretic. It is extracted from tea by hot water, in which, however, it is not always equally soluble, its solubility being modified by the other constituents.

"The following is the composition of the ashes of black tea:—

"Notwithstanding the extensive employment of tea in this country, it is no easy matter to ascertain its precise effects on the constitution. Its astringency, proved by its chemical properties, depends on the presence of tannin. Of this quality we may beneficially avail ourselves in some cases of poisoning: as by poisonous mushrooms, by opium or laudanum, or by any other vegetable substance containing a vegetable alkali, with which the tannin combines. Schwann found that tannin throws down a precipitate from the artificial digestive liquids, and renders this fluid inert. Does the copious use of strong tea, therefore, immediately after a meal, impede the process of digestion? The peculiar influence of tea, especially of the green variety, over the nervous system, depends on the volatile oil above referred to. This influence is analogous, in some respects, to that of foxglove; for both green tea and foxglove occasion watchfulness, and act as

sedatives on the heart and blood-vessels. These effects of tea are familiar to most persons. It is a common practice with those who desire nocturnal study to use tea; and, on the same principle, it may be employed as an anti-soporific to counteract the effects of opium and intoxicating liquors, and to relieve the stupor of fever. As a diluent and sedative, it is well adapted for febrile and inflammatory disorders, and most persons can bear testimony to its good effects in these cases. To its sedative influence, also, should be ascribed the relief of headache sometimes experienced by the use of strong tea. In colds, catarrhs, and slight rheumatic cases, warm tea is used as a diluent, diaphoretic, and diuretic. Strong green tea produces on some constitutions, usually those popularly known as nervous, very severe effects. It gives rise to tremor, anxiety, sleeplessness, and most distressing feelings. On others, however, none of these symptoms are manifest. Part of the ill effects sometimes ascribed to tea may be owing to the use of so much aqueous liquid—to the temperature of the liquid—to milk and sugar used with it—or to the action of the tannin on the digestive liquid. But, independently of these, tea possesses a specific and marked influence over the functions of the brain, not referable to any of the circumstances just alluded to. Weak tea rarely disagrees with the invalid, and is admissible in a variety of maladies, in most of which it proves refreshing and agreeable. It is well adapted for febrile and inflammatory complaints; and is particularly valuable when we are desirous of checking sleep. Moreover, if the suggestions of Liebig be correct, tea is by no means to be considered as a mere diluent, but as possessing nutritive powers of no mean kind."

TEAK-WOOD,—botanically *Tectona*. An evergreen, tropical timber-tree, of the verbena family. It is a native of many parts of India, and commonly attains a height of about 100 feet. It constitutes a genus of itself; and is specifically called *grandis* or the great. Its timber possesses vast economical value in India, and is generally used in ship-building, house-carpentry, and furniture-making. That of the Malabar coast is the most esteemed; and that of the Coromandel coast, near the banks of the Godavery, holds the second place. The plant was introduced to the botanical collections of Britain in the latter part of last century.

TEAL,—scientifically *Anas Crecca*. A British bird of the duck genus. It is an early and constant winter inhabitant of Britain, arriving in the latter part or about the end of September, and departing at a somewhat advanced period of spring. It is the smallest of our ducks, but a very prettily marked species, and one of the best as an article of food. The total length of the full-grown male is 14½ inches; the forehead and a narrow band on the top of the head have a rich chestnut brown colour; the part backward from the eye is marked with a patch of rich glossy green; the neck and the upper part of the back display a mixture of black and white in transverse lines; the breast and the belly are white; and the lower part of the front of the neck is partially marked with circular black spots.

TEAM. Two or more horses, oxen, or other beasts of draught drawing together the same agricultural implement or wheeled vehicle.

TEA-PLANT. See Tea.

TEASEL,—botanically *Dipsacus*. A genus of herbaceous calyciflorous plants, constituting the type of the natural order Dipsaceæ. This order is very nearly akin to the Compositæ, and possesses a very similar habit and general appearance. All its plants are herbaceous, and produce their flowers in heads. All are capable of very easy cultivation; some are eminent beauties of the flower-border; and a few possess economical or medicinal properties. About 120 species, belonging to 8 or 10 genera, occur in the wastes and gardens and botanical collections of Britain; and excepting about 10, which require the protection of the greenhouse, all are hardy.

The teasel genus comprises three indigenous species, four introduced species, and several known unintroduced exotic species. Its flowers are monopetalous, tubular, and four-cleft, and, together with the proper calyxes, stand on the summit of the single seed, which is terminated by an entire, cross-shaped crown; its involucrum or common calyx is many-leaved; and its receptacle is conical, and has long, rigid, entire chaff or paleæ. All the seven species in Britain are hardy biennials, propagable from seeds; they vary in height from 3 to 7 feet, and, for the most part, bloom in July; and four are purple-flowered, one blue-flowered, and two white-flowered.

The fuller's teasel, *Dipsacus fullonum*, occurs about the hedges of several parts of England, but is rare in its wild state, and has long been cultivated in the vicinity of some manufacturing towns, for its use in raising the nap of woollen cloths. Its root is fleshy, branched, and tapering; its stem is erect, strongly furrowed, prickly, leafy, branched at the top, and about six feet high; its leaves are sessile, entire, and beset with small scattered spines on their margins and surfaces,—and those of the stem are opposite and joined together at the base; and its flowers are very numerous, and have a whitish colour, with pale purple anthers, and grow in close, obtuse, conical heads, with the chaff or intermediate scales bristly at the edges, and rigid, spiny, and recurved at the points, and bloom in July. The scales are just strong enough to raise the wool of cloth, and give way before they can injure it; and they are used by being fixed round the circumference of a large broad wheel or cylinder, which revolves in contact with the cloth. Many mechanical inventions have been introduced to supersede them; but all have proved bad substitutes, and been found either inefficient or in-

jurious. From 1,500 to 2,000 heads of teasel are required for dressing one piece of cloth; and they are repeatedly used in different parts of the process.

The soil suitable for the field cultivation of fuller's teasel requires to be of rather strong texture or a rich superior loam, and to be in a state of very fine tilth and of thorough cleanness. A practice prevails in some places of raising teasel in a three years' course along with coriander and caraway; but this practice is seldom so good as that of raising the teasel alone. See the article Caraway. In March, land intended for teasel is brought into the highest possible state of tilth; about May-day, the seed is sown, either broad-cast or in drills, at the rate of from one to two pecks per acre; during the summer, the land is three or four different times worked over with long, narrow spades, to destroy all weeds; in November, the plants are adjusted by thinnings and fillings-up to distances of about a foot asunder; and if many more plants are taken up in the thinnings than are wanted in the fillings-up, they are transplanted on another piece of ground, previously prepared for their reception. The broad-cast method was formerly in general use; but the drill system is now found preferable, and possesses these two among other advantages, that it saves about one-fourth of the seed, and that it effects greater regularity in the original distances or saves much of the labour and cost of thinning and transplanting,—together with the incidental advantage, that plants which are never removed produce better heads than those which are transplanted. In the July of next year, the uppermost heads begin to bloom; and in the following month, they lose their blossom and become ripe. The gathering is performed at three successive periods, at intervals of about a fortnight, by means of a peculiarly constructed knife; and consists in cutting off the heads and tying them into handfuls. The cut heads require to be carefully kept from exposure to rain, and carefully and regularly dried; and either they are suspended in temporary sheds erected for the purpose in the field, or they are carried direct to the barn, and brought out and exposed to the sun on every clear dry day; and when they have become quite dried, they are separated into three kinds called kings, middlings, and scrubs, and made into packs of each 9,000 kings and 20,000 middlings,—the scrubs being of small value. An average or pretty good crop yields about 15 or 16 packs per acre; but a prime crop far exceeds this, and a very bad crop may be a total blank.

The wood or wild teasel, *Dipsacus sylvestris*, is very common about the moist hedges and road sides of some parts of Britain; and has been thought by some persons the normal or typal form, or remote origin, of the fuller's teasel. It is nearly or quite as tall as that species, but less robust. Its leaves are opposite and serrated; its flowers resemble those of the fuller's teasel, and bloom about the same period; its receptacle-scales are straight; and its common calyx is inflexed and longer than the head.

The small teasel, or pilose teasel, or shepherd's staff, *Dipsacus pilosus*, grows wild in moist shady places upon a calcareous soil. It is a useless but not troublesome weed; and it at the same time possesses sufficient beauty to deserve a place in the back-rows of the flower-border. Its stem is angular, leafy, branched, rough, with ascending hooked bristles, and 3 or 4 feet high; its branches are spreading; its leaves are stalked, ternate, ovate, pointed, strongly serrated, and of a deep green colour; its flowers grow in small globular heads, and have a white colour, and bloom in August; and its common calyx is deflexed and about the same length as the head.

TEATHING. Eating off turnips, upon young wheat crops, in the early parts of spring, by sheep or bullocks.

TEA-TREE. See Tea.

TECOMA. A genus of ornamental, ligneous, exotic plants, of the trumpet-flower order. It comprises one hardy deciduous climber, of commonly about 30 feet in height, three somewhat tender evergreen climbers of 8 or 12 feet in height, one greenhouse deciduous upright shrub of about 6 feet in height, and 8 hothouse evergreen upright shrubs of from 6 to 12 feet in height; and all these occur in British collections,—about one half were formerly included in the genus bignonia,—most have either yellow or orange-coloured flowers,—and the greater number love a soil of peaty loam, and are propagated from cuttings.

The rooting tecoma, or scarlet trumpet-flower, *T. radicans*, called by the old botanists *Bignonia radicans*, is the hardy climbing species, the best known one, and the most interesting. It is a native of Carolina, Virginia, and Canada; and was introduced to Britain in 1640; and has long been regarded by the most eminent British gardeners, and by landscape gardeners, as a plant of surpassing beauty. Its stem climbs to an amazing height upon advantageously situated edifices or trees, and strikes roots from the joints into whatever is near it; its leaves grow opposite by pairs at the joints, and are pinnate, and comprise each about four pairs of leaflets and a terminating odd one; its leaflets have a fine green colour, and are deeply cut in the edges, and drawn out into a long point; and its flowers come out in bunches at the ends of the branches, and are large and trumpet-shaped, and have a fine red colour, often approaching to orange, and bloom in July and August, and make a magnificent show.—A smaller variety, *T. r. minor*, differs from the normal plant, in the comparative smallness of the leaves and the flowers, and in the less tendency of the latter toward an orange colour, or in their having a purer and brighter red.—Both kinds may be raised, tediously, from seeds; or, more expeditiously, from cuttings of

the bottom part of the youngest shoots; or, best of all, from rootings of the shoots, laid upon the ground, and covered with a little mould.

TECTONA. See Teak-Wood.

TEDDING. See Haymaking.

TEEDIA. A small genus of ornamental, herbaceous, South-African plants, of the figwort family. Two species, the shining and the pubescent, both purple-flowered biennials of about two feet in height, the former blooming from April till July, and the latter from May till October, have been introduced to Britain; and they love a soil of peaty loam, and are propagated from cuttings.

TEESDALIA. A small genus of handsome, white-flowered, hardy, annual plants, of the cruciferous order. The naked stalked or irregular species, *T. nudicaulis*, grows wild in the pastures of some parts of Britain. Its root is slender and tapering; its stems rise in groups from one root, and are erect or spreading, and about 6 inches high,—the central one quite straight and always naked; its leaves are numerous, and spread on the ground, and are partly entire but chiefly pinnatifid; and its flowers grow in small corymbs, and have unequal petals, and naturally bloom from May till July.—The regular species, *T. regularis*, was introduced from the South of Europe in 1824; and is smaller than the preceding; and blooms from February till May.—Both species thrive in any common soil, and are very suitable for rock-work, and need only to be once sown, and will afterwards propagate themselves.

TEETH. The teeth of most of the higher orders of mammals—particularly those of man, of the quadrumana, of the carnivora, of the pachydermata, and of the hornless ruminantia—notwithstanding great and signal differences in the chief groups or genera, possess certain important common characters of both classification and composition,—or, in every case, comprise incisors, cuspidates, and molars, and consist of enamel, ivory, and osteous cement. They have different forms and arrangements and relative numbers in different genera, to suit to a nicety the special wants and feeding-habits of each animal; yet, in all instances, though more or less vigorously according to the saliency of their points and the refractoriness of the substances on which they operate, the incisors cut or nip, the cuspidates tear or lacerate, and the molars grind or bruise or pulverize. The three classes, as they exist in the horse, may be taken as a familiar specimen, and bear the popular names of nippers, tushes, and grinders, and have been described in our article Age of Animals. The enamel, the ivory, and the osteous cement, aggregately adapt the teeth to withstand the attrition of eating, the chemical action of substances incidentally lodged in the interstices, the action of the atmosphere, and the diversity of organic forces within the exposed and the unexposed parts of the teeth; and they are differently proportioned to one another, not only in the teeth of different species of animals, but in the different classes of the teeth of the same species, and in the different parts of the same tooth. The aggregate substance of the teeth enjoys incomparably more power of resisting both mechanical and chemical agency than the aggregate substance of common bone; the crown or exposed and working part of each tooth enjoys vastly more hardness and exterior strength than its root or unexposed and comparatively quiescent part; and the working surface of the crown, whether it consist of edge or points or laminæ, enjoys exactly the amount of superior hardness or intrinsic diversity which fits it for performing its mechanical functions in the best possible manner with the least possible wear.

The enamel is by far the densest and hardest of the three constituents of teeth; and will yield fire with steel like flint, and is not easily acted on by even the best tempered files. It never occurs alone, but always as a coating to the other constituents; and it serves so to temper the teeth, as steel tempers iron, that they may resist attrition, and continue unworn as long as the wants of the animal may require. In the incisors and cuspidates of the horse, it covers all the exposed portion; and in the grinders, instead of covering the surface generally, it forms distinct intertextured layers. It is supposed to consist of 78 per cent. of phosphate of lime, 6 of carbonate of lime, and 16 of gelatine; it has a crystalline compactness, but a minutely or very finely fibrous structure; it is secreted from the membrane of the pulp; and it does not contain any cartilage, and is capable of complete solution in diluted nitric acid.—The ivory is very considerably softer than the enamel, yet harder than common bone; and it differs from the latter principally in containing a greater proportion of phosphate of lime, and in some instances in containing fluorate of lime. It has a fibrous structure; and is secreted from the early pulp, and forms the rudimental and early portions of the teeth.—The osseous cement is softer than the ivory, and contains a large proportion of animal matter, and somewhat nearly resembles common bone. It is regarded by some naturalists as an ossification of the secreting membrane of the enamel; by others, as a specific secretion, like the enamel itself; and by others, as a correlative secretion with the enamel from one of two layers of a membranaceous capsule which surrounds the pulp of the ivory.

Two sets of teeth are given to man and the greater number of quadrupeds,—the one temporary, and commonly called shedding or milk teeth,—and the other permanent, and commonly called adult or full-grown teeth. The jaws grow much faster, and mature much earlier, in proportion, than the general system of the body; and therefore a temporary and comparatively small set of teeth is given them to suit their infant state,

and another and comparatively large set to suit their matured state. The interiors, the sockets, and the muscular adjuncts of the teeth are pervaded by ramifications of blood-vessels, nerves, and absorbents,—the first to form and maintain the secretions, the second to maintain sensation and vital energy, and the third to withdraw exhausted or useless matter from about the roots and the interior.

Caries or rotting of the substance of the teeth occurs more or less in all animals, but is peculiarly frequent and virulent in man, and very specially so in those members of the human family who think themselves most highly civilized. One cause of this disease in man is the want of a due degree of dental action, occasioned by the luxuriousness or soft forms of food; another is the rapid and mighty whirl of chemical forces acting on the teeth from the great diversity and rapid succession and piquant nature of the articles of diet; and a third and chief is the adherence to their teeth or their interstices of small particles of easily decomposable substances, such as flesh meat or animal sauces, or almost any of the mixtures of the most relished dishes. Decomposition of the particles is rapidly effected under the combined action of the heat and moisture of the mouth and the oxygen of the atmosphere; and an acid results which immediately attacks the phosphate of lime in the teeth, and after a series of times, so far accomplishes its decomposition as to set the teeth perceptibly a-decaying. A little hole is now made which henceforth constantly lets in the atmospheric air, the salivary secretions, and the decomposing particles of adhering food; and unless this hole is promptly stopped with some composition similar to what is used by dentists, a rapid decay of the entire tooth, on to its destruction, is inevitable.

One of the greatest enemies to human teeth is the concretion denominated tartar, which forms upon them like a crust, and would encase them wholly were there no impediment. Of the nature of this tartar and how it is formed a great deal has been written; but the whole that has been advanced and urged, sometimes very authoritatively and with great dogmatism, only goes to prove that the writers knew nothing of the matter. Of late, since the wonders of the world of animalcules, like a new creation, have occupied the attention of the learned,—since it has been shown that myriads of living creatures exist in a single drop of water,—since it has been conjectured by some hyper-hypothesists that the whole creation is made up of animalcules,—since mineralogy and general physics have entered the nursery, and Greek and Latin form a necessary part of a young lady's education, it has been the fashion to consider the tartar that is formed upon the teeth, as the work of animalcules,—as in fact nothing more than a mass of cells built by minute and invisible polypi, a sort of miniature coral reef, or wall of madrepore rock, like those raised by polypi in mid-ocean, and which serve as the foundation stones of islands. If this be true, whence come these diminutive creatures? —where and how are they bred, and what is their pedigree? All however that we really know on this head is, that the substance termed tartar does actually exist on the teeth, to which, if not removed, it is very injurious; and that the rapidity of its formation frequently depends upon the state of the stomach. In some idiosyncrasies, it is not formed at all; in others, only a little; in others, a great deal. Whenever it does appear, it should be removed; yet, even where there is an idiosyncratic tendency to its accumulation, it will not have time to form if the teeth were properly attended to,—a thing requiring more of the minuteness of attention than of actual trouble. If tartar be allowed to accumulate, which it almost always does in the permanent absence of tooth-brushes and tooth-powder, it not only gradually loosens and destroys the teeth, but corrodes the gums, and reduces them to a state of disease frequently mistaken for scurvy, even by medical men; and at length it occasions the total destruction of the teeth, and a sad unsightliness of the gums, with no other remedy left but to encase the latter in an artificial socket bearing a set of artificial teeth.

The diseases of the horse's teeth, as well as the proper treatment of them, differ considerably from those of man. Feverishness, loss of appetite, diarrhœa, and a number of other and widely dissimilar affections, either arising wholly from difficulty of dentition, or more or less severely aggravated by it, are so frequent in young horses, that, whenever any of them occurs, and is found on examination of the mouth to be accompanied with prominence and pushing of the tushes, a crucial incision ought to be made upon the gums. "In this way," says Mr. Percivall, "I have seen catarrhal and bronchial inflammations abated, coughs relieved, lymphatic and other glandular tumours about the head reduced, cutaneous eruptions got rid of, deranged bowels restored to order, appetite returned, and lost condition repaired."—The grinders of more advanced horses are apt to become roughened in the edges from irregular growth or from irregular wearing of the enamel, and may in this state give rise to bad ulcers in the mouth, and ought to be rasped smooth.—Part or whole of a back tooth or other grinder sometimes grows to a higher level than the rest of the teeth, and penetrates the bars above it, and causes serious ulceration, or interferes so constantly and ruinously with mastication as to occasion a general pining for want of due food; and whenever any such over-growth is detected, it ought to be reduced to the level of the other teeth by means of a saw.—A general irregularity in the surface of the grinders, though not marked by any very observable prominence in any one part, is sometimes so great as to occasion what is called quidding, and to constitute

great and almost incurable unsoundness. See the article QUIDDING.—Caries, though incomparably rarer in the horse than in man, yet sometimes occurs with such virulence as not only to destroy one tooth, but to communicate the rotting to neighbouring teeth and even to the jaw; and every carious tooth should be extracted,—not with the hammer and the punch, but with a keyed instrument similar to that used upon the human subject, but of a larger size.

TELEPHIUM. See ORPINE.

TELLURIUM. A rare metal, discovered toward the close of last century. It occurs in its proper metallic state chiefly in combination with silver and gold. It has a lamellated texture, a strong metallic lustre, and a tin-white colour merging toward lead-grey. It is very brittle, fuses at a heat below redness, volatilizes at a red heat, and has a density of 6·115. It ignites before the blow-pipe, burns with a greenish-blue flame, and disappears in grey, pungent, inodorous fumes. An oxide is formed during combustion, possessing the properties of a grey colour, fusibility at a red heat, and violent decomposableness before the blow-pipe. A soluble nitrate of the oxide results from the action of nitric acid upon the metal; and a volatile chloride, constituting a white crystalline solid at common temperatures, is formed by passing chlorine over moderately heated tellurium.

TELOPEA. A small genus of ornamental, exotic, ligneous plants, of the proteaceous order. The most showy species, *T. speciosissima*, was introduced to Britain in 1789 from Australia; and is one of the most lovely evergreen shrubs of the greenhouse or the conservatory. It has commonly a height of about 10 feet, and carries splendid scarlet-coloured flowers from May till July. Its habit of growth is firm and upright; and its general appearance, at all seasons, is handsome and imposing. It loves a soil of sandy peat, and is propagated from cuttings; but it is very liable to perish from too great cold in winter, or from excess or deficiency of water at any season, or from other causes which assail it in common with other proteaceous plants,—and, in consequence, it occurs in comparatively few collections, and is often found in a sickly state.

TEMPERATURE. The subtle principle or imponderable fluid whose degrees and fluctuations constitute temperature, is noticed in the article CALORIC; the instrument by which the scale, the intensities, and the changes of temperature are measured, is described in the article THERMOMETER; the part which temperature acts in the general phenomena of weather, is noticed in the article METEOROLOGY; the connexions which it sustains to the most conspicuous of particular meteorological phenomena, are pointed out in the articles EVAPORATION, CLOUD, FREEZING, HOAR-FROST, DEW, and RAIN; the offices which it performs upon the constituents of the air, and the relations which it bears to their various conditions, are mentioned in the article ATMOSPHERE; the control which it exercises over the aggregate adaptations of different zones and localities to the sustenance of organic existence, is discussed in the article CLIMATE; the part which it plays in the interior and vital economy of animals is described in the article ANIMAL HEAT; the offices which it serves in the exterior circumstances of animals, are mentioned in the articles FEEDING OF ANIMALS and SHELTER; the resistances which it makes to the healthy transmigration of any of the lower animals from their native region to a hotter or a colder one, are pointed out in the article ACCLIMATATION OF ANIMALS; the relations which it sustains to different latitudes of the globe and to different elevations above the level of the sea, and the determination which it exercises over the geographical distribution of plants, are treated in the article ALTITUDE; the offices which it performs upon plants, or the relations of stimulation, chemical action, growth, and resistance which it sustains to them, are noticed in the articles ORGANIC CHEMISTRY, AGRICULTURAL CHEMISTRY, GERMINATION, MANURE, SHELTER, BARK-BED, ACCLIMATATION OF PLANTS, and many others; the artificial raising and regulating of it in horticultural buildings, are discussed in the articles HOTHOUSE and GREENHOUSE; and the increasing and maintaining and modifying of it within the soil of fields, are pointed out in the articles DRAINING, FARM-YARD MANURE, and some others. Only three additional branches of the subject require to be discussed,—the general relations of temperature to the soil and to the meteorological conditions of the atmosphere,—the relations of the grasses to the temperature of different climates and of different years,—and the relations of exotic plants to the different temperatures of the soil and the air of gardens; and the second and the third of these are topics of great practical interest, to respectively the farmer and the gardener, and the first to all classes of persons whatever who are resident in the country; and we shall notice the second in the words of a writer in the 10th volume of the Quarterly Journal of Agriculture, and the third in those of a writer in the 13th volume of the Gardener's Magazine.

Humboldt, La Place, and many other modern philosophers, consider the fact of an internal heat in the earth as fully established, and they ascribe to it the origin and phenomena of volcanoes in connexion with metallic bodies, and with access of water to supply oxygen and hydrogen. At 8 feet deep, the annual temperature varies only from 5° to 7°; and at 4 feet, from 10° to 12°; while at one foot it ranges from 19° to 20°,—and in the open air it varies from 50° to 60°. At the depth of about 40 or 50 feet, the temperature of the earth is the same in winter and summer, apparently colder in summer, and warmer in winter; and the earth is believed to increase in heat, a degree in every 15 or 20 yards depth. In the

Catacombs at Paris, the thermometer through the year is between 52° and 54°, while on the surface it varies from 90° to 0° In Mexican mines it stands constantly at 74°. Depths of undisturbed air are like water. In a silver mine in Norway, 300 feet deep, the bottom is covered with snow; and so in other deep caves. While the air above snow is 70° below the freezing point, the surface of the ground below the snow is only 32°. It has been proved by experiment in latitude 56° 10′, by keeping thermometers fixed in the ground at various depths, that frost does not penetrate so deep in the earth as a foot; that at the depths of one, two, and three feet, the lowest temperature, during two years, was at one foot 33°, at 2 feet 36°, and at 3 feet 39°, while the highest was at one foot 35°, at 2 feet 52° 5′, and at 3 feet 52°. By other observations at one foot it varies 25° in the year, at 2 feet 20°, at 4 feet 15°, at 8 feet 9° 5′, and at 31 feet, 2° 7′; while at 40 or 50 there is no variation. In the deepest coal-mine in England, the mean annual temperature at 400 yards below the surface is 77°, and at 300 yards 70°; while at the surface it is but 48°, being about 1° of increase for every 15 yards. This explains the origin of hot springs, for at 3,300 yards the heat would be equal to boiling water, taking 20 to a degree. The heat of the Bath waters is 116°; hence they would appear to rise 1,320 yards. At great depths in the sea, as 4,000 feet, the difference is from 15° to 22° between the air and the water at that depth; and at 4,680 feet, the water is 26°, while the air is 48½°. By experiments made at the observatory of Paris, for ascertaining the increase of temperature from the surface of the earth towards the interior, 51 feet deep corresponds to the increase of 1°. Hence the temperature of boiling water would be at 8,212 feet under Paris. The mean annual temperature of the whole earth at the level of the sea is 50°. For different latitudes, it is as under, the third column showing the height in feet of constant freezing in those latitudes.

	Degrees.	Feet.
Equator	84·2	15,000
lat. 10	82·6	14,700
20	78·1	13,300
30	71·1	11,500
40	62·6	9,000
50	53·6	6,300
60	45	3,800
70	38·1	1,700
80	33·6	450

The mean heat at the equator is 84·2°, and at 45° it is 58·1°. Of 10,000 rays falling perpendicularly, 8,100 reach the earth,—7,000 at 50°, 2,800 at 7°, and 5 at 0°. Water seldom freezes till the meridian altitude of the sun is less than 40°. When the sun is in Aries and Libra, the relative heat of the equator, according to Humboldt, is taken at 1,000; at 20° is 940; at 40° is 750; and at 60° is 590. But when in Cancer or Capricorn, it is, for the same hemisphere, at 0°, 9,117; at 20°, 1,008; at 40° and 50°, 1,150; at 70°, 1,159; and at 80° and 90°, owing to sunshine for six months, 1,250.

The temperature in equal latitudes is from 4° to 8° less in the southern hemisphere; and this difference is supposed to arise from the extended surfaces of water, and from the sun passing through the southern signs 7¾ days less than the northern. The climate of the southern hemisphere is more equable than that of the northern. In May, at Cape Horn, latitude 56°, our November vegetation is flourishing. The sea is colder in the south, and ice extends 400 or 500 miles further from the south pole than from the north. There are currents from the poles towards the tropics, and then from east to west, in conjunction with the trade-winds. In latitude 75°, where the mean temperature is only 37°, only moss, lichen, dwarf willow, and sorrel grow. The earth, from the equator to the poles, resembles mountains in their kinds of vegetation from the base to the summit. Humboldt says the proportions in variety are, in the tropics 12; temperate zones, 1; and frigid, 0·1. The cold and heat of climates depend also on the vicinage of seas.—At Moscow the thermometer ranges from 6° to 70°, but at Copenhagen, in the same latitude, only from 27° to 65°; so at Vienna it ranges from 26° to 70°, but on the French coast, in the same latitude, only from 41° to 67°. In the Gulf of Guinea the thermometer rises to 130°; and Humboldt thinks that in the air it can never rise above 140°; at sea it never rises above 85° or 88°. The average heat at London in the first 16 years of this century was 50·93. The hottest day from 1774 to 1837 was in July, 1808, being 93·5; and the coldest, 25th December, 1796, 2° below zero. In 1830, the highest point of the thermometer was 90° in June, and the lowest 11° in January. The wettest month was 2·516 in July, and the driest 0·746 in February. In the past century, the severe frosts in England were in the winters of 1708, 1715, 1739, called the hard frost, 1742, 1754, 1776, 1788, 1796, and 1813. The highest temperature in the sun's rays at London is 154°; the highest of the air in the shade 90°; the mean temperature of the air 49½°, lowest 11°, and on the earth's surface 5°. In the counties round London, the mean temperature and rain in every month is as under:—

	Degrees.	Inches.
January	36·1	1·483
February	38·0	·746
March	43·9	1·44
April	49·9	1·786
May	54·0	1·853
June	58·7	1·83
July	61·0	2·516
August	61·6	1·453
September	57·8	2·193
October	48·9	2·073
November	42·9	2·4
December	39·3	2·426

The 14th January, on an average of years, is the coldest day in the year. The mean daily course

of temperature of the atmosphere is the same at all hours. According to a yearly mean, the coldest hour of the day, in Europe, is 5 o'clock in the morning, and the warmest hour of the day is from 2 to 3 in the afternoon. The rise is most considerable some hours after the minimum; the fall, some hours after the maximum. The heat increases for 9 to 10 hours, decreases for 14 to 15 hours. The greatest daily range of temperature in Europe takes place in July, and the least in December. The average temperature of the winter months in England is about 40°, and of the summer months 65°. Devonshire and Cornwall are about 4° warmer than London. The annual average of the thermometer at the north and south points of England, Carlisle and Sandwich, is 48° and 50°; the maximum in 1820 was 78° and 83°, and the minimum was 12° and 27°. The mean temperature of Ireland varies from 47° to 53°. At Kinfaun's Castle, in Scotland, latitude 56° 23′, the mean temperature for 1830 was 47·626; the rain 30·85 inches; the coldest day 10°; and hottest 79°; barometer from 30·53 to 28·73. In Leeds, Yorkshire, the thermometer was, July 18, 1825, at 92°; June 25, 1826, at 93°; and January 2, 1827, at 11°. The thermometer in Italy ranges between 75° and 96°; and in winter seldom descends below 40°, except in the mountains in the higher Apennines, where it falls to 20°. In New South Wales, the coldest month averages 54°, and the hottest 75°; it rains 100 days in the year; the north-west wind is a scorching sirocco; the air is generally dry, but the night dews are heavy. At the volcanic islands of the Gallipogos, half a degree north of the equator, the daily temperature is from 74° to 91°. The Red Sea is as hot as any part of the world; the thermometer ranges in 14 hours from 94° to 112°; from Babelmandel to Suez, the coast for 40 miles inland is a dry sand, without a blade of grass or drop of water. The cold at Tabreez in Persia, is so intense in February that persons are often frozen to death. The average heat of Boston is 47·3°; of Philadelphia, 53·7°; of Washington, 58·1°; of Detroit, 47·4°; of Cincinnati, 56·8°; of Pittsburgh, 54·2°; of New Harmony, 56·69°; of Charlestown, 57° to 60°; of Richmond, 56·1°. The temperature is so variable in South Carolina, that the thermometer sometimes varies 50° in 24 hours; it ranges no less than 83° in the year; the rain averages 50 inches. Sudden changes of temperature prevail in Africa; one is recorded of 27° in 24 hours. In Siberia and Hudson's Bay, mercury sometimes becomes solid, proving the cold to be 39° below zero; wine and spirits become a spongy mass of ice. At Bear Lake, Captain Franklin, on 7th February, found the thermometer at 58° below zero; and for two days it had been 57·5°. In the latitude of London, America is 13° colder than Europe; and in 40° latitude, is 8·6° colder than Europe. The mean temperature, according to Parry, for the 6 winter months, was at

	Latitude.	Temperature.
Winter Island	66° 30′	11° 7′
Igloolik	69° 20′	18° 3′
Melville Island	74° 45′	24°

No snow fell at Melville Island, and only 8 inches at Winter Island. An iceberg, seen by Parry, was above 250 feet out of the water, and therefore 1,800 feet thick. Spring is the most rapid in the Arctic regions. The snow disappears, and birds of passage re-appear; then, within a few days, the trees burst into foliage, the ground is covered with flowers, and mosquitoes are thawed in millions, while horseflies, sandflies, &c., render summer less comfortable than winter. Spiders, frogs, fish, &c., frozen and as brittle as ice, revive with the thaw.

In the temperate zone, the annual evaporation is 37 inches; but in the tropics from 90 to 100; and the mean quantity of rain is in the same proportion. In latitudes 46°, 47°, and 48°, the heat at sunset is the mean of the day. The mean quantity of water held in a cubic foot of air, in this climate, is 3·789 grains. All the moisture in the atmosphere is equal to a depth of 13 inches; and if all fell as rain it would cover the earth to the depth of 13 inches. The average fall of rain in the United Kingdom is about 34 inches; but in the western and hilly counties it is 48 or 50 inches. The average rain in London for 40 years, between 1777 and 1817, was 20·686 inches; at Paris in 15 years, was 18·649; at Glasgow in 17 years, was 21·033; at Manchester in 33 years, was 36·104; at Kendal in 1830, was 58·03. At Edmonton in 1831, the highest thermometer was 82°, and lowest 10°; barometer 80·5 and 28·9; rain 26·8; winds 232 days westerly, 8 north, 6 south. At Cheltenham, 1831, thermometer highest 77·5, lowest 25; barometer 30·26 to 28·52; rain 34·6; winds 166 days westerly, 36 north, and 55 south. Evaporation is everywhere as the surface of water, and as the temperature. There would be no interval between the solid and vaporous states but for the pressure of the atmosphere. All liquidity is, therefore, the effect of atmospheric reaction; and this is overcome when the force of the atomic motion of heat exceeds the compressive of 15 pounds to the square inch. It appears, therefore, to be the direct tendency of the motion called heat to disperse the atoms of a body; and vapour, steam, or gas is a conflict between the atoms of the body and those of the atmosphere. Hence it is that water fills the receiver of the air-pump with steam, and that it boils at such low temperature in elevations where the barometer falls considerably. Atmospheric air, at the freezing temperature, contains from a 200th to 160th of its weight of water, and double at every 22d or 27th degree. At 52°, it contains a 100th; at 74°, a 50th; and at 98°, a 25th. Hence, as cooled, it deposits the excess; and this is the dew of clear and calm nights. The earth is more heated by the solar rays than the air; and by night the

earth parts with more heat than the air, so as to become lower than the air. In light substances in contact with the earth, it is often from 15° to 20°. Hence 10 grains of wool, on a grass plot, in a night, gave 16 grains of dew,—9 on a gravel walk,—and 8 on mould. Hoar-frost is frozen dew. Grass is often but 30° when the air is 39°, and hence early freezing.

"The disputes," says the writer in the 10th volume of the Journal of Agriculture, "which have arisen regarding the merits of different cultivated grasses, have partly arisen from forgetting that a grass, valuable on account of its produce in one part of Britain, may, in another part, and consequently under a different climate, be found less profitable; and further, the power of becoming acclimated may be different in different species or varieties. 'The distribution of the cultivated grasses,' says Schouw, 'is determined not merely by climate, but depends on the civilization, industry, and traffic of the people, and often on historical events.' The truth of these remarks cannot be denied, but the first (climate, viz.) places impassable boundaries to the influence of the others. The same author remarks, 'The grains which extend furthest north in Europe, are barley and oats. These which, in the milder climates, are not used for bread, afford to the inhabitants of the northern parts of Norway and Sweden, and of a part of Siberia and Scotland, their chief vegetable nourishment.' In Norway, at Attengard, near N. lat. 70°, barley succeeds sometimes in the valleys, the snow line there is 3,600 feet; in N. lat. 65°, oats ripen. In Sweden, early barley reaches almost to the boundaries of the pine woods in N. lat. 69°, where the sun never sinks below the horizon from the latter part of May to the end of July. Oats, to the north of N. lat. 66°, very seldom ripen; the snow line here is 4,800 feet. 'In the course of the month of May,' remarks Dr. Richardson, 'ground was prepared at Cumberland House, and, toward the end of it, barley sown, to be reaped again in August, after an interval of about 90 days, whose mean temperature may be stated at 67°·8 Fahr. This place borders on the isothermal line of 32° F. According to Humboldt, barley, to be cultivated to advantage, requires, during 90 days, a temperature of from 47°·3 F. to 48°·2 F. Although the mean annual temperature of any place may be far below that at which seeds can germinate, still grain will come to maturity if the mean of the vegetating season reach a certain degree. Oats seldom ripen farther north than lat. 66°, the annual mean temperature being 33° F., that of the summer being 57°·8 F., while barley reaches to N. lat. 69°, where the annual mean is only 27° F., that of the summer being 54°·8. Professor Playfair proposed to date the vegetating season from 20th March to 20th October, and supposed that it is on the nature of that season that the quantity of the crop principally depends. He assumed 40° F. to be the lowest temperature at which corn will vegetate, and considered 56° F. as the mean temperature of a good vegetating season. The limit at which corn will not ripen he stated to be about 48° F. In the following table Professor Playfair's method has been adopted; and by the vegetating season is meant the period from 20th March to 20th October in each year. The fiars prices are assumed as fair criteria of the productiveness of the seasons, and are placed in comparison with the mean temperature of each year, the mean temperature of the vegetating season, and the total fall of rain. The fiars are those of Aberdeenshire as given in the Aberdeen almanack.

Years.	Mean of veg. season.	Annual mean temperature.	Excess of veg. season above 40°.	Rain in inches.	Oatmeal per boll.
					s. d.
1829	50°·94	46°·62	10°·94	28°·66	13 6
1830	51 ·24	46 ·81	11 ·24	30 ·60	16 8
1831	53 ·49	48 ·14	13 ·49	29 ·16	14 10
1832	51 ·98	47 ·83	11 ·98	21 ·07	12 0
1833	52 ·05	47 ·13	12 ·05	22 ·04	11 10
1834	53 ·22	49 ·18	13 ·22	12 ·28	14 6
1835	51 ·50	46 ·96	11 ·50	14 ·94	13 6
1836	50 ·92	46 ·14	10 ·92	24 ·69	18 0
1837	48 ·67	45 ·35	8 ·67	20 ·29	15 6
1838	48 ·58	44 ·25	8 ·58	34 ·40	21 6

Annual mean temperature at Aberdeen, from observations during the last sixteen years, = 47°·22.

"Professor Playfair says, 'Whether the quantity of the crop may be expected to be proportional to the excess of the mean temperature of the vegetating season, above 40° F., may deserve to be more accurately considered. There is every reason, however, to think that the variations of the crop, at least corn, will be greater than in proportion to the variations of temperature. By doubling the deficiency of the heat, we do a great deal more than double the deficiency of the crop, so that the latter varies in a higher ratio than the former. The limit at which corn will not ripen may perhaps be stated at 48°.' A writer in the Aberdeen Journal of January 18th, 1837, remarks, 'I have observed that if May, June, and July had an average of 54°·5 per diem, grain would fill and ripen notwithstanding an autumn as wet as that of 1829. In that year grain did ripen, while in the present year (1836) the average heat for the three months being 43°·29 F. only, the staple crops (barley and oats) in this district (Huntly) have ripened so imperfectly as in most cases to be unfit for seed, and deficient in weight compared with any crop since 1821.' In making such comparisons, it would be necessary to take into account the comparative temperatures of shorter periods of time. It is of importance to note the daily range of temperature, as this forms a prominent feature in the nature of the seasons. The study of the relation between climate and the productiveness of the different crops, is deserving of much attention. The difference between the nature of any two

seasons may be such as to be worthy of being considered equal to a difference of several degrees of latitude; hence the importance of selecting early or hardy kinds of grain, by which means the consequences of an unfavourable vegetating season may be much modified. The distribution of rain throughout the vegetating season constitutes also a very important feature of its character. Frequent rain, although not very copious, will be less favourable to vegetation than a greater quantity falling at longer intervals, provided it is not so overpowering as to cause lodging of the crops. Other circumstances might be mentioned as worthy of notice; the number of clear and of cloudy days, and the state of the atmosphere in respect to the vapour contained in it,—the lowness or highness of the dew point."

The maintaining of a preternatural temperature by artificial means, ranging from those of mere special tropical shelter to those of the highest requisite fire or steam heat, constitutes the grand difference between the art of gardening and the art of farming, and comprises all the kinds and varieties of what is technically called forcing, and deals more or less with all exotic plants which will not perform the offices required from them, of growing, or flowering, or fruiting, in the open ground of the climate or situation in which they are cultivated. "Now in what may be termed the higher department of forcing, there are, perhaps, fewer objectionable points than in the lower scale—where the plants are not kept in pots, and are consequently liable to great discrepancy between their terrestrial and atmospheric temperatures. Much has been written on the latter; and in practice it has been found best to approximate it as nearly as possible to that climate in which the given species of exotic plants naturally acquires the highest perfection. Beyond this, nothing need or can be advanced; but, with regard to what may be termed terrestrial temperature, something useful may be stated. The vine, for instance, as regards temperature, may be, and often is, so situated as to have its shoots in the climate of Syria, whilst at the same time its roots are in that of Britain. Such being the case, there need be less surprise at the ill success which occasionally accompanies its cultivation, than at the reputed inexplicable causes of bad setting, shriveling, and shanking of the grapes. The mean temperature of the soil, or that portion of the earth extending to several feet below its surface, is nearly the same as the mean temperature of the incumbent atmosphere. The soil of England, so far as the generality of roots penetrate, may therefore be estimated at about 50° Fahr. for the average. In Armenia and Syria (which may be reckoned the native region of the vine, for there, since the remotest accounts of history, it has felt itself at home,) the mean temperature of the soil will not be below 60°; and in the growing season its temperature will, doubtless, be above 70°, corresponding with the temperature of the atmosphere which is imitated in the vineries of Britain, but forming a great discrepancy with the temperature of the soil of this country. But, although this will be allowed to be bad, still the worst of the evil remains to be noticed. The above is only a medium case of general occurrence; and, although some may not be so widely different as 10° in the action of temperature on root and branch, yet there are, in all probability, a greater number of cases in which the difference is considerably increased, from various causes powerfully tending to lower the temperature of the border. In order to illustrate some of the causes which have this tendency, let us make an experiment wherein the agencies bear close analogy to what actually occurs. Let a box, water-tight, be nearly filled with loose mould or peat, or sand, or even the composition of a vine border; let this be tolerably dry, in order to increase its capacity for water cooled to the temperature of 50°; then saturated with snow water a little above the freezing point. This process, with the aid of a frosty night, will bring the contents of the box below 40°, and is supposed to take place in the winter or early part of spring. If the box be 3 feet deep, the sun's rays will not affect it far below the surface, since water is not easily heated from above; and, besides, the heat through the day will, at that season, be greatly counteracted by the cold at night. As the season advances, rain may be expected of a temperature above 60°; and this, under some circumstances, would produce a very considerable effect. Unfortunately, however, the box was made water-tight; and its contents, being completely saturated with nearly gelid water, cold, and heavy, and mechanically immovable by the descending warmer and lighter fluid, the latter must recede by the surface in quest of an unoccupied lower level, after producing only a slight effect on the surface of the contents of the box. The analogy between this and a badly drained outside vine border is so obvious that it need not be traced; similarity might, indeed, be substituted for analogy. Nor is it necessary to point out the injurious consequences that must accrue to the forcing vine. He that is not sufficiently impressed with this, has only to imagine his feet to be plunged in the one temperature, and his body in the other,—the bare idea of such will make him shudder. Let us now, with the same box, and similar materials, endeavour to produce a different result; commencing by piercing the bottom, and making a complete drainage; and, further, keeping the contents as dry as possible, and neither exposing them to the sleety shower, nor placing them exterior to the front of the vinery, where it would receive an overshot of snow from the slippery roof; but letting the surface be snugly covered, or thatched from all such drenching, till genial showers of the temperature of 60° or more begin

to fall. The latter may find it below 50°, but it is not likely to be much below. If it should be thus low, the water of the above warmth would percolate speedily from top to bottom, and communicate its heat during its progressive descent. The soil being dry, a portion of the water would be held by capillary attraction among the particles of the former in the first instance; superabundance to this would be carried off by the drainage at the bottom, making room for a fresh supply of water, imparting a farther elevation of temperature, till the whole became ultimately on a par with the rain, or very nearly so. This process might be greatly accelerated by stirring the surface, or inverting it, when well heated by the sun's rays, so as to turn up a fresh portion to their influence. A considerable heat might be worked in by this means, even to the depth of the upper roots of the plants, and farther than that penetrated by the rain; but, the presence of the latter being necessary in other respects, it becomes a useful and appropriate conveyer of heat to a greater depth among the roots than could be accomplished in the open ground otherwise than by its soft insinuation. It is hoped that these remarks will be the means of directing attention to the necessity of an approximation of terrestrial and atmospheric temperature as regards the cultivation of exotics, and particularly that of the vine; and also to the use of water as a medium by which an increase of terrestrial heat is speedily communicated, when the former is properly applied, that is, when it is of a higher temperature than the substances with which it is brought in contact; and to the negative injurious consequences which follow its application at a low temperature."

TEMPLETONIA. A small genus of ornamental, red-flowered, evergreen, Australian shrubs, of the genista division of the leguminous order. Two species, the retuse-leaved and the glaucous, both about two feet high, and blooming in spring and the early part of summer, have been introduced to the greenhouses of Britain; and they love a soil of sandy peat, and are propagated from cuttings.

TENACITY OF METALS. Brick and stone are from their brittle nature never thrown into a state of tension, or employed for supporting pendant loads; therefore their properties in this respect have not been estimated or examined; but the materials usually resorted to for this purpose, are bars of metal and chains, cylindrical or prismatic pieces of timber, ropes, and leather or raw hide; and the following tables show the power of those substances most commonly met with and used to support loads, the measure of their cohesion being the number of pounds avoirdupois, which are just sufficient to tear asunder a rod or bundle of one inch square. From this it will be easy to compute the strength corresponding to any other dimensions.

Metals.		lbs.
Gold, cast, varies between		20,000 to 24,000
Silver, cast,	do.	40,000 to 43,000
Copper, cast,	Japan	19,500
	Barbary	22,000
	Hungary	31,000
	Anglesea	34,000
	Sweden	37,000
Cast Iron varies between		42,000 to 59,000
Bar Iron	ordinary	68,000
	good	75,000
	best Swedish and Russian	84,000
Steel bar	soft	120,000
	tempered straw colour	150,000
Tin, cast,	Malacca	3,100
	Banca	3,600
	block	3,800
	English block	5,200
	Do. grain	6,500
Lead cast		860
Regulus of Antimony		1,000
Zinc		2,600
Bismuth		2,900

Unfortunately these numbers do not accord with those of Mr. Rennie, who observes, "that the metals were held by nippers made of wrought iron, with their ends adapted to receive the bars, which, by being tapered at both extremities, and increasing in diameter from the actual section, and the jaws of the nippers being confined by a hoof, confined both. The bars, which were 6 inches long and ¼ inch square, were thus fairly and firmly grasped." The following are a few of the experiments that were tried 30th of April, 1817.

	lbs. avoir.
¼ inch bar of Cast Iron, cast horizontally, broke with	1,166
" Cast Iron, cast vertically, "	1,218
" Cast Steel, previously tilted, "	8,391
" Blister Steel reduced by the hammer	8,322
" Shear Steel do. do.	7,977
" Swedish Iron do. do.	4,504
" English Iron do. do.	3,492
" Hard Gun Metal (mean of 2 trials)	2,273
" Wrought Copper reduced by hammer	2,112
" Cast Copper do. do.	1,192
" Fine Yellow Brass do. do.	1,123
" Cast Tin do. do.	296
" Cast Lead do. do.	114

As all these experiments were made on ¼ inch square bars, sixteen of which laid in close contact with each other, would constitute a square inch, it may be inferred that multiplying any of the numbers above given, would produce the amount of strain that would break a bar an inch square; but it is found in practice, that a number of small bars thus laid together, will bear a greater proportion of load than a single bar equal to the sum of all their areas. This anomaly is believed to proceed from the greater perfection with which small bars may be wrought and prepared than large ones, as all metals are improved in their strength by hammering or wire-drawing; so the effect of hammering sixteen small bars separately, will add more to their strength, than hammering on a large bar equal to the sum of their areas. Metals can only be improved in their strength by hammering or wire-drawing, in consequence of these operations

forcing their constituent particles into a closer state of aggregation; and this can easily be done in small bars, because from their want of reaction, they yield to every blow of the hammer, and its effect is transmitted through their whole substance; while the reaction of a large and heavy bar opposes this effect, and the condensation is more confined to the surface. A number of small bars acting simultaneously, are, therefore, found to produce more strength than one large bar equal in size to their sum. It likewise explains why a faggoted bar of iron should be stronger than one that has not undergone the operation.—*Millington.*

TENANT. A person who holds tenements or lands or both, during a limited period, on consideration of rendering stipulated services or paying a stipulated rent to the proprietor. See the articles Rent, Agreement, Lease, and Land (Property in). A tenant at will holds during the pleasure of the lesser; a tenant from year to year either holds during strictly one year, or holds during an undeterminate period on consideration of an annual rent; and a tenant for a fixed period of years holds during the time specified in express agreement or in lease.

TENANT RIGHT. The right of a tenant to all the productive results of any improvements which he makes upon his land, or to a fairly valued compensation for such of them as are unexhausted at the expiration of his term of occupancy. This right is to the full as obvious as that of lease-tenure, which we have contended for in the article Lease, and rests on substantially the same principles, and works out nearly the same effects; and were any such practices between landlord and tenant as those which we have advocated in that article to become universally approved and adopted, it would be so amply superseded as to find not an inch of scope for a separate existence; but, on the supposition that many landlords may still load all leases with oppressive conditions, that many others may pertinaciously maintain the system of very short lease-tenure or of absolute tenancy-at-will, and that neither class may be likely to adopt more correct views of what is due to themselves, to their tenants, and to the whole community, under any less gentle influence than that of an express and stringent act of parliament, the question of tenant-right gravely proposes itself as a fit and urgent subject of legislation. We do not see any need for our taking a side on this question; and we think we have said enough on all the grand principles of land-occupancy in the articles Land (Property in), Lease, and Rent; yet we shall present our readers with a brief abstract of the most telling part of a recent Prize Essay on the subject from the pen of Henry Corbet, secretary of the London Farmer's Club:—

"By the aid of frequent discussion at public meetings, and repeated notices from the press, many of the more intelligent farmers and active landlords will, no doubt, give the subject of tenant-right a place in their agreements; while, on the other hand, those who most require that impetus it carries with it would be left to keep on just as they so long have been. Tenant-right will never, or, at least, cannot for many years, come into general use from the efforts of such agency as this alone. Self-contented, unaspiring, stand-still tenants will pass it over again and again, precisely as they do now; and short-sighted owners, that, in the words of a noble lord who lately stood forward to represent them, 'would rather keep to their old tenants and old ways than put up with new at double the rent,' will 'pooh! pooh!' its progress, as they are doing at present. Look, for example, as to the gradual spreading of tenant-right, at the petition of the Lincolnshire landlords against the passing of any enactment for insuring it—unintentionally the best argument that was, perhaps, ever offered for making such an Act. Say the Lincolnshire landlords—'We have tenant-right already; we have long practised and profited to the full by its advantages. What then can be the use of enforcing by law what we do voluntarily?' Exactly so. The action of tenant-right has brought the bogs and fens of Lincoln from the worst to be the best cultivated land in the kingdom, and doubled and trebled its value to both landlord and tenant. This has been proved and known for many years, and has of course proceeded to this very natural consequence. Neighbours first, and their neighbours again, *ad infinitum*, have gradually adopted so excellent a plan, until at length the whole country has learnt the secret of the men of Lincoln, and brought its acres to vie in produce with those of that once favoured district. Is it so? and is any further inducement for following your example so entirely superfluous? Or rather does not the tenant-right part (only) of the county of Lincoln stand out at this moment like an oasis from the north, south, east, and west territory by which it is surrounded? This famous protest—and it will be worth while to proceed with it a little further—is framed in defiance of the first principle of legislation. Laws, be it remembered, are required not to compel the just, but to restrain the unjust,—in vulgar phrase, 'for rogues, not honest men.' Now a good and just landlord that does his duty voluntarily, and gives his tenant full recompense for all he may not have reaped, needs no enactment to induce him to this. Such a law could in no way affect him, for he does and has done all so provided for without it. The object is to make others follow his example, and ensure their doing that by law that many would hesitate, from ignorance, prejudice, or a worse motive, to do of their own free will. Thus, the answer to all who join in with the Lincolnshire landlords is plain enough: if, as you say, you have the tenant-right secured to you by the custom of your own district, our new Act will to you be as nothing, either good or bad; all we want is to extend that custom to others. So, to the argument of the tenant, who, happy in this custom, or with a full confidence in the honour of that high family who always have and always will, he is sure, do him justice, let us reply that our only desire is to see other landlords like his. In the strength of his own position such a measure may sound superfluous enough, but it may yet be much required elsewhere. We have, however, heard some go further than this, and in the gratitude of their hearts declare that the very fact of legalizing tenant-right would be the greatest insult that could be offered to the good landlord; because, as they say, it would convey a doubt as to his continuing to show that justice which had never been doubted before. In direct contradiction to this, we affirm it is the highest compliment you could pay him; it is the stamped approval of the course he has

pursued, drawing the eyes of all others upon him, and forcing them to imitate his well-doing. 'Imitation,' says the Spectator, 'is, after all, the sincerest flattery:' though here, we think, it pays homage of a more sterling character.

"But it may be demurred, before we proceed to frame new enactments entirely after this said example, it might be as well to see if there are any laws now professing to regulate the transactions between landlord and tenant. There are many; though, as far as any good or just consideration is concerned, they are almost all absolute nullities. To any one who could read over the Acts of this kind still remaining on the statute book, the necessity for some further addition to, or revision in them, would be strikingly apparent. As the state of society improves, as men gradually advance from comparative barbarism to civilization, it may be fairly assumed that corresponding alteration in those laws which affect their relative positions would accompany and facilitate such improvement. With agriculture, however, this has not been the case. Acts framed and passed when landlords were allowed the power of tyrants, and tenants were contented with the condition of slaves, are yet in existence, if not in actual use. So absurd and detrimental, indeed, would any application of them be, that landlord and tenant join together to prevent all possible reference to such relics of a by-gone age. The two unite, in the absence of any thing better, to make a law fit for the times they live in; and yet what is the consequence of this being done by individuals, instead of being provided for by government, and so brought into general practice? Why, such a substitute becomes, in effect, nearly as injurious to the real advance of agriculture as the old law in all its one-sided power of might would be. The agent whereby the new one is attained, and the old one avoided, is the long, elaborate, technical agreement, stipulating and providing for everything; and this said long elaborate agreement is declared by all practical men to be the greatest clog and impediment the tenant farmer can be burdened with. It confuses and frightens him, stays him from attempting anything not laid down exactly by rule and rote in it, and haunts him with provisions and penalties prepared by lawyers who know little of farming, to be acted upon by farmers who know as little of law. The agreement for the farmer should be made to suit the nature of the man, and be as plain, straight-forward, and as little verbose as possible. In fact, a long 'comprehensive' one, like a long rambling sentence, too often misses the point of that it aims at, and in striving to teach too much, finishes by defining little or nothing. To be truly useful and impartial, justice must speak the language of her people, and avoid in every way following in the steps of those senators of old who gave out their edicts rather to excite the awe than suit the understanding of those whose actions they were intended to influence. To extend, then, and establish that justice involved in the rights of tenants—to let all alike participate in their advantages—can be accomplished by legislative enactment alone. But then comes the difficulty of making this enactment practicable, or of carrying out the principle into general use. The ways of letting differ so in different counties, we are told—what is indispensable in agreement here, is never mentioned there; in a word, so many and curious are the customs, that, instead of one Act only to embrace all the country, you must draw out a different one for every different district. Now we maintain that the legal recognition of tenant-right can scarcely be made in terms too general. Let it be admitted on the understanding that it shall, in effect, embrace every part of the country; and let the Act be as simple and as short as possible. Let it contain a definition of the principle, 'a right of claim to compensation for unexhausted improvement,' and we shall be satisfied. Customs may vary, and times for going in and out not always the same; but still the main point may be made equally applicable everywhere. A man that has purchased and put on manures in Devonshire, ought surely to have his case as fairly considered and adjusted as if he had been living in Lincolnshire. A man who has drained or marled land in the south will do as much good to that land, and so should reap as certain a return, as if it had been in the north. The rate of labour perhaps, or the price of the material applied, may be higher or lower in one place than another; but this, after all, is nothing but what may be well met in the valuation. By valuation, then, would we make tenant-right feasible; by valuation would we accomplish for the agriculturist what has so long been done by the same means in every other kind of business, and than which nothing can be more straightforward or simple.

"The items which the tenant should be empowered to charge upon might be put under two heads,—as improvement which it is the proper business of the farmer to proceed with, and that which had better come direct from the landlord,—'Landlord's Improvements' and 'Tenant's Improvements.' The temporary and durable will be at once admitted as fit employment for the capital and labour of the latter, embodying as they do the great requisites for good and profitable farming; while the permanent—the building, road-making, fencing, and so on—should, we think, be done by the owner, or, at any rate, only undertaken by the holder on some special agreement. We have heard it advanced with much reason, that to give the merely temporary cultivator of the land a power of making and charging for any new buildings or fences he may choose to erect, would be imbuing him with too great, and the owner with too little, command over, and interest in the soil. Such a clause too, we fear, gets beyond that extreme simplicity with which we would have the measure carried out, and, indeed, can scarcely be brought within the accepted definition of tenant-right, viz., compensation for unexhausted improvement. Now the term unexhausted applies clearly to, in different degrees, both the temporary and the durable,—the means taken for 'amending the soil;' while the unexhausted good left at the end of a term in a barn or a stable is so entirely a different feature as to warrant, we should say, a different way of meeting it. In this view of the matter we are in a great measure supported by the opinion of the Tenant Right Committee of the London Farmers' Club, appointed to go through the different clauses of Mr. Pusey's bill, who, in their report, thus express themselves on this point:—'Do recommend that all items respecting buildings, roads, and fences, be left out of this bill, and that a clause be added, or a supplementary bill be prepared, to afford tenant-farmers those privileges in the removal of buildings erected by themselves, which manufacturers and tradesmen now enjoy—the landlord having, in the first place, the option of taking all, or any, by valuation.' This, in fact, is but further evidence of the tenant-farmer being still, as the law stands, regarded as little more than a serf, or, at least, a steward,—obtaining, may be, some reward for his care and industry, but with no recognised claim for what he may have spent, on his services being dispensed with. If a man erects a building for any possible purpose but that of agriculture, he may, on quitting, pull it down again and take it with him. The law allows it to be his: and if the landlord will not buy it, the tenant may sell the material to another, or carry it away for use elsewhere. While it provides for and protects one, the law oppresses his neighbour, by suffering a measure so out of all date yet to exist,—an enactment the action of which, if

ever through ignorance or carelessness permitted to come into force, can only be used to serve the ends of injustice. Once more we say, let the farmer be placed in the same condition, have the same acknowledged rights as other men who live by their labour —or, with the Tenant Right Committee. 'let him have those privileges, in the removal of buildings erected by himself, manufacturers and tradesmen now enjoy.'

"The natural advantage likely to accrue from the establishment of tenant-right becomes so thoroughly and prominently a part of the whole question, that a few words addressed to that particular point may not be out of place in concluding. The paramount duty of the government—the basis of the national prosperity—is the well-doing of the people; and that people at this very moment are suffering, more or less, from two great evils of over-population—a want of employment and a want of food. In direct antithesis to this, the producible land of the kingdom is cultivated as if there was actually scarcity of labour. The natural question that arises here is, how comes it that one evil is not made to destroy the other, by the application of the labour to the land? Simply because there is a hesitation as to embarking capital to bring them together; and yet, in the face of this hesitation, it is generally allowed that nothing will pay a better interest than money laid out in the improvement of the soil. The people want employment; the land wants more cultivation. The use of capital refused; and yet no use of capital known to pay better. Paradoxes explained and removed by the one simple remedy and right—security. Give but that, and you will make the island, as it should be, mainly dependant on its own resources for food, and its people for support. The national advantage must increase from such an increase of labour profitably employed, for money is really but the representative of labour so directed; and consequently the more labour profitably employed, the more wealthy must the country become. This is a remedy, moreover, that might be applied without sacrifice or expense to any one. The people would experience no revulsion to their ordinary habits, the government no embarrassment from the effects of it. It is only making general an act of justice that has proved strikingly advantageous wheresoever it has yet been administered."

TENCH,—scientifically *Cyprinus Tinca*. A British fresh-water fish, of the carp family of abdominal malacopterygians. It loves still waters, and chiefly frequents weedy and tangled places overshaded with rushes or brushwood; and it has prime qualities of flesh when found in rivers, but is far more abundant in pits, pools, and lakes. It begins to spawn in June, and continues to spawn in some situations till September; and is in its best season for the angler from the latter part of autumn till May. It lives long out of water; and may safely be removed in dry straw to a considerable distance. Its flesh is both wholesome and delicious food.—The tench seldom exceeds 4 or 5 pounds in weight. The body is proportionally thicker than long; the scales are very small and covered with slime; the eyes are large, and of a golden colour, and have red irides; the mouth is leathery, and sometimes has a small bark at each corner; the back and the dorsal and ventral fins have a dusky colour; the head, the sides, and the belly have a greenish hue, most beautifully mixed with golden tints; and the tail is quite even at the end and very broad.

TENDON. The white shining extremity of a muscle. The flexor tendon of the horse's leg is sometimes though rarely broken; and its ruptured ends should be stitched together and supported by a bandage.

TENDRILS. The organs by which climbing and twining plants attach themselves to shrubs, trees, poles, walls, or other objects for support. A tendril is generally a filiform and spiral process; and issues variously from stem, branch, petiole, or leaf; and is always much stronger than a shoot or twig of its own size. In most cases, in order to take secure hold, it simply twists itself into circumvolutions; but, in a few, it terminates in a flat, fleshy, adhering sole.

TENEMENT. A house, yard, or other fixed structural property held by a tenant.

TENORIA. A genus of ornamental, evergreen, exotic shrubs, of the umbelliferous order. Eight species, varying in height from 8 or 9 inches to 5 or 6 feet, all carrying herbaceous-coloured flowers, most blooming in the early part of autumn, and all propagable from cuttings, have been introduced to British gardens from Southern Africa and the shores of the Mediterranean. Two of the best known are noticed in the article Hare's-Ear.

TENESMUS. A continuous and vain effort of the horse or of any other animal to void dung. It arises from irritation in the rectum, and is generally cured by emollient or anodyne glysters.

TENURE. The kind of right or the set of legal circumstances by which fixed property is held either in perpetuity or during a limited period. See the articles Lease and Land (Property in).

TEPHRITIS. See Leaf-Miners.

TEPHROSIA. A genus of ornamental exotic plants, of the lotus division of the leguminous order. About 30 species have been introduced to British gardens, principally from India, America, and Southern Africa; and about 50 more are known. About one half of the introduced species, consisting principally of tender, evergreen undershrubs, with either purple, pink, or reddish flowers, are somewhat closely akin, in their botanical character, to the goat's-rue genus; and all these—as also all the others, most of which likewise are evergreen shrubs, but some of them taller—have pinnate leaves, with a terminating odd leaflet. Most love a soil of peaty loam, and are propagated from cuttings. The fish-poison species, *T. toxicaria*, an evergreen shrub of about 3 feet high, from South America, carrying pale red flowers in terminal panicled racemes, is cultivated in its native country.

TERAMNUS. A small genus of ornamental, tropical, red-flowered, twining plants, of the kidney-bean division of the leguminous order. Two species, the twining and the hooked, both about 10 feet high, and propagable from cuttings, have

been introduced to British collections from Jamaica.

TEREBINTHACEÆ. A natural order of ligneous, calyciflorous plants, represented by the turpentine-tree or *Pistacia terebinthus*. See the article PISTACHIA-TREE. This order is somewhat nearly allied to the Leguminosæ; yet has very indeterminate botanical characters, and consists wholly of trees and shrubs, with balsamiferous resin, alternate exstipulate leaves, and inconspicuous flowers. Their resin is very abundant, and resides chiefly in the bark and leaves, and is the principal character by which the limits of the order are determined. About 60 hothouse species, nearly 70 greenhouse species, and between 20 and 30 hardy species, occur in British collections; and they are distributed into 7 tribes or suborders, and into nearly 30 genera. The types of the tribes are plants of the genera anacardium, rhus, bursera, connarus, spondias, cneorum, and amyris. Many of the species, in spite of the inconspicuousness of their flowers, and for the sake chiefly of the beauty of their foliage, rank high as ornamental plants; a considerable number, such as the pistachia and the cachew, the mango and the spondias, are valuable for their fruits; many are serviceable, in ways widely different from one another, to medicine and the arts; and some, such as *Amyris toxifera*, and several species of sumach, possess very acrid and poisonous properties. The balsam of Mecca is obtained from *Balsamodendron gileadensis;* the balm of Acouchi, from *Icica heterophylla*; Venetian turpentine, from *Pistacia terebinthus*; various kinds of gum, from *Icica leptophylla*, *Amyris elemifera*, *Pistacia lentiscus*, and *Pistacia atlantica;* most fragrant incense, from *Boswellia serrata*, *Amyris balsamifera*, *Canarium commune*, and several species of *Icica;* excellent and valuable varnishes, from *Icica guianensis* and several species of *Rhus;* and medicinal preparations or economical substances of several kinds, from other species of *Rhus*.

TERMINALIA. A genus of ornamental, tropical, evergreen, greenish-flowered trees, of the combretum order. Nearly twenty species, chiefly about 20 feet in ordinary natural height, and all loving a soil of peaty loam, and propagable from cuttings, have been introduced to the hothouse botanical collections of Britain; and about a dozen more are known. One division of the genus has drupes compressed at the margins, and winged or much attenuated,—and another has dry or baccate drupes of ovate or sub-compressed form, with round and angulately sulcate putamen; and two species belonging respectively to the two divisions, and serving as a fair specimen of the whole genus, are described in the articles CATAPPAN and CHEBULA.

TERNSTRŒMIA. A genus of ornamental, tropical, thalamiflorous, ligneous plants, constituting the type of the natural order Ternstrœmiaceæ. This order is nearly allied to the camellias and the tea-plants, and exhibits a strict identity with them in general appearance, and consists wholly of trees and shrubs, with beautiful, white, yellowish, or reddish flowers. About a dozen hothouse species, 4 or 5 greenhouse species, and 6 or 7 hardy species, occur in British collections, and are distributed among 11 or 12 genera. Four species of the genus ternstrœmia, all evergreen shrubs of about 6 feet in height, blooming in the latter part of summer and early part of autumn, and propagable from cuttings, have been introduced to Britain from the West Indies and the tropical parts of South America; and nearly a dozen other species are known.

TERRIER. See DOG.

TESTICLES. The two glandular bodies which are contained in the scrotum of a male animal. In all species, they are formed in the abdomen; and in many, as in birds, they always remain there; but in others, as in the young colt, they remain during only a short time after birth, and then gradually descend to the scrotum,—and they carry with them thither a covering or investiture from the peritoneum, and are ever afterwards clothed with it. In man, whose erect posture would occasion a descent of intestinal matter through any opening, all communication between the abdomen and the scrotum is perfectly closed,—but in the horse and other quadrupeds, whose horizontal posture prevents all risk of such descent, a communication between the two cavities remains constantly open; and in man, an unusual quantity of fluid is sometimes secreted between the testicle and its investiture, constituting the disease called hydrocele,—while in the horse this seldom happens. The operation of cutting out the testicles of the lower animals is noticed in the article CASTRATION.

TETANUS, or LOCKED JAW. This is one of the most appalling maladies with which the veterinarian has to deal. It attacks all the three chief species of farm animals; but is of far the greatest consequence in the horse; and a brief notice of it in the case of that animal may sufficiently illustrate it in the case also of cattle and sheep.

Though a disease of the nervous system, its effects are more particularly visible in the muscles,—and most of all in the voluntary muscles,—which are all seized with a spasm or rigidity, so that the animal can move no part but with pain and difficulty, while some parts are altogether immoveable. The approach of the disease is generally slow. The animal commonly first shows some rigidity about the neck in turning his head to one side, which, in the course of a day or two, so much increases that he cannot turn his head at all without carrying his body round too. The refusal of his food leads to an examination of the jaws; and they also are found rigid, or greatly limited in their dilatation, so that the mouth can be opened only to a certain

extent, or even hardly at all. The eye becomes the next object of attention: every time any thing frightens or annoys him, the animal throws up his head, and at the same instant the haw is seen passing over the eye; and this forms a very striking character of the malady. The limbs, now, should they not have already become attacked, likewise grow stiff, either rendering progression awkward and unnatural, or else almost impeding it altogether. Indeed, in violent cases, the fore and hind legs are stretched out underneath the body like the four legs of a stool or form; the back and loins become shrugged up from rigidity; the tail is elevated and tremulous; the ears erect; the nostrils expanded; and the countenance displays a degree of eagerness and anxiety which, once seen, it is hardly possible to mistake. In short, the poor suffering animal exhibits altogether a truly impressive and pitiable aspect, too characteristic of the hopeless condition he is in, to admit of any possibility of doubt or dispute concerning the nature of his relentless disease. Locked jaw may arise of its own accord, or at least without any apparent cause; or it may be, and most commonly is, the consequence of some local injury. We have many examples of its having been induced by nicking, and docking, and punctured wounds, particularly into joints, or the feet; and the curious circumstance is, that the disease generally makes its appearance after the local wound is healed up, and we conclude all is well.—We are much in the dark concerning what mode of treatment ought to be adopted for this disease; though it would appear, that of all the declared remedies none deserves to stand so high as opium. It behoves him, however, who sets about to treat a locked jaw, to remember that it is a malady which has but very rarely yielded to remedy, and that opium, like every thing else, has too often failed to give the slightest apparent relief. In the first instance, it is advisable to draw blood, especially if the horse should happen to be in full condition; and also to administer, as early as possible, a dose of croton oil or two ounces of purging mass, whose operation may be promoted by injections. As soon as the bowels have become freely opened, or even before, should the case prove anywise urgent, begin with the opium; if possible, administer half an ounce in ball twice a-day; but, should the jaws not admit of this being accomplished, an equivalent quantity of laudanum should be exhibited. Blisters also may be applied, or setons inserted, along the course of the spine, and upon the head. Some veterinarians advise rubbing the jaws and throat with stimulating liniments; and Gibson recommends continual rubbing of the head, neck, and cheeks, or wherever the stiffness may appear, until the horse is relieved. He also observes, that locked jaw sometimes proceeds from the irritation of botts in the stomach; in which case he directs half an ounce of calomel to be given at one dose. When the disease appears to depend on a wound in the foot, either from a prick in shoeing or stepping on a nail, the part should be laid open with a drawing knife, and the actual cautery applied. As long as the horse is capable of swallowing, wheat-flour gruel should be frequently given.

TETHERING. The confining of a grazing animal to small and precise limits of pasturage by means of a rope or of a light chain, fastened to a long iron pin, which has a swivel ring and is driven into the ground. This practice is advantageous for a very few animals on lawns which are ornamented with shrubs, and on rich grass fields which have insufficient fences, or on plots of luxuriant grass adjacent to unprotected arable crops, as it obliges the animals to make clean work of the herbage, and at the same time prevents them from injuring the neighbouring vegetation; but it is unprofitable either for a large number of animals on rich pastures, or for even the smallest number on poor ones, as it would require a far too frequent and troublesome change of tether to comport with economy; yet it prevails throughout almost all France, even on common farms, and is somewhat abundant in some of the most impoverished districts of Great Britain and Ireland.

TETRACERA. A genus of ornamental, tropical plants, of the dillenia family. Three species, the drinking, the twining, and the alder-leaved, all evergreen twiners of upwards of 10 feet in height, loving a soil of peaty loam and propagable from cuttings, have been introduced to British hothouses from Africa and South America; and about 20 more are known.

TETRADYNAMIA. See Botany.

TETRAGONIA. A genus of exotic plants, of the order Ficoideæ. Two annual species, one biennial, one herbaceous evergreen, and six evergreen undershrubs, all green-flowered, and most between 10 and 25 inches high, have been introduced to the greenhouse collections of Britain from the Cape of Good Hope, New Zealand, and Peru; and several more are known. Only one species possesses any particular interest; and that is noticed in the article New Zealand Spinach.

TETRAGONOLOBUS. A genus of ornamental, hardy, trailing, exotic plants, of the lotus division of the leguminous order. Three annual species, with respectively yellow, purple, and dark purple flowers, and two perennial species, with yellow flowers, have been introduced to Britain; and one of the former, *T. purpureus*, called by Linnæus *Lotus tetragonolobus*, and popularly the purple-winged pea, a native of Sicily, is cultivated by the Sicilians as an economical plant.

TETRAMERIUM. A genus of ornamental, tropical, ligneous plants, of the madder family. Two species, the panicled and the sweetest-scented, both evergreen white-flowered shrubs of

5 or 6 feet in height, have been introduced to the hothouse collections of Britain, from Guiana and the West Indies; and two other species are known. The two introduced species are near akin to the coffee-tree; and they love a soil of loamy peat, and are propagated from cuttings.

TETRANDRIA. See Botany.

TETRANTHERA. A genus of ornamental, evergreen, ligneous, greenish-flowered, exotic plants, of the laurel order. Eight or nine species, varying in height from 6 to 25 feet, have been introduced to the greenhouse and hothouse collections of Britain from Australia, Mexico, China, and India; and some more are known. Most of the introduced species love a soil of peaty loam; and all are propagable from cuttings. The three-nerved and the rusty are two of the smallest, and need only greenhouse protection; and the glaucescent and Cervantes's are two of the tallest, and require the heat of the hothouse.

TETRAPELTIS. A recently discovered genus of ornamental tropical plants, of the vandea division of the orchidaceous order. The sweet-scented species, *T. fragrans*, is a white-flowered epiphyte, introduced 12 or 14 years ago to Britain from Nepaul. The name tetrapeltis signifies 'four-bucklered,' and alludes to the form of the pollen-masses.

TETRAPOGON. A curious, hardy, annual grass, of the chloris tribe. It constitutes a genus of itself, and is specifically called the villous. It is a native of Barbary, and was introduced to Britain about 30 years ago; and it has a height of about a foot, and blooms in July and August.

TETRAPTERIS. A genus of ornamental, tropical, ligneous plants, of the barbadoes cherry family. Two species, the box-leaved and the orange-leaved, both yellow-flowered, evergreen shrubs of about 6 feet in height, have been introduced to British gardens from Cayenne and the West Indies; and they love a soil of peaty loam, and are propagated from cuttings. Several other species are known.

TETRATHECA. A genus of handsome, Australian, evergreen, thalamiflorous undershrubs, constituting the main part of the small natural order Tremandreæ or Tremandraceæ. They have a peculiarly neat appearance, and exhibit considerable resemblance to heaths. Seven or eight species, principally about 12 or 15 inches in height, mostly with purple-coloured flowers, and all blooming in July and August, have been introduced to the greenhouses of Britain; and they love a soil of sandy peat, and are propagated from seeds. The hairy species, *T. hirsuta*, one of the most recently introduced, may serve as a sufficient specimen of the whole. It is a light, open, branching bush, characterised by neatness and simple elegance; and is all over hairy. Its leaves are alternate, small, oblong-ovate, and hairy, and give the branches a clothing of foliage; and its flowers are produced from the axils of the leaves, and stand on footstalks projecting at least an inch from among the foliage, and have each five nearly oval petals, spread out in a star-like form, and are at first of a bright pink colour, but afterwards assume a darker hue. It requires to be grown in a well-drained pot, and secured against damp in winter.

TEUCRIUM. See Germander.

THALIA. A small genus of ornamental, blue-flowered, exotic, herbaceous plants, of the Indian-shot family. The white species, *T. dealbata*, is a greenhouse aquatic of 4 or 5 feet in height, introduced to Britain about 58 years ago from Carolina, and blooming in July and August; and the jointed species, *T. geniculata*, is a hothouse, terrestrial, herbaceous evergreen of about 2 or 3 feet in height, introduced about 25 years ago from the West Indies, and blooming in August and September.

THALICTRUM. See Meadow Rue.

THAPSIA. See Deadly Carrot.

THATCH. The culms of cereal grass or the slender stems or fronds of other plants laid on the top of ricks, buildings, and other structures to protect them from wet. The thatching of ricks, both small and great, is noticed in the article Stack. The thatching of houses, sheds, and other edifices may be done in any one of various ways, and with any one of widely different materials, to suit convenience, appearance, durability, and other circumstances. Fern thatch, if obtained between the middle of September and the middle of October, and properly prepared and skilfully laid on, will last in a sunny exposure during 18 or 20 years, and will seldom cost more than about one shilling per square yard. Heath of a slender and pliant nature, obtained from an open situation, properly prepared, and laid on in horizontal layers or from end to end of the roof, and, in an elevated and airy place, or in any one which is free from undue closeness and humidity of atmosphere, will last between 20 and 30 years. Reeds form a very valuable and long-enduring thatch, and are sometimes cheaper in the end than any other material; but they cost comparatively very high at first, and are also thought by some persons to be too stubborn for common purposes. The thrashed straw of wheat, with the ears on it, is the thatch most generally in use throughout the plains and valleys of Britain; and, when well laid, forms at once a very neat, a quite secure, and a sufficiently or tolerably durable covering for most structures to which it is applied. Unthrashed wheat straw, without the ears, and provincially called reed, is the favourite thatch in the counties of Devon, Dorset, and Somerset, and possesses eminent advantages above thrashed straw, which ought to recommend it into use in all parts of the kingdom. It lasts nearly as long again as common straw, and does not offer the temptation arising from the grains of imperfectly thrashed corn, which induces mice and birds to infest the building, and to make holes in the thatch. The mode of

preparing it is simply to take a sheaf of wheat, and to place it in a press, made of two pieces of timber 10 feet long, and put on a stool, and to have women to lay hold of the ears and draw them out and cut them off, and then to bind up the sheaf for thatch. A covering with this straw is not only neat but elegant, while one with the thrashed straw is ragged and slovenly; and it has, in many instances, been preferred to all other coverings for cottages ornées in consequence of its picturesque effect. Rye straw is also neater, more durable, and less liable to be filled with water than common thrashed wheat-straw, in consequence of its having a solid stem. The art of fixing thatch on houses is similar to that of fixing it on ricks, but is much nicer and more elaborate, and requires thicker layers, stronger fastenings, and split willows or some similar materials instead of straw-ropes, and is properly the work of a separate class of artificers, who qualify for it by a regular apprenticeship.

THEA. See Tea.

THEAVE. An ewe of the first year.

THEEZAN TEA. See Buckthorn.

THELYGONUM. See Dog's Cabbage.

THELYMITRA. A genus of curious, tuberous-rooted, herbaceous, Australian plants, of the orchis order. Eight or nine species, principally blue-flowered, and all about a foot high, blooming from April till June, loving a soil of loamy peat, and propagable by division of the root, have been introduced to the greenhouses of Britain. See the article Orchis.

THEOBROMA. See Cacao.

THEOPHRASTA. A small genus of ornamental, exotic, ligneous plants, of the dog's-bane family. Jussieu's species, *T. Jussiœi*, is a white-flowered, evergreen shrub, of about 3 feet in height, introduced 30 years ago to the greenhouses of Britain from Central America. It requires a soil of rich mould, and is propagated from seeds.

THERMOMETER. An instrument for measuring heat, founded on the principle that the expansions of matter are proportional to the augmentations of temperature. With regard to aeriform bodies, this principle is probably well founded; and hence our common thermometers may be rendered just by reducing their indications to those of an air thermometer. Solids, and still more liquids, expand unequally, by equal increments of heat, or intervals of temperature. With regard to water, alcohol and oils, this inequality is so considerable as to occasion their rejection for purposes of exact thermometry. But mercury approaches more to solids than ordinary liquids in its rate of expansion, and hence, as well as from its remaining liquid through a long range of temperature, is justly preferred to the above substances for thermometric purposes. A common thermometer, therefore, is merely a vessel in which very minute expansions of mercury may be rendered perceptible, and, by certain rules of graduation, be compared with expansions made on the same liquid by other observers. The first condition is fulfilled by connecting a narrow glass tube with a bulb of considerable capacity filled with mercury. As this fluid metal expands one sixty-third by being heated in glass vessels, from the melting point of ice to the boiling point of water, if ten inches of the tube have a capacity equal to one sixty-third of that of the bulb, it is evident that, should the liquid stand at the beginning of the tube at 32°, it will rise up and occupy ten inches of it at 212°. Hence, if the tube be uniform in its calibre, and the above space be divided into equal parts by an attached scale, then we shall have a centigrade or Fahrenheit's thermometer, according as the divisions are 100 or 180 in number. Such are the general principles of the construction of thermometers.

The tubes drawn at glass-houses, for making thermometers, are all more or less irregular in the bore. Hence, if equal apparent expansions of the included mercury be taken to represent equal thermometric intervals, these equal expansions will occupy unequal spaces in an irregular tube. The attached scale should, therefore, correspond exactly to these tubular inequalities; or, if the scale be uniform in its divisions, we must be certain that the tube is absolutely uniform in its calibre. The first step in the formation of this instrument, therefore, is to graduate the tube into spaces of equal capacity. A small caoutchouc bag, with a stop-cock and nozzle, capable of admitting the end of the glass tube when it is wrapped round with a few folds of tissue paper, must be provided, as also pure mercury, and a sensible balance. Having expelled a little air from the bag, we dip the end of the attached glass tube into the mercury, and by the elastic expansion of the caoutchouc, we cause a small portion of the liquid to rise into the bore. We then shut the stop-cock, place the tube in a horizontal direction, and remove it from the bag. The column of mercury should not exceed half an inch in length. By gently inclining the tube, and tapping it with the finger, we bring the mercury to about a couple of inches from the end where we mean to make the bulb, and, with a file or diamond, mark there the initial line of the scale. The slip of ivory, brass, or paper, destined to receive the graduations, being laid on a table, we apply the tube to it so that the bottom of the column of mercury coincides with its lower edge. With a fine point, we then mark on the scale the other extremity of the mercurial column. Inclining the tube gently, and tapping it, we cause the liquid to flow along till its lower end is placed where the upper previously stood. We apply the tube to the scale, taking care to make its initial line correspond to the edge as before. A new point for measuring equal capacity is now obtained. We thus pro-

ceed till the requisite length be graduated, and we then weigh the mercury with minute precision. The bulb is next formed at the enameller's blow-pipe, in the usual way. One of a cylindrical or conical shape is preferable to a sphere, both for strength and sensibility. We now ascertain and note down its weight. A tubular coil of paper is to be tied to the mouth of the tube, rising in a funnel-form an inch or two above it. Into this we pour recently boiled mercury, and, applying the gentle heat of a lamp to the bulb, we expel a portion of the air. On allowing the bulb to cool, a portion of the mercury will descend into it, corresponding to the quantity of air previously expelled. The bulb is now to be heated over the lamp till the included mercury boil briskly for some time. On removing it, the quicksilver will descend from the paper funnel, and completely fill the bulb and stem. Should any portion of air appear, the process of heating or boiling must be repeated, with the precaution of keeping a column of superincumbent mercury in the paper funnel. When the temperature of the bulb has sunk to nearly that of boiling water, it may be immersed in ice-water. The funnel and its mercury are then to be removed, and the bulb is to be plunged into boiling water. About one sixty-third of the mercury will now be expelled. On cooling the instrument again in melting ice, the zero point of the centigrade scale, corresponding to 32° of Fahrenheit, will be indicated by the top of the mercurial column. This point must be noted with a scratch on the glass, or else by a mark on the prepared scale. We then weigh the whole. We have now sufficient data for completing the graduation of the instrument from one fixed point; and, in hot climates, and other situations, where ice, for example, cannot be conveniently procured, this facility of forming an exact thermometer is important. We know the weight of the whole included mercury, and that of each *gradus* of the stem. And, as from 32° to 212° Fahr., or from 0° to 100° cent., corresponds to a mercurial expansion in glass of one sixty-third, we can easily compute how many of our graduating spaces are contained in the range of temperature between freezing and boiling water. Thus supposing the mercurial contents to be 378 grains, one sixty-third of that quantity, or six grains, correspond to 180 of Fahrenheit's degrees. Now, if the initial measuring column were 0·6 of a grain, then ten of these spaces would comprehend the range between freezing and boiling water. Hence, if we know the boiling point, we can set off the freezing point; or, from the temperature of the living body, 98° Fahr., we can set off both the freezing and boiling points of water. In the present case, we must divide each space on our prepared scale into eighteen equal parts, which would constitute degrees of Fahrenheit; or into ten equal parts, which would constitute centigrade degrees; or into eight, which would form Réaumur's degrees. When we have ice and boiling water at hand, however, we may dispense with the weighing processes. By plunging the instrument into melting ice, and then into boiling water, we find how many of our initial spaces on the stem correspond to that interval of temperature, and we subdivide them accordingly. If the tube be very unequal, we must accommodate even our subdivisions to its irregularities, for which purpose the eye is a sufficient guide.

Thermometers are used for two different purposes, each of which requires peculiar adaptation. Those employed in meteorology, or for indicating atmospherical temperature, are wholly plunged in the fluid; and hence the stem and the bulb are equally affected by the calorific energy. But when the chemist wishes to ascertain the temperature of corrosive liquids, or bland liquids highly heated, he can immerse merely the bulb and the naked part of the stem under the scale. The portion of the tube corresponding to the scale is not influenced by the heat, as in the former case; and hence one sixty-third part of the mercury, which, at 32° Fahr., was acted on, has, at 212°, escaped from its influence. Hence a meteorological and a chemical thermometer ought to be graduated under the peculiar conditions in which they are afterwards to be used. The former should have its stem surrounded with the steam of boiling water, while its bulb is immersed an inch or two beneath the surface of that liquid, the barometer having at the time an altitude of thirty inches. A thermometer for chemical experiment should have its boiling point determined by immersion only of the bulb, and the naked portion of its stem below the scale, in boiling water. The water, of course, must be pure; and it ought to be contained in a metallic vessel. Before sealing up the end of the tube, we should draw it into a capillary point, and heat the bulb till the mercury occupy the whole of the stem. A touch of the blow-pipe flame on the capillary glass will instantly close it, and exclude the air from re-entering when the bulb becomes cool. If this has been skilfully executed, the column of mercury will move rapidly from one end of the tube to the other when it is inverted with a jerk. An ivory scale is the handsomest, but the most expensive. Those used in Paris consist of a narrow slip of paper enclosed in a glass tube, which is attached in a parallel direction to the thermometer stem. It is soldered to it above by the lamp, and hooked to it below by a ring of glass.

Comparative Scales of Thermometers.—A fertile cause of error in estimating and comparing the statements of temperature, is the very different manner in which they are made by scientific men of different nations. Wherever the English language prevails, the graduation of Fahrenheit is generally preferred. By the German authors Réaumur is used; and the French have, within

a few years, decided to adopt that of Celsius, a Swedish philosopher, calling it *thermomètre centigrade*. The Russians still use the graduation of De Lisle. The two remarkable temperatures of the boiling and the freezing of water are thus expressed by the several thermometers mentioned:

	Fahr.	Centig.	Réaum.	De Lisle.
Boiling point, .	212°	100°	80°	0°
Freezing point, .	32	0	0	150

So that the number of degrees of each, included between these two points in each, is 180° Fahr., 100° centig., 80° Réaum., 150° De Lisle; and of course 9° Fahr. = 5° centig. = 4° Réaum. = $7\frac{1}{2}$° De Lisle. Fahrenheit's is, therefore, the smallest degree, and Réaumur's the largest. The 0° is called the *zero:* all degrees below this are called *minus*, and are prefixed by a dash, thus –20°. In the Réaumur and centigrade scales, the degrees above zero are also called *plus*, and marked thus, +20°, to prevent one kind being mistaken for another.

Rules for changing the degrees of any one of the scales into equivalent degrees of another:

Fahrenheit into Réaumur.—Each degree of Fahrenheit is equal to four-ninths of one of Réaumur. As Réaumur, however, reckons his degrees from the freezing point, and Fahrenheit 32° below this point, we must, when the number of Fahrenheit's degrees to be reduced indicates a temperature above the freezing point, first deduct thirty-two, and then multiply the remainder by four, and divide the product by nine. The quotient is the corresponding number of degrees on Réaumur's scale. If the temperature indicated was less than the freezing point, we must also be careful to take the actual number of degrees, reckoning from the freezing point. Thus four degrees above Fahrenheit's zero is twenty eight below his freezing point; and this is the number to be reduced to Réaumur's scale.

Réaumur into Fahrenheit.—Each degree of Réaumur is equal to $2\frac{1}{9}$ of one of Fahrenheit. Multiply the given number of degrees of Réaumur by nine, and divide the product by four. If the degrees of Réaumur were minus, the quotient must be deducted from thirty-two, and the remainder will be the equivalent degrees of Fahrenheit. If the given degrees were not minus, the quotient must be added to thirty-two degrees, and the sum will be the equivalent sought.

Fahrenheit into Centigrade.—Each degree of Fahrenheit is equal to five ninths of one of the centigrade. Proceed as in the case of Fahrenheit into Réaumur, multiplying, however, by five and dividing by nine.

Centigrade into Fahrenheit.—Proceed as in Réaumur into Fahrenheit, multiplying by nine and dividing by five.

Réaumur into Centigrade.—Each degree of Réaumur is equal to $1\frac{1}{4}$ of the centigrade. Multiply the given number of degrees of Réaumur by five, and divide the product by four; the quotient will be the equivalent number of degrees on the centigrade scale.

Centigrade into Réaumur.—Each degree of the centigrade is equal to $\frac{4}{5}$ of Réaumur. Multiply the given number of degrees of the centigrade by four, and divide the product by five; the quotient will be the equivalent number of degrees on Réaumur's scale. Extensive tables of the correspondence of these thermometrical scales, and of some of the most remarkable temperatures, may be found in the *Treatise on the Thermometer and Pyrometer*, in the Library of Useful Knowledge.

THERMOPSIS. A genus of ornamental, hardy, yellow-flowered, perennial-rooted herbs, of the sophora division of the leguminous order. Four species, of from 12 to 25 inches high, blooming in June and July, loving a rich soil, and propagable by radical division, have been introduced to Britain from the temperate regions of Asia and America. The name thermopsis signifies "lupine-like," and is descriptive.

THESIUM. See Bastard Toadflax.

THESPESIA. A small genus of ornamental, tropical, evergreen trees, of the mallow tribe. The poplar-leaved species, *Thespesia populuca*, called by Linnæus *Hibiscus populneus*, is a native of India, and was introduced about 80 years ago to the botanical collections of Britain. It has naturally a height of about 30 or 35 feet; and it loves a soil of peaty loam, and may be propagated from cuttings. Its flowers are white; its timber is used by the Hindoos for making wheels, bandy-bodies, and similar articles; its bark is employed in powder as a medicinal alterative, and in strong decoction as a wash for certain cutaneous affections; and the juice of the fruit is employed in the same way as the decoction of the bark.—The great-flowered species, *Thespesia grandiflora*, was introduced to Britain from Porto Rico in 1827; and has scarlet flowers, and is naturally of similar height to the poplar-leaved species.—The name thespesia signifies 'divine,' and was suggested by the practice of planting the trees around the churches of their native regions.

THICKET. A dense growth of trees or shrubs, such as cannot be easily penetrated by men or cattle.

THICK-WIND. A chronically morbid state of the lungs of a horse, resulting from certain varieties and terminating influences of pneumonia. It consists in the conversion of part of the lungs into a substance similar to the liver, and involves a constant abridgment of the proper function of the lungs, and occasions continual shortness and difficulty of breathing, and is indicated by comparative shortness and violence of both inspiration and expiration, and by the emission of a peculiar sound which, when once heard, is ever afterwards easily recognised. An experienced veterinary surgeon, by means of auscultation, can estimate pretty closely the degree of it, and tell in how far it will diminish the horse's working power, or permanently diminish his value; but he cannot do any thing of a surgical or of an actively medicinal nature either to cure or to palliate it. The best treatment for preventing disastrous consequences from the disease, and at the same time for gradually and most effectually lessening it, is to feed the animal on such nutritious food that a comparatively small bulk of it will satisfy him,—to allow him ample rest after every meal, before beginning

to work him,—and to train him carefully and regularly up to the full stretch of his breathing powers, but not a jot beyond them, either in daily work or in daily exercise, so that he may acquire an increase of them by the force of habit. —The constitutional breathing action which the heavy draught horse has of a distinct and contrasted nature from that of the racer or the hunter is sometimes, but improperly, called thick-wind. See the articles HORSE, BROKEN-WIND, and PNEUMONIA.

THILL-HORSE, or THILLER. The last horse of a team yoked in line,—the horse that goes between the thills or shafts.

THINNING. See PLANTATION.

THISTLE. A large group of composite-flowered, herbaceous plants, comprising many of the most common and troublesome weeds of agriculture. The strictly proper thistles constitute the genus Carduus, and form the type of the suborder Carduaceæ. This suborder is very extensive, and comprises four divisions or tribes,—first, the true Carduaceæ, containing native and imported plants of at least 30 genera,—next, the Vernoniaceæ, containing plants of about 20 genera,—next, the Gnaphalieæ, containing plants of about 15 genera,—and next, the Echinopsideæ, containing plants of about 13 or 14 genera. A large proportion of the true Carduaceæ either are popularly called thistles or may very readily be mistaken for them,—particularly all the species of the old genus Cnicus, and of the modern genera Carduus and Cirsium, and many or all of the species belonging to the genera described in our articles THISTLE (PLUME), CARLINE THISTLE, COTTON-THISTLE, LEUZEA, SAW-WORT, RHAPONTICA, SILYBUM, and CENTAUREA. Some plants also are popularly called thistles which do not belong to any division of the Carduaceous suborder,—particularly those of the cichoraceous genus noticed in our article SOW-THISTLE.

The strictly true thistle genus, Carduus, comprises at present 3 indigenous species, about 40 introduced exotic species, and about 60 unintroduced known exotic species; and it formerly comprised some other species, both indigenous and exotic, which are now assigned to the genera cirsium, serratula, and silybum. A few of the species in Britain have sessile or petiolated leaves, but the vast majority have decurrent leaves; some have an aggregate inflorescence, but a greater number have a subsolitary inflorescence; two or three have red or white flowers, and all the rest have purple flowers; a few have a height of only from 6 to 20 inches, and a few are so high as 5 or 6 feet, but most have a height of from 2 to 4 feet; about a dozen are annuals, and the rest are, in pretty equal proportions, biennials and perennials. The musk or nodding species, *Carduus nutans*, is an annual indigen of the grass lands of Britain, about 2 feet high, with decurrent leaves and purple subsolitary flowers, blooming in July and August. The acanthus-like species, *Carduus acanthoides*, is an annual indigen of the waste grounds of Britain, about 2 feet high, with decurrent leaves and purple subsolitary flowers, blooming from June till August. The slender-flowered species, *Carduus tenuiflorus*, is an annual indigen of the hedge-banks and similar situations of Britain, about 2 feet high, with decurrent leaves and purple aggregate flowers, blooming from June till August.

The principal annual plants of the popular thistle group which infest the farm-lands of Britain are the three true thistles which we have just noticed, the common or potherb sow thistle, *Sonchus oleraceus*, and the centaury star-thistle, *Centaurea calcitrapa;* the principal biennial ones are the welted, curled, or Virgin Mary's thistle, *Silybum marianum*, the common carline-thistle, *Carlina vulgaris*, the marsh plume-thistle, *Cirsium palustre*, the bull-thistle, spear-thistle, or common plume-thistle, *Cirsium lanceolatum*, and the common cotton thistle, *Onopordum acanthium;* and the principal perennial ones are the corn-thistle, way-thistle, or common field plume-thistle, *Cirsium arvense*, the various-leaved plume-thistle, *Cirsium heterophyllum*, the meadow plume-thistle, *Cirsium pratense*, the common or corn-field sow-thistle, *Sonchus arvensis*, and the dwarf thistle or stemless plume-thistle, *Cirsium acaule*.

Thistles are an exceedingly troublesome and destructive class of weeds; and they demand the sedulous care, not only of individual farmers, but of whole communities, for keeping them down and exterminating them. They tend to occupy an aggregately large area of cultivated land to the exclusion of useful plants; they appropriate a large amount of the nutrimental principles within the soil, to the starving of the crop or the herbage amidst which they grow; they present so fierce an obstacle to the reapers of corn as to tempt them to grip and handle loosely the culms, and in consequence to leave a large amount of waste upon the field; they, in many instances, maintain so pertinacious a hold upon spots where they have taken root as to be very difficult of extermination; they, in all instances, so facilely and multitudinously scatter their winged downy seeds far and wide upon the wind that one free growth of them in a single nook of a district, or on a part of only one neglected road-side or one slovenly-managed farm would speedily propagate them over an area of many square miles; and wherever a rich lea soil, capable of producing the most luxuriant crops of grain, is newly broken up, they so invariably and sometimes so profusely arise as to have given occasion to the adage for a blind man's choosing land, "Tie me to a thistle." A law exists in France obliging all farmers to free their lands from thistles at the proper season, and empowering any one to sue a neighbour who neglects this work, or to employ other people to do it at his expense; and a similar law in Britain, and in all other countries, would be of great economical value.

Thistles are vastly less troublesome on grass lands than on arable lands; and when any of the most common kinds are once eradicated thence, and kept from growing and seeding along the hedges and ditches, they seldom give any further annoyance. Their seeds do not readily vegetate unless on any soil which is not loose; and are so much and greedily sought after by little birds, that they rarely lie long enough to germinate, especially in the early part of winter, except when wholly or partially covered with earth. The common carline thistle, the centaury star thistle, and the stemless plume-thistle infest pastures with sandy or calcareous soils oftener than loamy or clayey grass lands; and, whenever they greatly prevail, they cannot be effectually subdued by any operation short of breaking up the land and subjecting it to a course of crops. The marsh plume-thistle, the various-leaved plume-thistle, and the meadow-plume thistle prevail most in loamy and clayey soils; and must be dealt with in the manner of other perennial thistles. All annual and biennial thistles, on whatever kind of land they grow, may be readily subdued by either carefully pulling all up before they run to seed, or frequently mowing them over close to the surface, and rolling.

The removal of thistles from arable land under drilled crops, is more or less fully effected, in ordinary circumstances, by the operation of the horse-hoe; but the weeding of them out of broadcast crops, can only be done by manual operation, and is much more difficult. The common kinds may be destroyed by means of weeding pincers, or by pulling them up between the finger and the thumb from loose soil, or by cutting them over in the bleeding season, and applying a little salt to the stumps of the cut stems; but some of the perennial kinds, in consequence of their living roots or rootlets remaining in the ground, and throwing out new shoots or stems every year, can, in many instances, be effectually or even tolerably subdued only by deep ploughing and frequent harrowings, or by subjecting the land to a complete summer fallow, or by laying it down to grass. Either the stemless plume-thistle or any similar species, which infests sainfoin, lucern, or any other crop of a protecting and overshadowing character, may be reduced by the application of a little salt to the crown of each plant. The application of salt, in fact, has sometimes been proclaimed as a panacea against all thistles; and, whenever tried, the salt should be laid on the centre of the thistle, with the finger and the thumb, to the amount of about a teaspoonful to each plant, at some time before the thistle has attained a large size; and, in the course of a day or two, the plant may turn black, and in the course of nine or ten days will die down to the root. The best time for eradicating perennial thistles on any piece of ground which they have long infested is when they are in full bloom and beginning to form their seed.

THISTLE (Carline). See Carline Thistle.

THISTLE (Cotton). See Cotton Thistle.

THISTLE (Plume). A large group of carduaceous plants, of the true thistle tribe. It was formerly identified with the old genus *Cnicus*,—a genus which modern botanists have broken up, and distributed among the genera cirsium, leuzea, rhapontica, silybum, and serratula; and it may now be regarded as not far from being identified with the genus Cirsium, to which the major portion of the cnicuses have been assigned. See the article Cirsium. All the plume thistles are prickly herbaceous plants, differing from the true thistles principally in their down being not merely rough but evidently feathery; and some have decurrent leaves, and red or purple subsolitary flowers,—others, decurrent leaves, and pink or purple aggregate flowers,—others, sessile leaves, and purple subsolitary flowers,—others, sessile leaves, and purple aggregate flowers,—and others, sessile leaves, and white or yellow flowers,—though no species of either of the last two of these subdivisions grows wild in Britain.

The common or spear plume thistle, *Cirsium lanceolatum*, is a biennial indigen of the roadsides, banks, and waste grounds of most parts of Britain. Its stem is 3 or 4 feet high; its leaves are decurrent; and its flowers are purple and subsolitary, and bloom from June till September.—The marsh plume thistle, *Cirsium palustre*, is a biennial indigen of the moist meadows, the moist pastures, and moist spots of the road-sides of Britain. Its stem is from 3 to 6 feet high; its leaves are decurrent; and its flowers are purple and aggregate, and bloom in July and August.—The meadow or English plume thistle, *Cirsium pratense* or *Cirsium anglicum*, is a perennial-rooted indigen of low meadows and pastures, particularly among trees, in various parts of Britain. Its root is fibrous; its stem is 3 or 4 feet high; its leaves are sessile; and its flowers are purple and subsolitary, and bloom in June.—The tuberous plume thistle, *Cirsium tuberosum*, is a perennial-rooted indigen of the woods of some parts of England. Its stem is 3 or 4 feet high; its leaves are sessile; and its flowers are purple and subsolitary, and bloom from August till October.—The wool-bearing or wool-headed plume thistle, *Cirsium eriophorum*, is a biennial indigen of the road-sides and waste mountainous grounds of the calcareous districts of Britain. Its stem is 4 or 5 feet high, and, together with its foliage, gives the plant a massive and conspicuous appearance; its leaves are sessile; and its flowers are purple and subsolitary, and bloom in July and August.—The various-leaved or melancholy plume thistle, *Cirsium heterophyllum*, is a perennial-rooted indigen of the moist mountainous pastures of Scotland and the north of England. Its stem is about 2 feet high; its leaves are sessile; and its flowers are purple and subsolitary, and bloom in July and August.—The corn or way or creeping plume thistle, *Cirsium arvense*,

is a perennial-rooted indigen of the road-sides and cultivated fields of Britain; and is very troublesome, and not a little difficult of extirpation. Its root is fleshy and very vivacious, and both creeps far and strikes deep, so as to resist every slight or ordinary effort to destroy it; its stem is from 2 to 4 feet high; its leaves are sessile; and its flowers are purple and subsolitary, and bloom in July.—The dwarf or stemless plume thistle, *Cirsium acaule*, is a perennial-rooted indigen of the cultivated lands of Britain, particularly of grass lands which have a light soil. Its root is woody and runs deep into the ground; its stem is the mere root-crown, or rather is entirely a-wanting; its leaves are large, bright green, and sessile, and spread close to the ground in a circle of nearly a foot in diameter, and choke all grasses and other herbage within their range; and its flowers are purple and subsolitary, and bloom in July and August.—Forster's plume thistle, or the branching bog plume thistle, *Cirsium Forsteri*, is a perennial-rooted indigen of the bogs and moist woodlands of some parts of England. Its root is tapering; its stem is 3 or 4 feet high; and its flowers have a crimson colour, and bloom in July and August.

THISTLE (Star). See Star Thistle.

THISTLE (Way). See Saw-wort and Thistle (Plume).

THLASPI. See Shepherd's Purse.

THOMASIA. A genus of ornamental, evergreen, Australian shrubs, of the byttneria family. Six or seven species, some apetalous, others with white, pink, or purple flowers, most about 3 feet high, and all loving a soil of sandy peat, and propagable from cuttings, have been introduced to the gardens of Britain. The large stipuled species, *T. stipulacea*, introduced in 1844, may be taken as a specimen of the whole. Its leaves stand on long footstalks, and are heart-shaped, hairy, and deeply notched; and its flowers come out in little racemose clusters opposite the leaves, and are large and lean all one way, and have a pink colour with a shady suffusion of light purple, and bloom in profusion toward autumn. Most of the other species, however, bloom from April till July.

THORAX. The chest-cavity of an animal's body, containing the lungs, the heart, and part of the windpipe and the gullet. It is divided into two parts by a duplicature of the pleura, and separated from the abdomen by the diaphragm.

THORN. Any ligneous plant which possesses a spinous armature,—but particularly the hawthorn and other indigenous, economical, spinous shrubs and small trees. See the articles Hawthorn and Spine.

THORN. A spinous process, whether the true spine of such plants as thistles, or the woody, spear-like armature of the hawthorn and other powerfully prickly shrubs. A thorn, as distinguished from a spine, grows only on ligneous plants, and has a woody nature, and may be regarded as an abortive, indurated, sharply-pointed bud. When a thorn pierces a horse, and breaks, and remains in the wound, it ought with all possible speed to be drawn out with small pincers, and, if necessary, first loosened and made easily extractable by means of an incision; and, if it cannot be removed, or if it be neglected till inflammation set in, poultices should be applied to encourage suppuration.

THORN-APPLE, — botanically *Datura*. A genus of ornamental, hardy, annual plants, of the nightshade family. Nearly a dozen species occur in British collections,—principally natives of America, China, and Northern Africa; and most are about 2 or 3 feet high, and have white flowers, and love a soil of rich mould, and bloom from June or July till September, and possess very active properties of a poisonous or dangerously medicinal nature; but two, the Tatula and the proud, have respectively blue and purple flowers,—and the first of these, and also the Stramonium and the fierce, thrive best in a light soil.

Stramonium or the common thorn-apple, *Daturo stramonium*, is the best known species, and has a place in the pharmacopœias, and may serve as a sufficient specimen of the whole genus. It is a native of America, and was introduced to Britain, by way of Constantinople, toward the close of the 16th century, and is now naturalized, so as to grow in a wild state among the rubbish of waste grounds, of dunghills, of road-sides, and of the vicinity of gardens. Its stem is cylindrical, branching, dichotomous above, spreading, leafy, and 2 or 3 feet high; its leaves spring on long cylindrical footstalks from the forks of the stem, and are large, triangularly ovate, unequal at the base, sinuated on the margin, dark green above, and pale below; its flowers stand on short erect footstalks, and are solitary, axillary, and large, and have a white funnel-shaped plaited corolla, and bloom from July till September; and its fruit are large, fleshy, somewhat ovate capsules, armed with sharp, awl-shaped spines, and containing a great number of compressed kidney-shaped seeds. The whole plant emits a fetid, narcotic, sickening odour; and the leaves, the capsule, and the seeds possess very fierce narcotic, stimulating, and poisonous properties. Stramonium, when eaten by mistake, has produced fatal effects; and when cautiously administered, in the way of potion, has produced bewilderment and stupefaction, and aided some of the most horrid designs of wicked men; and when smoked in the manner of tobacco, relieves the paroxysms of spasmodic asthma; and when intelligently used by physicians, according to well-tested pharmaceutical formula, in the various forms of extract, powder, tincture, ointment, and cataplasm, has been found to act beneficially in a number of widely different diseases. But it is eminently one of the class of terrible drugs

which no quack or unscientific or inexperienced person should dare to touch. One analyst found, in 178 parts of it, 58 of gummy extractive, 6 of extractive, 64 of chlorophylle, 15 of albumen, 12 of resin, and 23 of phosphate of lime and magnesia; and other analysts have found in the seeds a peculiar, narcotic, alkaline principle, called daturine, which exists in combination with malic acid, and which, when separated, crystallizes with difficulty, and is nearly insoluble in water, and forms neutral salts with most acids.

THOROUGH-DRAINING. See Draining.

THOROUGH-PIN. A bursal enlargement in the horse's hock, similar in nature to bog-spavin. When the tumour is pressed on one side, the fluid within is forced to the opposite side; and hence the fantastic name thorough-pin. When the disease causes lameness, it may require to be attacked by blistering or firing; but it seldom does this, and may in general be best let alone.

THOROUGH-WAX. The round-leaved hare's-ear. See the article Hare's-Ear.

THORTER-ILL. See Louping-Ill.

THRASHING. The operation or process of separating the seed from the stems of corn, pulse, oleiferous seed plants, and all similar crops. The place on which the Hebrews, the Egyptians, the Romans, and other ancient nations adjacent to the Mediterranean performed this operation, was not the floor of a barn or of any other building or enclosure, but an open circular area in an elevated part of a field or on the tabular summit of a mount or hillock, levelled and beaten firm, and commonly about 30 or 40 paces in diameter. The thrashing-floor of Araunah the Jebusite—incomparably more remarkable in its associations than all other recorded thrashing-floors whatever, and most gloriously signalized as part of the site on which Solomon afterwards built the Temple of the true Deity—seems to have been simply a large esplanade on the broad and flattened top of Mount Moriah. All thrashing-floors required to slope slightly from the centre to the circumference, and to have a very smooth and perfectly firm surface; and they were variously formed by levelling rock, by laying pavement, by compacting clay, or by depositing some sort of mortary compound, according to the nature of the situation, and character of the soil. "Make a thrashing-floor in this manner," says Cato in reference to any ordinary kind of ground: "dig the soil, and sprinkle it with amurca, and allow the amurca to be imbibed; then pulverize every bit of hard earth, and smoothen all the surface, and work it hard with beaters; and afterwards sprinkle it again with amurca, and allow it to dry; and if the thrashing-floor be thus made, ants will not hurt it, nor will herbs grow upon it." Other Roman writers recommended that the thrashing-floor should be so situated as to be easily observable by the landlord or by the steward,—that it should be on high ground and much exposed to the wind, in order that it might naturally be maintained sweet and clean,—that it should be distant from gardens, orchards, vineyards, and groves, so as not to become defouled by their fallen foliage,—that it should be raised in the middle, in order that rain might readily drain away from it,—and that it should have a circular outline, so as both to economize space and to afford the most convenient scope for thrashing action by either oxen or implements. Some thrashing-floors, in wet climates, had roof-coverings, to shelter them from rain; others, in hot climates, had awning-coverings, to shelter them from the heat of sunshine; and others, in pastoral districts, were encompassed with a stone wall, to protect them from trespass by animals. In some instances, the workmen reposed on the awning-sheltered thrashing-floors during the heat of the day; and in not a few—as in that of Boaz, recorded in the book of Ruth—the proprietors or others slept on them during the night. The several varieties of thrashing-floor now used in the barns of Britain are noticed in the article Barn.

The operation of thrashing, in warm and dry countries, where seeds have a comparatively slight adherence to their envelopes, is much easier than in cold and wet countries, and requires a correspondingly facile class of appliances. In the earlier periods of the Hebrew commonwealth, a mere rod or cudgel seems to have been the ordinary thrashing implement, and perhaps the only one; but in the more advanced periods of that commonwealth, as well as among contemporary nations of the East, and among some later nations of Southern Europe, the treading of oxen and the action of several kinds of toothed and wheeled machines were used for most large crops or large quantities, and the rod or cudgel reserved only for small kinds of grain or for small quantities. One Jewish thrashing-implement, called baerkanim, is obscurely known, but seems to have been a square piece of wood, armed on the lower side with sharp stones; another, called morag, comprised four beams so joined as to form a square, and had three revolving cylinders set between the beams, and each furnished with three iron wheels, having teeth like those of a saw; and a third, called harootz, was formed like the second, except that the cylinders, instead of having iron saw-toothed wheels, were furnished with sharp pieces of iron, six inches long and three broad. The Jews, when obedient to the Divine law, "did not muzzle the ox that trod out the corn;" but the ancient Greeks, according to Ælian, besmeared the mouth of the poor animal with dung, in order to prevent it from eating. The Jews, so far as we know, may have used oxen both to tread out the corn by walking loosely over it, and to draw the heavy varieties of their thrashing implements; the ancient Greeks appear to have used chiefly the loose treading of oxen; and the ancient Romans, as well as the more polished of the nations who

were subject to them, used variously the flail, the loose treading of horses, the loose treading of oxen, and the draught-power of oxen in attachment to a machine which they called tribulum. "This machine," says Varro, "is made of a board rough with stones or iron, which, with a driver placed upon it, or a great weight, is drawn by yoked cattle to beat the grain from the ears; or it is made of a plank, with little rollers in place of teeth,—and this latter kind is called plostellum pœnicum."

At what period the flail was invented is not known. But it gradually superseded all the other methods throughout a large portion of the Roman empire; and was for many centuries the chief or only thrashing implement among most of the European nations; and continues still to maintain that place in very many of the small farms of Britain, and to be everywhere in request for the thrashing of small crops and small quantities. See the article FLAIL. The subject of modern thrashing machines will be discussed in the next article; and the comparative merits of these and of the flail, and also the details of labour throughout the modern processes of thrashing, are noticed in the article BARN-MANAGEMENT.

"In commencing the operation of thrashing with any large modern thrashing-machine, the power should be applied at first with caution. A great and rapid force of water, steam, or wind, at first, is apt to strain some weaker part of the machinery; and even if all the horses start strongly off at first, the course-wheel may be heard to creak. A full velocity of the mill should be produced before any corn is put in. In preparing the sheaves, the band should be loosened, and laid along the sheaf to which it belongs; but, as time is often limited to this operation of loosening the bands, many people who are careful prefer to throw them aside and thrash them by themselves afterwards; in which case, the corn knot is completely loosened out, and the thrashing is perfect. Less careful people, on the other hand, cut the band with a knife, and allow it to pass along sidewise with the sheaf, when the corn knots are frequently unthrashed, particularly when the straw is short. In feeding the mill, some dexterity is requisite. One sheaf at a time is quite sufficient for most mills, and a large sheaf is even too much. No more should be presented than what the mill can pass through without the least apparent retardation of its velocity. A velocity which permits the man who feeds to count the strokes of the scutchers of the drum is too slow; and it impresses one with the idea that the mill is fatigued, and is likely to be overcome. Then much of the corn will escape untouched. Oats with long straw in a dampish state is the most apt to produce this retarding effect, though the moving power of the mill be quite adequate to its task. Wheat with strong and long straw will produce a similar effect; but, with wheat, this effect often arises from a deficiency in the moving power. Damp oat-straw sometimes warps itself round the upper feeding roller; and in some mills, this warping is got rid of by reversing the motion of the feeding rollers, by means of a bayonet which operates on their pinions. Where this device is awanting, the warped straw must be cut away in pieces by a large knife, which should be kept at hand for the purpose. The sheaf should be spread evenly on the feeding-in board, for should any part of it be thicker than the rest, the upper feeding roller will be elevated by it, and the thinner parts will escape with the corn attached to it. To give the man full command of the sheaf, one only should be upon the table at a time, and that only replaced by another, when the former is removed by the man. This arrangement is very necessary for the performance of good work; but it is one which those who loosen the sheaves very readily neglect, because it causes them to be more attentive to the removal of the sheaf by the man who feeds in, and it prevents them throwing a large heap of sheaves upon the table, during the removal of which they got leave to rest or talk. Opportunity, however, for this neglect arises only at the outset of the thrashing process, when the sheaves are piled near the mill. Besides laying the sheaf even, the man who feeds should shake the straws loose in the sheaf, and draw them out thinner, that the drum may have access to every ear of corn. A screen should be placed between the man's face and the rake, to protect it from the grain, particularly wheat, which is thrown by the scutchers of the drum with inconceivable velocity against the rake; but the screen should be removable at the will of the man, that he may have an opportunity of seeing whether any of the straw is fastened on the teeth of the rake, and revolves round with it. In a fine season the grain is easily separated from the straw, and few or any unfilled grains occur in such a season. But in a cold and sunless season, the grains separate very reluctantly from the chaff. Indeed, in the case of wheat and oats, the grain and chaff often go together, and the awn from the barley is broken through the middle; and, in the case of all inferior or middle-rate or old-fashioned mills, nothing but repeated thrashings will completely separate the grain of wheat from the chaff. Nor will any kind or number of thrashings effectually break off the awn of barley; and to effect this purpose, a hummeller is attached to some thrashing machines." See the articles BARN-MANAGEMENT and HUMMELLER.

THRASHING MACHINES. The earliest recorded attempts to construct a modern thrashing machine, were made by the distinguished Jethro Tull; but they seem to have been somewhat crude, and they were very unsuccessful. The next attempt was made almost immediately after by Mr. Michael Menzies, brother to the

then sheriff-depute of East-Lothian; and, in consequence of its partial though brief success, is commonly mentioned as the germ of the whole system of thrashing machinery. Mr. Menzies' machine was patented in 1732, and declared by the Society of Improvers in Scotland to be likely "of great use to farmers, both in thrashing the grain clean from the straw and in saving a great deal of labour." It was driven by a water-wheel, and contained a series of flails, which were made to revolve upon a cylinder; but, owing perhaps to the velocity which was found requisite for the correct performance of the work, the flails were soon broken in pieces, and the whole machine became useless.

About the year 1758, a machine of a widely different construction, and of far more promising character, was invented by Mr. Michael Stirling, farmer in the parish of Dunblane, in Perthshire. This machine, somewhat similar to a flax-mill, had a water-wheel and perpendicular shaft or axle, into which were fixed four arms, enclosed in a cylinder about 3 feet high and 8½ feet in diameter. The shaft and its arms, within the cylinder, were driven with considerable velocity; the corn was presented by hand, and was let down through an opening in the top of the cylinder, and underwent smart scutching strokes from the arms, so as to undergo a separation of the straw from the ears or grain; and the straw passed outward through an opening in one side of the cylinder, while the ears fell down through an opening in the floor into a mechanism of rakes and fanners, and there underwent a final separation into grain and chaff. This machine was found to break off the ears of barley and wheat instead of clearing them of the grain, and proved to be tolerably suitable only for oats; yet it came into extensive use, and continued till quite a recent period to be used in some parts of Scotland, and driven either by water or by cattle.

In 1772, a machine was invented by Messrs. Alderton and Smart, two gentlemen in Northumberland, "by which the sheaves were carried round between an indented drum of six feet diameter, and a number of fluted rollers, which, pressing by means of springs against the fluted concave, rubbed out the corn from the ears." In 1785, a machine, denominated "a mill for separating grain from straw," and constructed on a similar principle to the coffee-mill, was patented by Mr. William Winlaw of Marylebone, but it was found, not only to thrash the corn, but to bruise and grind the grain. In the latter part of last century, some other machines were invented for thrashing corn in the way of rubbing; but all, as well as Winlaw's, more or less damaged the grain, and were in consequence discarded. In 1792, a machine was patented by Mr. Willoughby of Bedford in Nottinghamshire, constructed on a somewhat similar principle to the original one of Menzies, and comprising a series of loose or hinge-hung flails, which were kept in rapid play by means of a horse-wheel, and made to act upon a grated platform. In 1795, an invention was brought out by Mr. Jubb of Lewes for "passing the straw between two rapidly revolving beaters, under which it was held by two feeding-rollers, whence the corn fell into a winnowing-machine." About the year 1796, a machine was introduced to England, invented by Mr. James Wardropp of Ampthill in Virginia, and so formed as to be worked by two men. It was made with flails or elastic rods 12 feet in length, of which twelve were attached in series, each having a spring requiring a power of twenty pounds to raise it three feet high at the point. A wallower shaft, with catches or teeth, in its revolution successively lifted each flail in alternate movements, so that three of the flails were operated upon by the whole power, viz., twenty pounds, while three were two-thirds raised, three one-third raised, and three at rest; consequently, the whole weight to be overcome was 120 pounds. The flails beat upon a grating, to which the corn was introduced by hand. "In communications from M. D. Musigny to the Society of Arts," continues Mr. Ransome, from whose work on Agricultural Implements we have taken the preceding description, "a curious account is given of a machine worked by one horse, which, walking round a circle of forty feet, caused a cylinder, upon which thirty-two flails were placed, to revolve at the rate of twenty revolutions to one of the horse-wheel. The unthrashed straw, being laid on the circle to be described by the cylinder, must have been difficult to confine to its correct position, and awkward both to place and to remove; while the corn would be thrown about in a most slovenly manner. Another plan, patented in 1796, by John Steedman, of Trentham, has also been exhibited, by which a number of flails fixed upon a rotatory cylinder were made continually to play upon a given spot, while a circular table, revolving horizontally, brought a fresh supply of straw under their influence."

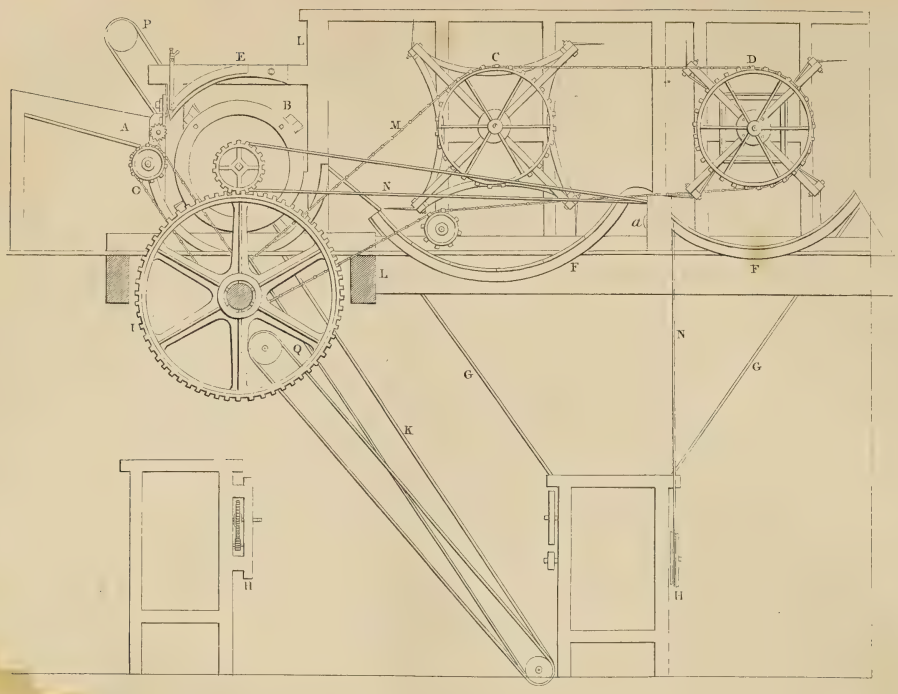
All the machines we have hitherto noticed, from Menzies' onward, may now be regarded as obsolete in practice, and as serving mainly two purposes on record,—to evoke gratitude from farmers for the superior advantages enjoyed in the machinery of the present day, and to warn young genius against any needless and wasteful expenditure of its inventive power. Another one, too, which was invented by Sir Francis Kinloch, upon hints which he borrowed from inspection of Messrs. Alderton and Smart's, went more rapidly into desuetude than any of them, and yet had the rare merit of provoking the origination of the model machine of all the best which are now in use. A large model which had been made under Sir Francis's direction was sent by him to Mr. Andrew Meikle, civil engineer at Houston Mill, near Haddington, in order that it might be tested by means of the water-wheel of

Mr. Meikle's barley-mill; and in a few minutes after it began to be tried, it was torn to pieces;—and the like fate befel a machine of full size which Sir Francis erected, a few years afterwards, for one of his tenants.

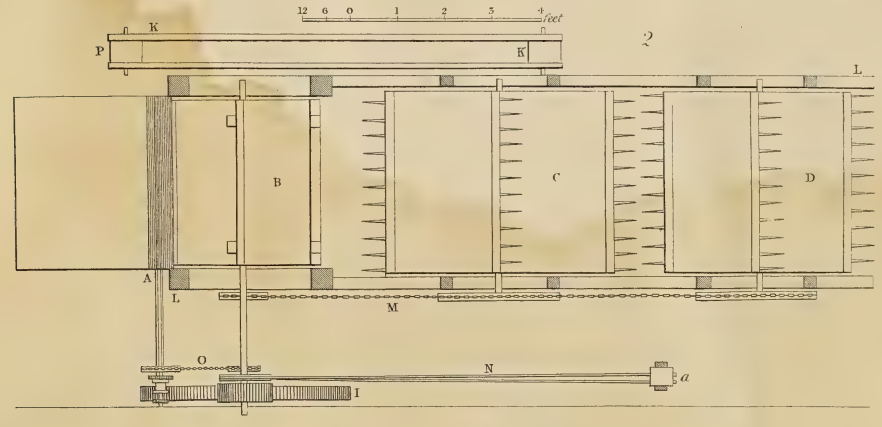
"Mr. Meikle," says Sir John Sinclair, "was at this time induced to try if the work of thrashing corn could be accomplished upon a principle, which had not been previously acted upon by any other person. It is evident, that the power required to thrash corn in a perfect manner, or even in any quantity, must be considerable; for no machine is capable of performing this operation correctly, if the scutchers do not move with a velocity of 2,500 feet in a minute. He therefore resolved to attempt thrashing by means of a cylinder or drum, placed in a horizontal position, upon the circumference of which thrashers or scutchers should be fixed, in such a manner, as to endure the necessary motion; being quite satisfied, that corn, without velocity in the thrashing-drum, could not be detached from the straw in a satisfactory manner. The attempt was made, and the success completely answered his expectations and wishes. The first thrashing-machine erected by Mr. Meikle, was on account of Mr. Stein, at Kilbagie, in Clackmannanshire, about the year 1786; and a certain proof that such a machine was then altogether unknown, may be inferred from the agreement about this erection, it being therein stipulated, that Mr. Stein was to furnish the materials, and if the machine did not answer the intended purpose, Mr. Meikle was to receive no payment for the workmanship. This thrashing-machine being successful, another, on the same principles, was erected for Mr. Selby, at Middleton, in Northumberland, which was immediately copied and imitated by several mill-wrights in that county; one of whom had the singular modesty to claim the invention, because he had previously made a model of Mr. Alderton's machine, which was constructed on quite different principles. The utility of Mr. Meikle's machine being satisfactorily ascertained, a patent for the invention was obtained, securing its benefits to him and his heirs for the period of 14 years. It is a singular circumstance, that though this patent was obtained at considerable expence, it was not acted upon. When ten years of the patent were expired, some of Mr. Meikle's friends stood forward, and endeavoured to put it in force; but there was then such a number of erections by others, that the design could not be executed, without risking an expence, which would not have been compensated by any profits that could have been gained during the unexpired years of the patent. Since the invention of this valuable machine, various improvements have been introduced, not only by the inventor, but also by others, all tending to simplify the labour, and to augment the quantity of work performed. When first erected, though the corn was equally well separated from the straw, yet, as the whole of the corn, straw, and chaff, were indiscriminately thrown into a heap, the work could only be considered as half executed. But, by the addition of shakers and fanners, all driven by the same power, the different processes of thrashing, shaking, and winnowing, are now all performed at once, and the grain immediately prepared for the market."

The modern Scotch thrashing-machine, constructed on the principle of Meikle's, and comprising all the most important improvements up to the year 1839, is represented in *Plate LXI. Fig.* 1 is an elevation, and *Fig.* 2 a ground plan; and the same letters refer in both figures to the corresponding parts. AA represent the position and arrangement of the feeding rollers, B the drum, C the first rake, D the second rake, E the apron, FF the screen, GG the hopper, HH the first and second fanners, I the connecting spur-wheel, K the elevators, LL, &c., the framing of the mill, M the rake-chain, NN the fanner-rope, O the roller-chain, P the upper pulley, for elevators of 'shorts,' Q the upper pulley for elevators of second fanners and hummellers.—The drum is the most important part; and in giving it motion, a very great portion of the moving power is expended. It being the standard for the dimensions and the velocity of the other parts, its construction and velocity are of much importance. To thrash clean, the drum requires to move with a velocity of 320 revolutions per minute, where its diameter is 39 inches, this diameter being, after numerous experiments, considered the most effective. The length of the drum, that has been in like manner determined from a train of experiments, is 3 feet 6 inches, for a machine of six-horse power. From the velocity at which the drum moves, and the force with which the beaters strike the straw, it requires to be made of materials at once light and durable. These consist of an axle of malleable iron, with arms of the best hard wood, fixed in malleable iron flanges. The best covering for the drum is sheet iron, No. 24, being both clean and light. The beaters are made of the best hardwood, 2 inches thick, and $3\frac{1}{2}$ inches deep, faced with malleable iron, steeled, and $\frac{3}{8}$ths of an inch thick on the striking edge. To prevent the straw from winding about the axle of the drum, the frame is exactly fitted to its length, so as not to have a void of more than one-half inch at each end of the drum.—The feeding rollers are about one inch longer than the drum; and they should have weight sufficient to prevent the beaters from pulling the corn faster through than the rollers pass it, and should present the corn to the beaters as directly as possible. These objects are attained by solid cast-iron rollers of 4 inches diameter. Some corn from its nature, and others from its state, requiring a greater number of strokes to thrash it than others, the feeding rollers are fitted up so as to

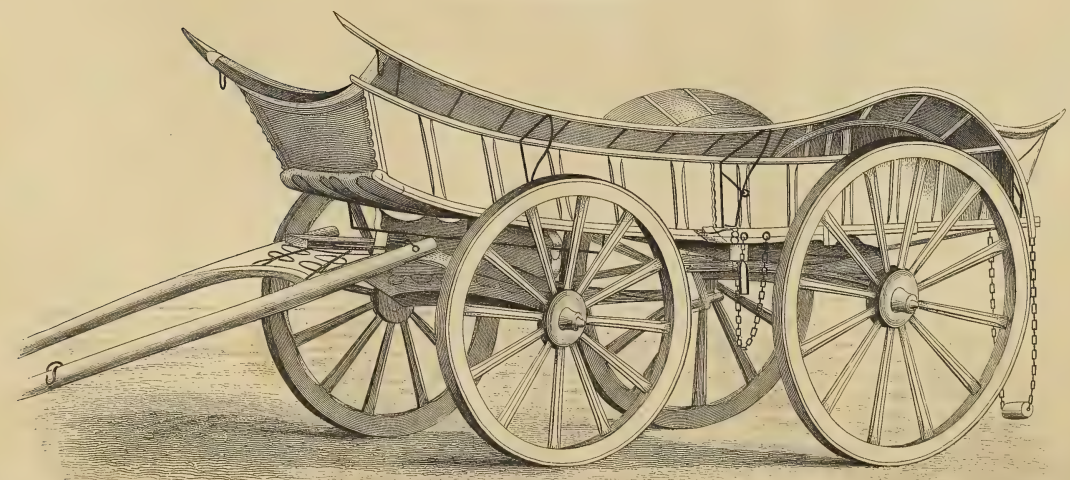
1



2



Narrow Wheel Hoop Waggon



admit of two rates of velocity,—one in which they make one revolution while the drum makes $5\frac{3}{4}$, and another in which they make one while the drum makes 4; and these two velocities have been found sufficient for all cases. The best form of fluting for the feeding rollers is, for the upper one a concave flute, and for the under an angular flute; and the most approved gearing for working them is two pairs of spur-pinions, on parallel spindles with a sliding clutch between the pairs of driving pinions. This pair of pinions has each a round eye which admits of their revolving loose on the spindle, when not fixed by the clutch. By attaching the clutch to the one or the other of the driving pinions, the motion of the rollers is instantly changed from quick to slow, or *vice versa*, without stopping the machine. The sliding clutch is carried round with the shaft by means of a feather fixed in the shaft or spindle, and is slid by means of a lever, the long end of which rests on a plate with three notches. To change the motion of the rollers, the end of the lever is moved from one extreme notch to the other extreme; and to stop the rollers, it is removed into the centre notch. The distance of the rollers from the beaters, like their velocity, depends very much on the state of the corn to be thrashed; but as a general rule, five-eighths of an inch may be considered as very good; yet a variable distance is best,—and one of the simplest contrivances for effecting this is to have the block in which the rollers run made separate from the frame of the thrashing machine, and afterwards fixed to the parts of the frame by strong bolts with a head on one end, a fixed collar between the block and the post, and a screw on the other end working in a nut sunk into the post, so that by turning the head of the bolts, the distance may be varied at pleasure. The under roller has its centre at least four inches above the level of the centre of the drum, and neither rises nor falls; but the gudgeons of the upper roller work in a perpendicular fork, whereby they are at liberty to rise or fall as the feed varies. The best coupling for the spindles or shafts of feeding rollers is an oblong box of malleable iron, welded to the end of one part of the shaft, and receiving that of the other part.—The apron of the drum is made in the form of an arc of a circle, whose diameter is about six inches greater than that of the drum. The lower end is placed five-eighths of an inch from the rollers, and the upper about $3\frac{1}{2}$ inches above the beaters. The best position of the rakes, in relation to the drum, is when their centre is placed 10 inches above the centre of the drum, and the extreme points of the first rake 10 inches from the beaters. The length of the rakes ought not to be less than six inches more than the drum. The diameter of the first rake is 6 feet over the extreme points,—and of the second 5 feet; and both make 18 revolutions per minute. The simplest and most economical mode of communicating motion from the moving power to the first rake, and from that to the second, is by a pitch-chain, arranged as shown in *Fig.* 1.—The fans of the winnowing-apparatus are 3 feet in diameter, and 21 inches broad; and the most effective velocity is 213 revolutions per minute. The simplest method of communicating motion from the thrashing machine to the fanners is by a rope from the drum passing over the leading pulleys *a*, and on to the pulley of the fan; and for the old shoe and riddle, may be substituted an endless web moving round two small rollers. This is placed underneath the hopper, and receives motion by a belt from the spindle of the fanner; and receiving the grain as it drops from the hopper, conveys it regularly forward till it falls before the fans. The endless web moves at nearly one-fourth of the velocity of the fans. While it is less expensive, and more easily kept in repair than the shoe and riddle, it also answers better, as it presents the grain more equally to the action of the fans. The method of working the second fanners is, in general, by a motion from the machine. But when a separate power can be obtained at no great expense, as may be easily done when water is the power employed, it would be advantageous to adopt it to drive both fanners, as the regularity of their motion, requisite for producing good work, would not then be interrupted by the irregularities of the machine.—The most economical mode of raising the grain from the first to the second fanners is by elevators; and these may consist of an endless web, formed into a continued series of square or oblong boxes, with a belt on each edge of the web, revolving on two pairs of parallel pulleys; but though the sides and bottoms of the boxes are formed of the endless web, their ends are of wood. It is obvious that the length of the elevators depends on the height that the grain has to be raised; the width of the boxes is regulated by the mouth of the fanners' spout; and their depth is about $2\frac{1}{2}$ inches. The velocity of the elevators is about 180 feet per minute; and the motion is communicated to them by the upper pulleys. The elevators for the 'shorts' are constructed on the same principle, and of the same materials, only larger.—The screen is made of cast-iron, hoop-iron, or wood; the spaces between the spars are squares, whose sides measure $1\frac{1}{2}$ inch; and the spars, when of cast-iron, are five-sixteenths of an inch thick, and half an inch deep. The screen would with decided advantage be extended under the drum; but this could be done only in barns of greater elevation than most at present possess. The length and breadth of the top of the hopper are regulated by the length and breadth of the screen, and the height of it by the elevation of the barn. The sloping of its sides should not, however, be less than 50°.

The suitable dimensions of the lower barn for a thrashing-machine of two-horse power, are 27 feet long, 16 broad, and $7\frac{1}{2}$ high; for one of four-

horse power, 36 feet long, 18 broad, and 8½ high; for one of six-horse power, 40 feet long, 20 broad, and 9 high; and for one of eight-horse power, 44 feet long, 21 broad, and 9 high. A suitable drum for a machine of two-horse power is 2½ feet long, and makes 180 revolutions per minute; for one of four-horse power, is 3 feet long, and makes 300 revolutions per minute; for one of six-horse power is 3½ feet long, and makes 320 revolutions per minute; and for one of eight-horse power, is 4 feet long, and makes 340 revolutions per minute. Suitable feeding-rollers for a machine of two-horse power are 2 feet 7 inches long, and make one revolution for every 4½ or 6½ revolutions of the drum; for one of four-horse power are 3 feet 1 inch long, and make one revolution for every 4¼ or 6 revolutions of the drum; for one of six-horse power are 3 feet 7 inches long, and make one revolution for every 4 or 5¾ revolutions of the drum; and for one of eight-horse power are 4 feet 1 inch long, and make one revolution for every 3¾ or 5½ revolutions of the drum; and all, for whatever amount of horse power, have the same diameter. The form of the apron, the position of the rakes, the diameter of the fans, and the form of the screen are the same for all powers; but the diameter of the rakes is variable; and the breadth of the fans for a two-horse power is 15 inches, for a four-horse power 18 inches, for a six-horse power 21 inches, and for an eight-horse power 24 inches.

The drum of some thrashing-machines is armed with beaters, and that of others with scutchers. This diversity occurred even in the original machines of Meikle's patent; and it has been considerably modified and extended in subsequent inventions. The beater stands out rectangularly, and strikes with a flat edge; and the scutcher stands out at an acute angle, and strikes with a somewhat sharp edge; and, in improved machines by different inventors and millwrights, the latter has a considerable diversity of both inclination and form. The action of a beater may be understood by supposing a handful of corn to be held in the hand, and to have its ears struck with the flat sides of a thin strip of wood; and the action of a scutcher, by supposing a sharp blow to be given, not on the ears, but in the direction of them, and not with the flat sides of the strip of wood, but with its thin edge. Beaters appear to do always best, as to at once the quantity, the quality, and the cost of the work, in cases of heavy corn, loose in the husk, wheat, pease, and beans; and scutchers are cheaper, and sometimes more efficient, in all or most cases of barley and oats. But, to adopt the opinion and the words of Mr. Ransome, "although the operation of scutching may be performed at less expense of power, if partially executed, and that a greater quantity of straw may pass the machine, and consequently more corn may be obtained in a given time, yet, unless the scutchers are placed very near the concave, the work will be imperfectly performed, and much of the corn will remain in the straw, and escape. But, if placed so near as is requisite for clean thrashing, the liability to break off the ears will be increased, which will involve the need of rethrashing; and the friction, from the narrowness of the interval, will then require, to the full, as great power as the beaters." An improved system of beaters was introduced to notice, in 1839, by Mr. Ritchie of Banff; and consists in the use of eight half beaters instead of four entire ones,—four of the halves being placed intermediately to the other four,—each having but half the resistive power of an entire one,—and all so operating as to equalize the aggregate resistance by means of the increased frequency and double distribution of the strokes.

The shaker of most thrashing machines consists simply of revolving rakes, and, in very many instances, is so constructed as both to involve very considerable waste of moving power, and to allow a considerable portion of the grain to be carried away.—A new mode of shaking, invented in 1839 by Mr. Docker of Finden in Banffshire, comprises a peculiar arrangement of two series of light batons of wood by means of cranks, to which each series are separately attached, the batons 1, 3, 5, &c. forming the one series, and the batons 2, 4, 6, &c. forming the other; and their motion is saltatory and alternately progressive, and causes the straw to pass both vertically and horizontally forward.—Another shaker, invented in the same year by Mr. Ritchie, is the same in principle as Mr. Docker's, but differs slightly in the method of producing the motion of the batons.—A shaker, invented in 1840, by Mr. Archibald Ainslie of Peaston, is simply a large skeleton cylinder, framed of wood covered in the interior with trellis-work, but entirely open at both ends. It lies at an angle of about 13°, and rests upon four plain square-edged pulleys; and the driving of two of the latter by the machine, gives motion by contact to the cylinder.—A small shaker of the common rake-form is usually placed between the drum and the cylinder, by which the straw is delivered into the latter; and when a portion of straw has entered the cylinder, it is carried round till it reach the apex, when it falls to the lower side at a point somewhat in advance of that at which it first began to ascend. When the portion of straw has again reached the apex, a second fall occurs to a point still more in advance, and so on until discharged at the lower end. A succession of such parcels of straw are, of course, in constant progress through the cylinder, rising and falling from five to seven times in their passage.—An improvement of a very simple and obvious kind, introduced in 1840 by Mr. Shennan of Lairdlaugh in Dumfries-shire, consists in the application of a screen in the place of the second shaker commonly employed. The screen lies at an angle of about 20°, jointed at the upper end to the mill-frame, and is kept in rapid vibration by a short crank

applied at the lower end, and moving at a rather high velocity.

The Scotch thrashing-machines in ordinary use throughout the country, when viewed in the aggregate, are far from being in a satisfactory or creditable condition, and do not by any means display the amount of excellence and efficiency which the history of Meikle's invention and of the many subsequent improvements on it might lead us to expect. "Most of the machines in present use," said an account in 1832 which instructively points out some permanent and general causes of their defects, "are either ill-calculated for a simultaneous action of their component parts, or they are so loaded with machinery that the moving power has a difficulty in overcoming their weight. It is very easy to overload a horse-power thrashing-mill with a multiplicity of wheels and pinions; and it will be found that the least failure of power under the ordinary thrashing-power leaves much of the straw unthrashed; the short heavy portions, called in Scotland the roughs or shag, which should descend into the second hopper, will fall down among the good grain, and create a vast additional labour in separating what the mill ought to have done. These heavily constructed machines are great evils anywhere, but especially in the interior of the country, whence carriages are long and heavy to sea-port market-towns, and hence, where the obtaining of water-power to thrashing-mills is so very desirable on account of the horses. From what we have seen and experienced in the matter, we have no hesitation in affirming, that numerous as thrashing-mills are in this country, few of them are constructed upon the correctest principles, and that much emendation may be made in this department of mechanical agriculture. Indeed, we have seen a mill constructed of a water-wheel belonging to one mill, the shafts and drum to another, the rake to a third, and the winnowing part to a fourth. This mill, when finished, cost a hundred guineas; it thrashed well; but how could a machine constructed of such patch-work be expected to do all its work satisfactorily? It may suffice to mention, that it required repair twice or thrice every winter. That machines of this description will sometimes be erected, need not excite our surprise, when we reflect on the circumstance, that many of the country millwrights set up in business with very limited capitals. They cannot procure a sufficient stock of patterns, which are calculated to form parts of the same machine, but are obliged to borrow patterns from neighbouring millwrights or founders. Besides, many millwrights think, that if the thrashing part of the mill, the drum, and its immediate mover the spur-wheel, be good and substantial, and finely hung, that all the rest are of secondary consideration. They think they show their engineering powers to the greatest degree in the construction of these parts. The overshot water-wheel may move with the velocity of a fly one, or the horses be obliged to walk at the rate of five miles an hour before the drum can be brought up to the thrashing speed, or the shakers and fanners may half choke and blow every thing before them; these may all occur from time to time without exciting much emotion, so that the drum perform its part with firmness and steadiness, at the true velocity. We are persuaded farmers just take such mills as are erected for them, for they generally do not possess sufficient knowledge of the matter to enable them to detect any error in the construction of them; and, after having got them erected, and paid for, their wounded pride will not allow them to say one word against their own machine. We do not remember of ever having heard a farmer confess that he had a bad thrashing machine, though an examination of all the parts when at work, the oppressive effects produced on the animals, and the quality of the work performed, might soon convince any one that the machine might be much better than it was. The ill-judged desire of the farmer to have a mill that will not cost much money, often leads the millwright to adopt expedients in its construction, which he is conscious are not suited to work well together. This is one reason among many others to prove the propriety of landlords erecting thrashing machines at their own expense upon the farm-steadings, and of giving the tenants the use of the mills, as well as the steadings, and of obliging them to keep the mills in repair, as in the case of the buildings."

The thrashing-machines of England have risen from a broader origin, and comprise a greater diversity of structure, than those of Scotland. In 1795, a machine was patented by Mr. Wigfull of Lynn, which attempted to combine the impulse of the flail with that of revolving beaters, but which, though much extolled at the time, soon passed into neglect. Its beaters, instead of being fixed on the drum, were loosely attached by means of brief chains, so that, when the drum was in rapid motion, they were flung by the centrifugal force with great velocity against the corn, which passed between two rollers and was held long enough to be thrashed, and then, by means of a shaking screen and an endless web, was carried forward to the action of a winnowing apparatus.—At a later period, a machine was introduced by H. P. Lee, Esq. of Maidenhead-Thicket, which embodied the principle of feeding without the aid of rollers, and contained the germ of the whole plan on which many of the English thrashing-machines of the present day are formed; and during the succeeding forty years, inventions and improvements, too numerous and diversified to admit of being profitably enumerated, were flourished before the public view, and secured by patents, and, in several instances, rewarded by honorary medals of the Bath Society and the Society of Arts.

The thrashing-machines now in general use through the eastern counties of England do nothing but thrash, and have neither circular rakes nor fanners attached to them, and are mostly portable, and often carried along, in an itinerating manner, from farm to farm, and let temporarily out to any farmer who wants them. "The beaters, four, five, or six in number," says Mr. Ransome, "are so placed round the drum that their beating edges radiate from the centre. These strike upon the straw, which is passed along a feeding-board placed at an inclination of about 30°, tending to a point equidistant from the centre and upper part of the circumference of the drum. The concave or screen which surrounds the drum describes the third part of a circle, and is formed alternately of iron ribs and open wire-work in segments, so placed that its inner surface may be brought into near contact with the edges of the revolving beaters, and admitting of adjustment by screws to increase or diminish the distance. The usual plan is to place it within about 1½ inch space at the feeding part, and gradually to diminish the distance to an inch or ¾ of an inch at the lower end, where the straw is delivered upon a fixed harp or riddle, through which such part of the grain as is not driven through the wired part of the concave falls, while the straw is removed by forks. The thrashing part, commonly called the barn-work, occupies a space of 6 feet by 4½, and together with the apparatus by which motion is communicated (which is made either for two, three, or four horses' power), may at pleasure be elevated upon a pair of wheels and axle, and thus removed by two horses."—One of the most highly improved and most efficient and economical of these machines is Garrett's four-horse power, which is figured in its travelling position in *Plate LX.*, and is described as follows in its manufacturer's catalogue:—"The requisite speed of the drum is gained by three motions, or pairs of wheels, instead of two only, as was formerly the case; and this alteration, combined with the general improvements throughout the machine, has considerably added to its ease in working, and lessened the wear and tear. It is fitted with an iron horse-wheel, turned on the upper and under surfaces of the rim in a lathe, to admit of toothed segments of eight parts, securely bolted to the rim with a seating of wood between, rendering the wheel perfectly true, and gearing properly with the pinion wheel that it drives, instead of having cogs cast on the rim as heretofore; so that when the teeth are worn or accidentally broken, one or any number of parts may be replaced by the attendant of the machine, without a mechanic; it is also turned on the upper surface of the rim, to afford a true bearing for the friction wheel. The drum or thrashing cylinder is made entirely of iron, with five beaters, peculiarly formed of wrought iron, extremely light and strong, occupying less than the space of four wood beaters, and thus giving one-fifth more thrashing power without increased speed or friction. The concave that surrounds the drum is likewise formed of wrought-iron ribbed plates, rendering the whole of the thrashing part less liable to breakage and very easy to repair. There is a bridge or cover of iron for the leading bar, which has an extra joint and bearing outside the horse-walk, so that that part of the bar which the bridge covers lies horizontal, that the horses may step over, without a possibility of injury; and being attached to the horse frame with a bolt only, it is easily taken off for the convenience of carriage. This addition is the more essential when the barn floor, upon which the thrashing power stands, lies higher or lower than the horse-walk; as the end of the spindle, next the barn-work, may incline upwards or downwards, as the situation may require. An arrangement is made for attaching the connecting bar to either side of the thrashing part, by shifting the driving wheel of the drum, so as it may be worked, with equal convenience, from either side of the barn or stack. The instrument used for loading and unloading the machine is a lever purchase, readily applied and managed by one man, and is extremely portable. An additional concave to surround the drum is also provided; and that, being substituted for the one used for general purposes, will effectually draw clover, vetchling, and other small seeds."

The bolting thrashing-machine is used for wheat in cases where the straw is required to be tied in bolts or bundles for sale in large towns, or in which it is wished to be perfectly straight and regular for particular purposes in the country; and when the machine is so constructed as to work well, it neither bends the straw, nor bruises it, nor in any other respect injures it. "This machine is not very dissimilar in general character from the Suffolk portable thrashing-machine, with the exception that the drum and concave are made of sufficient width to admit the sheaf lengthwise of the straw instead of presenting the ears foremost. The drum is not a skeleton with beaters, but is a cylinder entirely cased with plate iron, and forms what is called a 'whole drum.' Upon this the beaters, eight in number, are placed longitudinally; they are formed of small strips of iron projecting not more than ¼ of an inch. The concave extends about three-fifths of the circumference of the drum; and the sheaf is introduced between two feeding rollers, as in the older machines, in order to prevent too great a quantity or too thick a wad from choking and clogging the machine, which necessarily requires to be adjusted so as to leave but little space between the drum and concave. When this machine is required to thrash beans or pease, two wooden beaters, projecting about an inch from the surface of the drum, are added, and the concave is set at a proportionate dis-

tance." A highly improved variety of this machine, made by Messrs. Garrett & Son, is figured in *Plate LXII.*

Earl Ducie's thrashing-machine has been introduced to public notice within the last six years; it possesses both a high degree of merit and a considerable amount of novelty; it not only thrashes corn and winnows it, but sacks the grain for the market; it was pronounced by the judges at the Shrewsbury Meeting of the Royal Agricultural Society in 1845 "a powerful machine, meriting high commendation and encouragement, although possibly adapted to the very large rather than to the moderate-sized farm;" and declared by Mr. Ransome "excellent in the greater part of its detail, and the most complete of any that had fallen within the range of his observation." The following account of it is abridged from a description by Lord Ducie's manager, John Morton, in Mr. Ransome's volume: — "This machine is worked by a steam-engine of six-horse power. The corn is brought from the stack upon waggons running along a tram-road upon an inclined plane, to the doors of the building, whence, sheaf by sheaf, it is thrown by children into the buckets of an elevator, which, in its rotation, carries them to the feeding board. This feeding board is placed at a tangent from the drum parallel with its top; and, as in Lee's machine, and the portable machines in Suffolk and Norfolk, the feeding rollers are dispensed with; an endless web gradually carries the unthrashed straw to the feeding mouth, from which the revolving scutchers rapidly convey it to the concave. The drum is about 18 inches diameter, formed of sheet iron strained round a cast iron skeleton, accurately turned. Upon this the beaters, or rather scutchers, formed of angle iron with its edges planed, are so placed as to describe an angle with the surface of the drum, pointing forward in the direction of its motion; these project about seven-eighths of an inch. The screen, or concave, incloses the drum to the extent of about one-third of its circumference, and consists of four or five arched pieces of grating, three inches wide, jointed together. It is made of cast iron bars, having a square section placed so that every one shall present an edge to the passage of the straw, uniting (as is not uncommon in other machines) the fluted concave of the Scotch machine with the wired grating of the English ones. The screen is supported on iron bolts, so that it approaches to within about one-eighth of an inch of the edge of the scutcher. Spiral springs surround these bolts, which permit the bars of the concave to yield when too much pressure may at any time occur between them and the revolving drum. The grain is thus separated, most of it passing through the screen of the concave; but in order that no grain shall be allowed to pass away with the straw, it is thrown upon the shaker below. This is a moveable harp or screen, and is made of spars $\frac{3}{4}$ of an inch from one another, 2 inches deep, $\frac{3}{4}$ of an inch wide, and 6 feet long; they are 30 in number, and are thus arranged over a width of 3 feet 9 inches. These spars are fixed to two pair of frames,—the odd numbers, 1, 3, 5, &c., being attached to one pair, and the even numbers, 2, 4, 6, &c., to the other pair. These frames are supported by two iron shafts, each having two cranks projecting $3\frac{1}{2}$ inches on each side of them; the frames are attached to these cranks by arms with brasses, in which the cranks revolve; the shafts are connected together by a rod, so that they both move at the same time. In the revolutions of the cranks, everything attached to them also revolves; so that each point of the arms, frames, and spars revolves about a centre belonging to itself only. At the same time, the regularity in the length of the crank, and the uniform motion of the two shafts, has the effect of keeping the frames always parallel; their position at any one point being parallel to their position at any other. The blows occasioned as each series of spars strike the straw from beneath, effectually remove every particle of loose grain, while the shaker rapidly carries forward the straw, and at its termination deposits it in the straw-house, while the corn sifted out by its action falls before the blast of a fanner; and all the light grain and short straws thrown out by the first winnowing into the light corn spout is then taken up by another elevator, deposited again upon the feeding board, and passed a second time through the drum, in order effectually to separate any that may remain. After passing through another winnower, the thoroughly cleaned corn is taken up by a third elevator and dropped into a hopper, through which it passes into a sack, which is placed on a weighing machine, and it is there weighed and left thoroughly fit for market."

The choice of the moving power for a large thrashing-machine is sometimes a subject of grave consideration. Wind-power is inconstant, and not available for work during more than from 6 to 8 months in the year; so that, wherever thrashing work may be wanted at all seasons, this power must be supplemented by a horse-mill or a steam-engine. The cost of erecting a wind-mill, of the best materials and construction, including tower, may be fairly estimated at £350, exclusive of the carriage of building materials. Its annual tear and wear, from constant exposure, is very great, and this, whether working or not; and it requires the constant attendance of a person, to watch and regulate its motions.—Water may be regarded as the best of all moving powers; and is, under almost all practicable circumstances, the most economical; but of course can be available only in the immediate vicinity of a stream, of sufficient volume, and with a sufficient fall. The expense of a substantial water-wheel, including

mason-work of fall or mill-race, varies from £70 to £110; the average may be taken at £90. The forming of the water-course and tail-race seldom exceeds the cost of making a large open drain of the same length; but, in many cases, there is the additional expense of forming a reservoir for collecting and preserving the water, which, with the water-course and tail-race, may occupy a space equal to two acres of ground. The repairs of a water-wheel are trifling; and it requires almost no superintendence while working. If the supply of water is abundant, it is available at all times, without interrupting other labour.—Horse-power is facile and always available; but the expense of it is comparatively high, and cannot, without difficulty, be very closely calculated. The expense of a horse-wheel for a Scotch machine, including the building to cover it, cannot be reckoned at less than £120; and on a farm extending to 250 or 300 acres, a horse-mill occasions the keeping of a pair of horses more than would be necessary for labouring the farm, if steam or water-power were employed. The expense incurred by a pair of farm horses has been variously estimated by eminent agriculturists, who have turned their attention to the subject. Mr. Middleton of Middlesex estimates the expense of food, harness, shoeing, farriery, interest on purchase, decline in value, and insurance, at £157 10s. per annum; Mr. Brown of Markle, at £135 1s.; Mr. Kerr of Berwick, at £120; the General Report of Scotland, at £94 14s. 6d.; the West Lothian Report, at £90; and the Dumbarton Report, at £80. The average of these various estimates is £112 17s. 7d.; and this may be assumed as the average expense incurred by keeping an additional pair of horses. To this is to be added the expense of other two pairs of horses for every day the mill is employed; and being the severest labour to which farm horses are ever applied, it not only wears them out faster, but, from overheating them, occasions many diseases. Add to this, that while the horses are engaged at the thrashing machine, field-labour, however urgent, must, for the time, be suspended. The usual diameter of the horse-walk for a Scotch machine is 25 feet. The best speed for the horses is their ordinary pace, equal to 2½ rounds of a horse-walk of 25 feet diameter, per minute, or about the rate of two miles per hour. When a spur horse-wheel is employed, the diameter is 28 feet; and when a face-wheel, the diameter is 18 feet. The face-wheel seems preferable, being not only easier for the horses, but admitting of the least complicated and most advantageous mode of connection with the thrashing-machine. Thus, with a face-wheel, the mode of connection is by a horizontal lying shaft, with a large spur-wheel inside driving the drum-pinion, while the rollers and rakes, by means of a pitched chain, receive their motion from this lying shaft, without the intervention of other shafts and wheels.—Steam power is available at all times, without interrupting field-labour; and, when water power cannot be had, saves the expense of a pair of horses. With a properly constructed thrashing machine, a four-horse power steam-engine, on the high-pressure principle, is capable of doing as much work as can be done with a six-horse engine, applied to one of inferior construction; and hence it may be inferred, that, for farm purposes, a four-horse engine may be held as a sufficient power. Assuming this, the expense will be, for the engine, £110; for the engine-house and chimney-stalk, about £70; and for making a well, from £5 to £7. The engine requires the attendance of a handy person, who may also act as fireman. The cost of repairs does not much exceed that of the horse-mill. The only other item is the cost of fuel. If chew-coal or culm can be obtained, its price, exclusive of carriage, may be taken at 3s. 6d. per ton; and ten cwt. will be the consumpt per day of ten hours.

Whatever be the moving power used, it should be made to act with an equal force throughout the whole operation of thrashing the same stack. An unequal application of power deceives the man who has the charge of supplying the mill with sheaves. If he have a dread of uncertainty, he may put in too much at one time, when the machine will not be able to thrash the straw clean of its corn; and if, on the other hand, the sheaves be supplied too scantily, the wind of the winnowing-machine may prove too powerful, and blow away some of the good grain among the chaff. To insure regularity of motion, in the case of horse power, it is necessary for the man who drives the horses to walk round in a contrary direction to them, so that he may nearly meet each horse twice in the course of one circuit; and, in the case of water power, which will gradually fail as the height of water in the dam sinks down, the sluice should be drawn farther up, so that the same depth of water may always flow upon the wheel. A short time's experience will enable any man who has the charge of a thrashing-machine to acquire these minutiæ in practice; and the neglecting to attend to them, may cause a greater loss in a waste of grain, or, what is always valuable on a farm, in a waste of time, than may at first sight be credible. When any small proportion of grain is either taken away among the straw, or blown away among the chaff, whenever a stack is thrashed, it is not only itself lost in the form of grain, but may afterward appear in the shape of growing corn among a green crop,—the manure for which is seldom fermented, but is carted out of the courts and applied to the land; and it may give rise to a very injurious fama against the credit of the farmer's management.

Hand thrashing-machines are now made, of various sizes and of excellent construction, by some of the principal agricultural implement manufacturers, for use on small farms; and in

all instances, they merely thrash corn, or leave it in the same condition as the flail, without performing any winnowing operation. One of the oldest of any note was introduced to public notice about twenty years ago by the Very Reverend Principal Baird; and this consists merely of a chain with its beaters and other thrashing appliances, and has a toothed pinion on its axis, and is worked by means of a toothed wheel, with handle and large regulating fly-wheel,—the pinion having 6 teeth and the wheel about 50, so that, by making 20 revolutions of the handle per minute, the chain with its beaters is impelled at the rate of 200. This machine, however, absorbs a comparatively great amount of power, and requires the labourers employed upon it to be relieved at intervals, and has never come into general use. Ransome's, which obtained the commendation of the judges at the Liverpool meeting of the Royal Agricultural Society, is made on a different principle, and moved by means of a lever on the one side and a crank handle on the other, and worked by four men, who relieve one another by change of motion. Two of the most convenient in use, and at the same time distinguished for efficiency, are Garrett's large-sized hand thrashing-machine, which may be worked either by four men or by one horse, and Garrett's middle-sized thrashing-machine, which is just equal to the power of two men.

The quantity of work done by the thrashing machines of former days, particularly when compared with the cost of erecting them and the amount of accompanying labour in working them, was very unequal, and throws great light, in the way of comparison, upon the working efficiency of the best machines of the present day. The following instances, extracted by Mr. Ransome from the Agricultural Reports, may be taken as a good specimen:—

	Thrashing per Day.
In the reports of Roxburgh and Selkirk, in 1796, R. Douglas states that mills by water, or with 4 horses, would do great execution.	25 or 30 bolls, or from 150 to 180 bushels.

In the report of Norfolk, in 1804, Arthur Young gives an account of machines which belonged to the following parties:—

Droziers, Reedham, built by Wigfull, cost £120, worked by 7 persons and 6 horses.	40 co. wheat, or 50 co. barley, or 60 co. oats or pease.
Farrow, Shipdam, built by Wigfull, worked by 7 persons, and by 4, 5, or 6 horses.	20 co. wheat, or 30 co. barley, or 40 co. oats or pease.
Beck, Castle Rising, built by Wigfull, cost 200 guineas, worked by 6 persons, and 4, 5, or 6 horses.	32 co. wheat, or 64 co. barley, or 80 co. pease.
Whiting, Tring, built by Fordyce from Scotland, cost £200, worked by 6 persons and 6 horses.	24 co. wheat, or 55 co. barley, or 63 to 84 co. oats.
Bevan, Riddlesworth, built by an engineer from Leith, cost £100, worked by 10 men and 8 horses.	40 co. wheat, or 40 co. barley, or 50 co. oats.
Coke, Holkham, cost £600, worked by 12 men and 8 horses.	64 co. wheat.
Reeves, Heverland, built by Assby, Blyboro', cost 100 guineas, worked with 2 or 3 horses.	30 co. wheat, or 32 co. barley, or 40 co. pease.
Styleman, Smithsham, cost £300, worked by 10 persons and 8 horses.	80 co. wheat, or 120 co. barley, pease, or oats.
In the report of Kent, R. Boys, in 1805, remarks on the only thrashing-mill then in Kent, which, by a number of improvements, and after many alterations, he finds to answer extremely well; and he states that it requires 4 horses and 12 men to work it.	24 qrs. wheat, or 32 qrs. barley, or 40 qrs. oats.
In Sir John Sinclair's *System of Husbandry*, published in 1812, we find an account of R. Kerr's machine, which, with 6 horses, 4 men, and 4 women, would thrash	50 bolls, or about 300 bushels of wheat.

An ordinarily good Scotch thrashing-machine of the present day, even though it possess none of the improvements which have been introduced within the last ten years, if a two-horse power, ought to thrash and clean, on the average, 14 bushels of wheat or 20 of barley or oats in the hour, and requires an attendance of 5 persons,—if a four-horse power, ought to thrash and clean 26 bushels of wheat or 32 of barley or oats per hour, and requires an attendance of 7 persons,—if a six-horse power, ought to thrash and clean 32 bushels of wheat or 38 of barley or oats per hour, and requires an attendance of 9 persons,—and if an eight-horse power, ought to thrash and clean 38 bushels of wheat or 44 of barley or oats per hour, and requires an attendance of 10 persons. A good four-horse power portable thrashing-machine, such as is made by the Messrs. Ransome and the Messrs. Garrett, ought, on the average, to thrash about 40 bushels of wheat or of mown barley in the hour, provided the crop have been reaped in fair condition; and two of these machines, when worked under stimulated exertion at the meeting of the Royal Agricultural Society in 1841, actually thrashed each a little upwards of 61 bushels; yet every such machine suffers enormously in comparison with a Scotch one, as it thrashes only and does not clean, and requires to be attended by no fewer than eight men and five boys. A good English hand thrashing-machine, worked by a power of four men, ought to thrash from 10 to 12 bushels per hour of wheat of average yield and in fair condition, but will thrash proportionally less of wheat which is either poor in yield, long in the straw, or reaped with the scythe.—*Ransome's Implements of Agriculture.—The Annual Register of Agricultural Implements.—Reports upon Shows of Agricultural Implements in the Journal of the Royal Agricultural Society.—The General Report of Scotland.—Communications to the Board of Agriculture.—Cata-*

THREAF. A handful, pottle, or bundle.

THREAVE. Twenty-four sheaves of corn.

THRESHING. See THRASHING.

THRIFT,—botanically *Armeria.* A genus of ornamental, small, evergreen plants, of the plumbago family. It was formerly included in the genus statice; and, as now constituted, it comprises two indigenous species, and about 18 exotic ones,—all of which have been introduced to Britain, and deserve a place in the flower-garden. One species is a greenhouse shrub of about 2 feet in height; and all the others are hardy perennial herbs, varying in height from 4 to 25 inches. Most of the species have pink flowers; and the others have either scarlet, crimson, purple, flesh-coloured, or white flowers. Nearly all thrive best in a soil of sandy loam; and all are propagable by radical division.

The sea-side thrift, or sea-pink, *Armeria maritima,* called by the older botanists *Statice armeria,* abounds on the marshy sea-shores of many parts of Britain. It occurs chiefly in places which are regularly overflown at high water; and it sometimes adorns great tracts of sea-marsh, and renders them deeply verdant at all seasons, and brilliantly beautiful during the season of bloom; and it is raised and cultivated in many a flower-garden as an edging for borders. Its leaves are very narrow, short, and plain; its stems seldom rise more than 4 inches high; and its flowers grow in small dense heads at the top of the stems, and have a red or flesh colour, and bloom from May till July.—The mountain thrift, *Armeria montana,* grows wild on some of the lofty mountains of the Scottish Highlands, and is about the same height as the preceding, and has pink-coloured flowers, and blooms in May and June.

The common thrift, *Armeria vulgaris,* is a native of the Alps and of other cold mountains of Continental Europe, and was long ago introduced to Britain, and has long been more or less esteemed as an edging-plant for flower-borders, and is often mistaken for the sea-side thrift. Its roots are fibrous, and divide into heads; its leaves are numerous, narrow, and grass-like, and have three corners at their base, and sit close to the root-heads; the stems rise from the embrace of the mutually overlying parts at the bases of the leaves, and are naked and about 6 inches high; and its flowers grow in heads, on one common scaly calyx, at the top of the stems, and have a pale purple colour, and bloom from June till August. A variety of this species has bright red flowers, and makes a much better appearance, and is more esteemed for edgings, than the normal plant.—The broad-leaved thrift, *Armeria latifolia,* has much larger leaves, and much loftier stems, than the common thrift, and carries light red flowers from May till July; and it was introduced to Britain upwards of a century ago, and makes considerable claims on the cultivator's attention; but it differs from almost all the other thrifts in loving a soil of a somewhat peaty kind.

THRINCIA. A genus of yellow-flowered herbaceous plants, of the succory division of the composite order. The simple-haired species, *T. hirta,* grows wild in the grass lands of some parts of Britain; and is perennial-rooted, and has a height of about 20 inches, and blooms in July and August. Two annual species, and a tuberous-rooted one, all hardy and about a foot high, have been introduced from other countries; but neither these species, nor the indigenous one, possess much interest.

THROATING. The mowing of beans against their bending. This is done only with a thin crop.

THROATWORT,—botanically *Trachelium.* A genus of exotic, ornamental, herbaceous plants, of the bellflower family. The blue species, *Trachelium cæruleum,* grows naturally in shady woods in many parts of Italy, and was introduced to Britain in 1640. It is a hardy biennial or short-lived perennial. Its root is fleshy and tuberous, and sends out many wide-spreading fibres; its radical leaves are ovate-lanceolate, serrate, pointed, and about two inches long and one inch broad; its stems are irregularly garnished with similar leaves to the radical ones, and have a height of from 18 to 25 inches; and its flowers grow in compound, many-flowered umbels, and have a small funnel-shaped corolla of an azure colour, and bloom from July till September. This plant is propagated from autumn-sown seeds, and loves a soil of rich mould, and also thrives well and maintains itself for an indefinite period and makes a fine appearance upon old walls which contain a sufficient quantity of soil for the lodging of its seeds and the anchoring of its roots.—The name throatwort is likewise borne by a beautiful indigenous plant of the bellflower genus. See the article BELLFLOWER.

THRUSH,—scientifically *Turdus.* A large and interesting group of passerinous song-birds. They have a compresed and arcuated bill, not hooked in the point, and graduating off, in some of the species, into a resemblance to that of the shrikes; and they have solitary habits, and feed for the most part on berries or similar fruits. One great subdivision of them, comprising the blackbird and the brown thrushes, have the colours of the plumage uniform or distributed in large masses; and another large subdivision, comprising the

truest or spotted thrushes, or what the French call grives, have the plumage marked with small black or brown spots.

Three of the best known British species are noticed in the articles Blackbird, Fieldfare, and Redwing; and some others are glanced at in the article Hedge-Birds. The ring-ouzel, ring-blackbird, or stirling, *Merula torquata* or *Turdus torquatus*, is a bird of passage, and frequents highland districts. Its feathers are black, partly edged with white; and its breast is marked with a shield of the same colour.—The missel-thrush, *Turdus viscivorus*, is eleven inches long, and has a prevailingly brown colour of plumage, but is white on the under surface of the body, tinged with yellow, and profusely marked with black spots. Its eggs are 4 or 5 in number, one inch and three lines long, eleven lines broad, and of a greenish-white colour, spotted with dark red brown.—The song-thrush, *Turdus musicus*, is rather less than nine inches long, and has the under parts of the wings yellow, and is a better songster than any other of the European true thrushes. Its nest is formed of green moss and fine roots; and its eggs are 4 or 5 in number, one inch and one line long, ten lines broad, and of a beautiful light blue colour, with a few black spots.—White's thrush, *Turdus Whitæ*, is a rare and recently observed species, measuring 12½ inches in length. The species of thrushes foreign to Europe are very numerous.

THRUSH. A diseased condition of the sensible frog of the horse's foot. It results from inflammation, and occasions the secretion and discharge of a fetid, semipurulent fluid, and is remotely caused by contraction of the foot, or by the heat and foulness of the stable. It commonly has its primitive seat in the cleft of the frog; and it is supposed to drain off morbid matter from other parts of the system, so as to prevent or obviate other diseased affections; and when, on the one hand, it is suddenly checked, it is liable to occasion derangement of some other organ, while, on the other, if it be neglected or abused, it is liable to degenerate into canker. It always involves so much tenderness as to occasion limping for a few steps after the foot presses upon a stone; and it may generally be regarded as an indication of the commencement or progress of contraction in the foot; yet it does not often produce absolute lameness, and seldom impairs in any serious degree the general usefulness of the animal. The proper treatment of it is to remove or reduce the causes which excite it, to pare away ragged parts so as to lay quite bare the diseased surface, to apply lotions and brushings and soakings of any suitably diluted mineral astringent, such as a solution of blue or white vitriol or a mixture of tar and diluted sulphuric acid, and, in bad cases, to employ poultices for two or three days, or stimulating stoppings every day or every alternate day, according to the symptoms and other circumstances.

THRUSH. A disease of the mouth of cattle and sheep. See the article Aphthæ.

THRYALLIS. A small genus of ornamental exotic plants, of the barbadoes cherry family. The short-spiked species, *T. brachystachys*, is a very handsome, yellow-flowered, evergreen, hothouse climber, of about 10 or 12 feet in height, blooming throughout most of autumn, loving a soil of peat and sand, and propagable from cuttings; and it is a native of the tropical parts of South America, and was introduced to Britain in 1823.

THUJA. See Arbor Vitæ.

THUNBERGIA. A genus of highly ornamental, exotic, evergreen, climbing and twining plants, of the acanthus family. The golden-eyed species, *T. chrysops*, was introduced to Britain from Sierra Leone in 1844; and is a fair specimen of the whole genus. It has a herbaceous or sub-shrubby character, and a neat habit, and admits of being so trained as to be all-over ornate from root-crown to summit. Its leaves are opposite, somewhat heart-shaped, minutely serrated on the margin, and acutely angular at the point; and its flowers are numerous, large, delicate, and showy, and come out singly at the axils of the leaves, and have a funnel-shaped corolla with an out-spread mouth,—the eye or centre of a golden colour, surrounded by a belt of light blue, and the outer portion, comprising five broad segments, of a rich dark purple colour.—The winged species, *T. alata*, introduced from the Cape of Good Hope in 1824, and suitable for greenhouse cultivation, is the best known species, and has a deep purple eye and either a yellow or a white expanse.—Seven other species, varying in height from 3 to 10 feet, with severally scarlet, white, yellow, and blue flowers, all requiring hothouse culture, and most blooming from May till September, have been introduced from India, Nepaul, Madagascar, and the West Indies.—Most of the species love a soil of peaty loam, and are propagated from cuttings; but the winged species does best to be propagated from seeds.

THWARTIL-ILL. See Louping-Ill.

THYMBRA. A genus of curious, exotic, evergreen undershrubs, of the labiate order. The spike-flowered thymbra, or mountain Macedonian hyssop, *T. spicata*, is a native of Syria, Greece, and Spain, and was introduced to Britain about the close of the 17th century. It has a heath-like appearance; and branches out into slender, ligneous, leafy stalks of 6 or 8 inches in length, covered with brown bark; and emits from its bruised foliage an aromatic odour. Its leaves are sessile, narrow, acute-pointed, and about ½ an inch in length; its floral spikes grow terminally on the stalks, and are thick, close, and nearly two inches long; its calyxes are stiff and hairy; and its corollas have a purple colour, and are two-lipped, and peep out of the calyxes, and bloom in June and July. Two other species occur in

British collections; and all are propagated from cuttings, and require a little winter protection.

THYME,—botanically *Thymus*. A genus of ornamental, evergreen undershrubs, of the labiate order. Three species grow wild in Britain, and at least 30 have been introduced from Continental Europe and Northern Africa. Nine or ten of the species are creeping or procumbent, and all the others are erect; a small number have white, striped, or red flowers, and all the others have purple flowers; a few are 12 or 15 inches high, and the rest vary in height from 3 to 10 inches; five or six require a little winter protection, and all the others are quite hardy; two or three require a soil of rich mould, and the rest thrive in any common soil or in sandy loam; some are most readily propagated from seeds or by radical division, and the rest are propagated from cuttings; one is cultivated for culinary and medicinal purposes, and the others are merely or principally ornamental, and all are more or less fragrant, aromatic, and pungent.

The wild thyme, or mother of thyme, *Thymus serpyllum*, abounds on the heaths and the dry mountainous pastures of many parts of Britain. It has a procumbent habit, and a height of about 3 inches, and blooms from June till August. The normal plant has purple flowers and no fragrance; but one variety, called the white-flowered, has white flowers,—another, called the shrubby, has pale red flowers,—another, called the variegated, has variegated leaves,—another, called the narrow-leaved, has an odour similar to that of the leaves of the walnut-tree,—and another, called the lemon, emits an agreeable aromatic fragrance similar to that of lemons. Several of the varieties are allowed a place in flower-gardens, on account of their beauty or fragrance; and the lemon one requires always to be propagated from slips and cuttings. Pastures and moorlands overrun with wild thyme have long and generally been known to produce a superior flavour of mutton and venison; but whether they owe their excellency to the sheep and deer eating the thyme itself, or to their eating the peculiar combinations of herbage with which it is associated, or to the influence of the qualities of soil and climate which render it luxuriant, is matter of dispute.

The outdrawn thyme, *Thymus exserens*, is a native of the heaths and mountainous pastures of Britain, of very similar habit and height and time of blooming to the wild species.—The woolly thyme, *Thymus lanuginosus*, is a native of some parts of Scotland, and also grows procumbently, and carries purple flowers from June till August.

The common or garden or culinary thyme, *Thymus vulgaris*, is a native of the South of Europe, and was introduced to Britain about the middle of the 16th century. It has an upright habit, and a height of about a foot, and carries purple flowers from May till August; and it comprises one variety with comparatively broad leaves, another with variegated leaves, and another with yellowish colour and a lemon-scented odour. The variegated is cultivated almost solely for sake of its ornamental foliage; but the other varieties are cultivated for sake of at once the ornateness of their appearance, the pleasantness of their living fragrance, the essential oil which they yield by distillation, the medicinal aromatic uses of their herbage and oil, and various culinary and flavouring uses of their tops. Thyme, though strictly a perennial, becomes stunted after three or four years, and requires, at comparatively short intervals, to be reproduced. A light, dry, and rather poor soil is most conducive to its best condition; and a rich or a moist soil renders it luxuriant, but occasions it to be deficient in fragrance, and greatly tends to make it perish in winter. The situation cannot be too open. The plant may be propagated either from top-slips or parted roots in spring, planted 6 or 12 inches asunder, or from seed sown in April, broadcast or in drills; and the plantlets from seed may either be transplanted in summer or allowed to remain in the drills,—and those transplanted must be occasionally watered till they become established. In autumn, decayed stems and branches should be cleared away, and a little fresh soil scattered among the old plants. Young plantlets of thyme may be planted close along the margin of a border to serve as an edging.

THYMELÆA. See Olive (Wild).

THYSANOTUS. A genus of ornamental, herbaceous, Australian plants, of the asphodel order. The name signifies "fringed," and alludes to a beautiful fringe upon the three inner sepals. Seven or eight species—some tuberous-rooted, others fibrous-rooted, and most purple-flowered and from 6 to 15 inches high,—have been introduced to the greenhouses of Britain. The stem and branches of one, *T. intricatus*, are very curiously and complexly interwoven; the foliage of some is scanty, yet harmonizes well enough with the inflorescence; and the bloom of several, particularly of *T. proliferus*, is very abundant, while that of most remarkably combines quiet beauty with striking singularity. One of the finest in appearance, as also one of the earliest in bloom, is *T. tuberosus*, about a foot high, and introduced in 1825. Most love a soil of sandy peat, and are propagated from offsets.

THYSSELINUM. See Milk-Parsley.

TIARELLA. A genus of ornamental, exotic, herbaceous plants, of the saxifrage family. The name signifies "a little diadem," and alludes to a sort of mitred structure in the capsule. The heart-leaved species, *T. cordifolia*, is a native of North America, and was introduced to Britain in the former part of last century. It is a hardy evergreen. Its root is fibrous, creeping, and reproductive; its leaves are numerous, heart-shaped, unequally indented, and of a light green colour, and come out on slender footstalks of about 3

inches in length from the crown of the root; its flower-stems arise from among the leaves, and attain a height of from 4 to 6 inches; and its flowers grow in loose terminal spikes, and are small, of a herbaceous white colour, and bloom in April and May. Two other species of similar character, but with taller flower-stems, have been introduced from North America and Nepaul; and all are propagated by radical division.

TIARIDIUM. A small genus of ornamental, tender, blue-flowered, annual plants, of the borage family. Two species, the velvety and the Indian, both about a foot high, have been introduced to Britain from the West Indies.

TICK. A parasitical insect, similar to a louse, and infesting sheep and dogs. It is many times larger than a louse, and of a different colour, but not of so frequent occurrence. It varies in size from a pin's head to a small bean, but is commonly about as big as a pea; and when not gorged with blood, it is flat,—but, when bloated, is round and of a brown or black colour. It has six legs, and runs with much speed; and attaches itself to the skin by means of sharp claws at the extremity of the legs, and pierces the skin by means of sharp instruments in its head; and when once it fastens on a spot, it seems to remain quite fixed for several weeks or even months; and it becomes surrounded with numerous young ones, who appear at first like red points, but afterwards acquire a brown colour as they grow. It propagates rapidly; and is often found in great numbers on a single sheep; and commonly prefers the animal's neck and shoulders to other parts. It is thought by some persons to breed upon the ground, and to spend only the later stages of its existence upon sheep; and certainly it frequents some farms and districts far more than others, and is seldom found on some badly managed farms where it might naturally be expected, and cannot without great difficulty be banished from some well-managed farms and very healthy flocks where it might be supposed not at all to occur. It is, of course, a sad pest to the animals whom it affects, destroying their peace, diminishing their fleece, and disturbing the general economy of their health and growth; and it ought, in every case, to be promptly and exterminatingly attacked. One effectual remedy is rubbing with mercurial ointment, but is liable to produce salivation or dangerous exposure in unsuitable seasons or weather; another effectual remedy, at times when the mercurial ointment cannot be prudently applied, is washing with tobacco-water, but lies under the disadvantage of giving a depreciating tinge to the wool; another efficient remedy, at all times, is dipping in a solution of arsenic, but involves the risk of terrific casualties to both man and beast from the use and presence of so dreadfully poisonous an agent; another always efficient remedy is washing with a lotion of one ounce of corrosive sublimate, one-fourth of a pint of spirit of wine, and three quarts of water, but is liable, in a large degree, to the same objection as the preceding; another, almost equally efficient, and somewhat less objectionable, is washing with a lotion of two ounces of tobacco, $2\frac{1}{2}$ ounces of soft soap, 11 lbs. of white calx of mercury, and 8 gallons of water; and another, considerably less efficient, but correspondingly less unobjectionable, is the application of linseed oil or of turpentine. Careful hand-picking is practised by some shepherds; and of course is efficient as far as it goes, but, in all bad cases, is an endless and quixotic task. See the articles Sheep, Salving of Sheep, and Fly-in-Sheep.

TICKSEED, — botanically *Corispermum*. A genus of exotic herbaceous plants, of the goosefoot family. About a dozen species, all hardy apetalous annuals, blooming about the end of summer, and varying in height from 6 to 20 inches, have been introduced to the botanical collections of Britain, principally from Eastern Europe and Northern Asia; and some other species are known. Both the popular and the botanical names refer to the bug-like form and appearance of the seed.

TIDES. The ebb and flow of the sea are evidently connected with the moon's motions. The level of the ocean is slightly disturbed by the attraction which is alternately exerted and withdrawn. The waters, for a large space under the moon, being more attracted than the great body of the earth, are thus rendered lighter than those parts of the ocean which are at the same distance as the earth's centre; and, being lighter, they are forced upwards a little by the surrounding mass, which is heavier; just as water and oil will stand at different heights in the two branches of a siphon tube; or just as ice, which is lighter than water, is made to rise a little higher, on that account, when placed in water. If the earth rested immoveably upon a fixed support, there would be a tide, or rising of the waters, only on the side towards the moon. But the great body of the earth is just as free to move as a single particle of the ocean, and, if suffered to yield to the moon's attraction, would be carried just as fast. Hence, for the same reason that a particle of water, on the side of the earth towards the moon, is drawn away from the centre, or has its downward tendency diminished, so the solid earth itself is drawn away from the mass of waters, on the side of the earth farthest from the moon. It is the difference of attraction in both cases, between the surface and the centre, which causes the lightness of the waters, and the consequent elevation. It will be seen, therefore, that, taking the whole earth into view, there are always two high tides diametrically opposite to each other, and two low tides also, mid-way between the high ones. The high tides are two great waves, or swells, of small height, but extending each way through half a right angle. These waves follow the moon in its monthly

motion round the earth, while the earth, turning on its axis, causes any given place to pass through each of these swells and the intervening depressions in a lunar day, or twenty-four hours fifty minutes. What we have said with respect to the moon's influence in disturbing the level of the ocean, may be applied also to that of the sun; only, in the case of the sun, although its absolute action is about double that of the moon, yet. on account of its very great distance, its relative action upon the surface of the earth, compared with that at the centre, is but about one third as great as that of the moon. At new and full moon, when the sun's and moon's actions conspire, the tides are highest, and are called *spring tides.* But at the first and last quarters of the moon, the action on one body tends to counteract that of the other; and the tides, both at ebb and flow, are smallest, and are called *neap tides.* We have supposed the highest tides to happen at new and full moon, and the lowest at the quarters. But the waters do not yield instantly to the action exerted upon them; the greatest effect takes place some time after the attractive influence has passed its point of greatest power. Thus the spring and neap tides actually occur about a day and a half after the times above indicated. So, also, for a similar reason, the real time of high water, in the daily tides, happens about three hours after the moon has passed the meridian.

It will be perceived, from what has been said, that the sun's and moon's influence will vary with a change of distance, being greatest when the attracting body is nearest, and *vice versa.* The phenomena of the tides are modified, moreover, by the situation of the sun and moon with respect to the equator, and the particular latitude of the observer. When, for instance, the moon passes near the zenith of the observer, supposed to be in one of the temperate zones, the opposite high tide will be in the same latitude on the other side of the equator; consequently, under the above circumstances, the high tide, when the moon is above the horizon, exceeds the high tide when the moon is below the horizon; and at a point in the direction of the nearest pole, fifty degrees from the place where the moon is vertical, there will be only one tide in twenty-four hours. The different heights to which the same tide rises, in places but little distant from each other, depend upon local circumstances; as the particular form of the coast, the meeting of currents, &c. Where a bay grows narrower and narrower, like a tunnel, as it runs up from the ocean into the land, the swell of water must rise higher as the passage becomes more contracted in breadth. Thus, in the bay of Fundy, which answers to this description, and is of great extent, the tide sometimes rises to the height of seventy feet. It is frequently asked, why there are not tides in the inland seas and larger lakes. If we observe, upon an artificial globe, the very small space occupied by the largest bodies of water of this description, we shall readily perceive that there can be no appreciable difference in the action of the moon upon so small a portion of the earth's surface; the whole of the lake, or sea, therefore, becomes lighter when the moon is over it, and there is no heavier mass of water ninety degrees distant to force it above its natural level.

TIGER-FLOWER,—botanically *Tigridia.* A small genus of hardy, bulbous-rooted, herbaceous, magnificently-flowering, Mexican plants, of the iris order. The peacock species, *Tigridia pavonia*, called by Linnæus *Ferraria tigridia*, was introduced to Britain in 1796, and is well known to all amateur florists as one of the most gorgeous glories of the parterre. Its bulb is tunicated, and of smaller size than that of the common narcissuses; its leaves rise from the root-crown, and are lanceolate, channelled, erect, large, and of a bright green colour; its floral footstalks rise from among the leaves to the height of about 10 or 12 inches; and its flowers are as large as those of the largest irises or lilies, and display the most brilliant mixtures and spottings of orange and red, in the manner of the tiger's skin, and are so startling and superb as, at the very first glance, to astonish and delight even the most apathetic observers, and may be made to bloom in succession from May till September, but are individually among the most evanescent of sublunary grandeurs, and last each during only a part of one day, and scarcely unfold their magnificence to the sun or the breeze till they begin to wither and die. A variety called the lion-flower, *T. p. leona*, and a species called the shell-flowered tigridia, *T. conchiiflora*, were introduced in 1823; and the latter has a predominance of dark yellow in its corolla, and is scarcely less beautiful than the normal tiger-flower, yet does not display the same diversity and depth and brilliancy of tints. All the three kinds love a soil of sandy peat, and are propagated from offsets, and may be grown in clumps or beds of the open ground, in the same manner as any other hardy bulbous-rooted bloomers. The common treatment is to cut down the stems and take up the bulbs in autumn, and to replant the latter in a dried state in spring; but a much better one is to lift the plants in autumn with balls or masses of attached soil, to put them in pots of sufficient capacity to admit the attached balls, and to keep these in a cold pit till the time of replanting in spring.

TIGLIUM. See Croton.

TIGRIDIA. See Tiger-Flower.

TILE. A thin brick fabric, either flat, undulated, semi-cylindrical, tubular, or of any other form. Tiles of various kinds have, in recent times, come into very extensive use in georgy as materials of subsoil drains; and, in consequence, possess great interest to all persons who have any sort of connexion with agriculture,—and very eminently to farmers and landed proprietors. A

notice of the principal varieties hitherto used, as well as of their comparative merits, and of the methods of employing them, occurs in the last section of our article on DRAINING; and a further notice of the comparative merits of some of the best of these, as well as some hints on the processes of manufacturing them, may be proper in this place.

Three different kinds of tiles—one tiles and soles, another tiles and covers, and another pipe tiles, all prime of their respective classes, and each comprising several sizes or varieties—were prominently noticed about six years ago, in connexion with an award of silver medals by the Royal Agricultural Society of England to the Tweeddale Patent Tile and Brick Company of London for their hand-tile machine, invented by the Marquis of Tweeddale,—to Mr. Etheredge of Woodlands, near Southampton, for his new patent machine for making tiles and covers,—to Mr. John Read of London, for an invention of cylindrical or pipe tiles,—and to Messrs. Ransome of Ipswich, for a Beart's brick-machine, improved by Mr. A. Stickney of Ridgemont, Holderness. The dimensions, weight, and price of these various tiles were as follows:—

Kind of Tile.	Internal Dimensions.	Area.	Weight per thousand.	Length.	Weight per 1000 feet.	Lineal feet per ton.	Thickness of Material.	Price per thousand.	Price per 1000 feet.

The machine for making the Tweeddale tile is well known, and needs no description. Its advantages consist in economising the labour of making to a small extent, in giving a greater certainty to the quantity made, and in producing a better article than tiles of the same kind manufactured in the ordinary manner. The superior quality arises from the greater density given to the clay in passing through the machine than can be obtained by hand labour. The machine requires a man and a stout lad to work it, and two boys to carry the tiles to the drying shelves; and it is adequate, in a fair season, to the production of about 600,000 tiles, and as many soles. Its present price is £40; and it requires a pug-mill, and the usual appurtenances of a tilery.

Mr. Etheredge's machine consists in the adaptation of a series of dies of a peculiar form to the bottom of a pug-mill, through which the clay is expressed, and received on mandrils answering to the form of the die. The mill erected at his works at Eling, and substantially made by Messrs. Ransome, contains eight of these dies. It is driven by one horse at a time; and by changing the horse every three hours, the constant working of it can be satisfactorily performed by two blind but able horses. This machine is represented as capable of producing 1,000 tiles and as many soles or covers per hour; but it may, perhaps, be advisable to consider its average work in a season at 8,000 per day. The hands employed are one man to fill the mill,—two boys to cut off the pipes and place them on barrows,—one man and a boy to wheel away and set them to dry on frames, provincially termed hakes, covered with cloth, supported on iron standards, and two men, a boy, and a burner to fill the kiln, burn, and draw the tiles, the kiln holding 36,000. Much ingenuity has been exercised in the construction of the mill and dies. Two tiles and two soles or covers are comprised in each pipe extruded from the machine, which being nearly severed within in four vertical lines whilst passing through the die, breaks by the shrinkage consequent on drying into four parts. The form, dimensions, and substance of the tile may be varied from the perfect hollow cylinder, to the oval, horse-shoe, angular, or any other desirable figure. The price of the mill with eight dies is £43, and proportionally less or greater for smaller or larger machines; and the cost of an establishment will vary from £150 to £350, according to the number of tiles required to be made during a season.

The pipe-tile machine is of the simplest construction, and costs only about £6 or £7. It consists of a mere frame of wood, having a cross-bench or platform, upon which is placed an iron cylinder about 17 inches long, by $6\frac{3}{4}$ inches diameter, fitted with the mould or die at its bottom. Its capacity is about 608 cubic inches, which bulk of clay suffices for the production of 24 pipes of the smallest or No. 5 size. This cylinder, when filled with well-washed and pugged clay, is placed on the platform over a hole, and has an iron-ring on the top fitting the inside, upon which rests a wooden piston or plug attached to a cross-bar, which slides up and down in a groove formed in each upright of the frame. By means of a wooden axle connected by two short cords with the piston cross-bar, and a

handspike, the man forces down the piston, and expresses the clay through the die. The pipe is received by a boy on a stick, loosely fitting its bore, which also gauges the length of each pipe; and it is then cut off by a wire, placed on a hand-barrow, and carried to the adjoining drying-shed by another boy. One man and two boys make about 1,800 per day of the smallest sized pipe. It is requisite that the clay be well washed and sieved before pugging, for the manufacture of these tiles, or the operation of drawing them, would be greatly impeded by having to remove stones from the small space surrounding the die which determines the thickness of the pipe. But, it results from this necessary washing, that the substance of the pipe is uniformly and extremely dense, which consequently gives to it immense strength, and ensures a durability which cannot belong to a more porous though thicker tile. The clay is brought from the pug-mill so dry that, when squeezed through the machine, not a drop of water exudes; moisture is, indeed, scarcely apparent on the surface of the raw pipe. Hence, the tiles undergo little or no change of figure whilst drying, which takes place very rapidly by reason of their form and slight substance. They are placed in the kiln when containing only about 12 per cent. of moisture, in consequence of which there is but trifling loss in the burning; and each shrinks about 15 per cent. in its length between its raw state from the press and when burnt; yet these particulars will vary a little with the nature of the clay used. A manufactory of pipe-tiles may be added to any existing brick-field, at an expense of about £100, and for a less sum where kilns and pug-mills are in use. This estimate includes the machine with a single die, a pug-mill, washing apparatus, kiln, and drying-shed. The manufacture might be carried on throughout the winter by securing the raw pipes against frost. This would necessarily occasion some additional outlay, but it is thought would not enhance the cost of the tiles, as the hands would not lie idle. It is a consequence arising from the small dimensions and weight, together with the comparative dryness of the tile when produced, which properties diminish to a *minimum* the bulk of the material used, and the space required for manufacturing and drying. Such an establishment would suffice for the annual production of 540,000 tiles, which is equivalent to the annual drainage of about 240 acres of land, from 30 to 36 inches in depth, at a mean of about 20 feet between the drains, and at a cost not exceeding £3 per acre in clays and firm-bottomed soils, unencumbered with stones. Other important advantages attending the cylindric figure and light weight of the pipe-tiles, are the diminished cost of carriage, and the faculty of conveying them into the field by hand.

Time is the only criterion for forming a perfect estimate of the durability of such an article as the drain-tile; but density and toughness are acknowledged tests of good pottery; and it can scarcely be questioned that the densest tile will endure the longest in the ground. After a careful investigation of the solid contents and weights of the tiles registered in the table, the following facts appear as regards their density:—

	Weight. Oz.	
Tweeddale,	0·973	per cubic inch of matter.
Etheredge,	1·091	,,
Read, No. 1,	1·138	,,
,, 2,	1·174	,,
,, 3,	1·204	,,
,, 4,	1·322	,,
,, 5,	1·401	,,

These results seem to be in strict conformity with the degree of preparation of the earth, as well as with the nature and amount of the force to which the respective tiles are subjected in the apparatus employed; and it is seen that the density of the cylindric tile increases in the inverse ratio of the magnitude of the orifice through which the clay is expressed from the cylinder. It must, however, be borne in mind that, in order to render comparisons of this kind free from error, the clay of differently made tiles should be alike.

An establishment, with all requisite appurtenances, for making drain-tiles with Hatcher's machine—a considerably different one from any of those already glanced at—may be set up on any estate or farm at a cost of £25 for the machine, £10 for the pug-mill, £5 for the kiln, and £10 for the sheds and straw, or of £50 for the whole; and whenever the proprietor has made as many tiles as he wants for his own use, he may either continue the manufactory for the sale of tiles to others at a profit to himself, or sell his machine and his pug-mill at very nearly their original price. The machine, too, makes roofing-tiles of prime quality, at less than half the price of those made by hand, and of a much lighter, closer, and straighter character; and, in general, it highly recommends itself both by the simplicity of its construction, and by the small amount of hand-labour required to work it. All clay intended for use throughout any season must be dug as early as possible in winter, in order that it may undergo the most thorough exposure to the action of air and frost and snow. Care must be taken if there are small stones in it, to dig it in small spits, and cast out the stones as much as possible, and also to mix well the top and the bottom of the bed together. It is almost impossible to give minute directions as to mixing clay with loam, or with marl when necessary, for the better working of it afterwards, as the difference of the clays in purity and tenacity is such as to require distinct management in this respect in various localities. But all the clay dug for tile-making will require to be wheeled to the place where the pug-mill is to work it; and it must be there well turned and mixed in

the spring, and properly wetted, and finally spatted down and smoothed by the spade, and the whole heap well covered with litter to keep it moist and fit for use through the ensuing season. One man and three boys will turn out from Hatcher's machine nearly 11,000 pipe tiles of one-inch bore in a day of ten hours, and so in proportion for pipes of a larger diameter. This machine, also, has the great advantage of being moveable; and those who work it draw it along the shed in which the tiles are deposited for drying previously to their being burnt. Each tile, therefore, is handled only once,—for it is taken off the machine by the little boys, who stand on each side, and at once placed in the rows on either side of the drying shed; so that the use of shelves in the sheds is wholly unnecessary,—for the tiles soon acquire a solidity to bear row upon row till they reach the roof of the sheds on either side; and they dry without warping or losing their shape in any way. The pug-mill is necessary to ensure the due mixing of the clay, as well as to form it into the exact shape to fill the cylinders of the machine; and it must be worked by a horse; and in general one day's work at the mill will furnish rather more prepared clay than the machine will turn into tiles in two days. The only sheds necessary for drying the tiles are of a temporary kind, and may be made of ordinary farm-hurdles, without either diminishing their value or occasioning any serious inconvenience from their temporary appropriation. The sides of the sheds may be formed of strong hurdles pitched firmly in the ground in two parallel straight lines, 7 feet apart; and the roof may be formed of hurdles placed endways and tied together at the top, as well as to the upper slit of the hurdle, with strong tarred twine, forming the ridge of the roof exactly over the middle of the shed; and the hurdles must then be lightly thatched with straw or heath, and the sharpness of this roof will effectually protect the tiles from rain. Two of these sheds, each 110 feet long, will keep one kiln in full work; and they should be so built as to have one end close to the pug-mill and the clay-heap, only leaving just room for the horse to work the mill, and the other end near the kiln. The kiln is circular; 11 feet in diameter, and 7 feet high. It is wholly built of damp earth, rammed firmly together, and plastered inside and out with loam. The earth to form the walls is dug out round the base, leaving a circular trench about 4 feet wide and as many deep, into which the fire-holes of the kiln open. If wood be the fuel used, three fire-holes are sufficient; if coal, four will be needed. About 1,200 common bricks are wanted to build these fire-holes and flues. If coal is used, rather fewer bricks will be wanted, but then some iron bars are necessary—six bars to each fire-hole. The earthen walls are 4 feet thick at the floor of the kiln, and are 7 feet high, and taper to the thickness of 2 feet at the top; and this will determine the slope of the exterior face of the kiln. The inside of the wall is carried up perpendicularly, and the loam plastering inside becomes, after the first burning, like a brick wall. The kiln may be safely erected in March, or whenever the danger of injury from frost is over; and after the summer use of it, it must be protected by faggots or litter against the wet and the frost of winter. A kiln of these dimensions will contain 47,000 pipe tiles of 1 inch bore, 32,500 of $1\frac{1}{4}$ inch bore, 20,000 of $1\frac{3}{4}$ inch bore, or 12,000 of $2\frac{1}{4}$ inches bore, and the last-mentioned size will hold the same number of the inch pipes inside of them, making therefore 24,800 of both sizes. In good weather the kiln can be filled, burnt, and discharged once every fortnight; and 15 kilns may be obtained in a good season, producing—705,000 pipe tiles of 1 inch bore, 487,500 of $1\frac{1}{4}$ inch bore, or 300,000 of $1\frac{3}{4}$ inch bore; and so on in proportion for other sizes. If a kiln of larger diameter be built, there must be more fire-holes, and additional shed room. Prize Essays of somewhat detailed character, on the manufacture of drain-tiles in more extensive establishments or by more elaborate processes than we have described, occur in the 12th and 14th volumes of the Highland Society's Transactions.

TILE-DRAINING. See Draining.

TILE-ROOT, — botanically *Geissorhiza*. A genus of ornamental, bulbous-rooted, Cape-of-Good-Hope plants, of the iris order. About a dozen species have been introduced to the greenhouses of Britain, varying in height from 6 to 20 inches, carrying either white, yellow, blue, violet, or variegated flowers, most blooming in the early or middle part of summer, and almost all loving a mixed soil of sand and peat and loam, and propagable from offsets.

TILIA. See Lime-Tree.

TILL. A hard, obdurate, retentive boulder-clay,—or a stiff, refractory, impervious, clayey subsoil, imbedding a considerable quantity of gravel, or interspersed with pebbly and bouldery water-worn stones. It is a variety of the drift or diluvium of geologists, and constitutes one of the most churlish subsoils of farmers. The word, however, is provincial, and probably has different shades of meaning in different districts.

TILLÆA. A small genus of curious herbaceous plants, of the crassulaceous order. The mossy species, *T. muscosa*, is an indigen of the barren sandy heaths of some parts of England. It is a minute succulent annual, of only an inch or two in height, and carries pellucid flowers from June till October.

TILLAGE. Breaking up, turning over, stirring, pulverizing, and otherwise working the soil preparatorily to the raising of crops from seeds, offsets, or other germs. The principal operations of it are ploughing, grubbing, harrowing, rolling, and horse-hoeing; and a very complete close

series of them occurs in summer-fallowing. See the articles Ploughing, Plough, Harrow, Grubber, Rolling, Roller, Hoeing, Horse-Hoe, Fallow, Pulverization, and Drill-Husbandry.

TILLANDSIA. A genus of ornamental, tropical, herbaceous plants, of the bromelia family. About 30 species have been introduced to British gardens from the tropical and subtropical regions of America; and about 20 more are known. Almost all are epiphytes, and naturally vegetate among the black mould which collects in hot moist countries upon the bark of trees; and some form dense festoons among the branches of trees, and in deep and gloomy forests. Those in British gardens vary in height from a few inches to 6 or 8 feet; most love a soil of sandy peat, and are propagated from suckers; the majority have blue flowers, and the rest either purple, pink, yellow, or white flowers; and a few bloom in autumn or the early part of winter, but most in June and July. Among the most beautiful or otherwise interesting are the moss-like, *T. usneoides*, purple-flowered, July-blooming, and commonly 6 or 8 feet high, introduced from the West Indies in 1823; the xiphium-like or sweet-smelling, *T. xiphioides*, white-flowered, July-blooming, and commonly about two spans high, introduced from Buenos Ayres in 1810; the strict, *T. stricta*, blue-flowered, either November-blooming or spring-blooming according to treatment, and commonly about 10 inches high, introduced from Brazil in 1810; the fair, *T. pulchra*, pink-flowered, November-blooming, and commonly about 10 inches high, introduced from Trinidad in 1823; the bulbous, *T. bulbosa*, blue-flowered, August-blooming, and commonly about 6 or 8 inches high, introduced from Trinidad in 1823; the bladdered, *T. utriculata*, pale-yellow-flowered, and commonly about 2 feet high, introduced from South America in 1793; and the flexuose, *T. flexuosa*, blue-flowered, June-blooming, commonly about a foot high, introduced from the West Indies in 1790, and comprising a yellow-flowered variety, *T. f. pallida*, introduced in 1815. Some of the species may be cultivated in the manner of air plants; and most require similar treatment, and make similar displays, to the epiphytous, tropical orchidaceæ. See the articles Air-Plants and Orchis. The strict species, while one of the most handsome, is one of the most easily cultivated, and forms a tempting subject to a beginner in tender, epiphytous floriculture. In June, it may be taken out of the stove, and suspended from a wall in the open air; from June till the decline of autumn, it should remain in this position without either protection, watering, or any other attention; in October, it will be found withered, discoloured, and seemingly half-dead, and must then be submitted to a full and regular course of house-protection, heat, and moisture; in a few weeks, it will lose all trace of its previous sufferings, and display a rich healthy vegetation; and, after throwing out suckers on each side, it will shoot up its spikes of bright blue flowers, and bloom from March till the end of April, and then harden and droop and become ripe for removal to the open air in June.

TILLERING. The branching of the culms of the cereal grasses or pulse plants from the root crown, or the rising of several shoots or stems from one seed. This depends partly on the constitutional proliferousness of species or varieties, partly on favourable circumstances of soil, situation, climate, and weather, and partly on the character of the tillage, the manner of sowing, the depth of the seed, and the aggregate circumstances of the husbandry; and, in a general view, it occurs vastly oftener and far more powerfully under the most improved methods of drill-culture than under the old slovenly methods of broadcast culture.

TILLS. Common cultivated vetches.

TILTH. The condition into which the soil is worked by tillage, or the fitness which it possesses for the incorporation of manure and the reception of seed.

TIMBER. The wood or solid substance of the stems and branches of shrubs and trees. The name is applied loosely and popularly to all felled or cut wood which can be used for fuel, paling, or any ordinary purpose of art or economy, and strictly and technically to wood of at least 8 inches in diameter or 2 feet in circumference, such as can be employed in some department of carpentry. A plant which furnishes timber in the former sense may be only a shrub or a sapling, while that which furnishes it in the latter sense must be a tree; and a great tract of the former may be only a thicket or a coppice, while a great tract of the latter must be a forest. The heart-wood or main body of timber is noticed in the article Duramen; the sap-wood or soft exterior layer, in the article Alburnum; the sheath which envelopes and protects the whole, in the article Bark; the cultivation and management of the plants which yield it, in the articles Forests, Plantation, Planting, Pruning, Felling, Coppice, Barking, Tree, Wood, Dry-Rot, Kyanizing, Oak, Elm, and a multitude of others; and some of the most interesting facts and phenomena connected with the natural history of these plants, in the articles Age of Plants, Absorption of Plants, Ascent of Sap, Cambium, Cellular Tissue, Lignin, Ashes, Resin, Canker, and many others.

The entire substance of timber, exclusive of water and of gummy, resinous, oleaginous, saline, and extractive secretions, consists of cellular tissue and of woody fibre,—the former constituting its tissue, and the latter constituting its filling-up or main-bulk. "The distinction between these two elements of wood," says M. Boussingault, "was first made by M. Mohl; but M. Payen was the first who fixed the opinion of chemists and of vegetable physiologists

upon their true nature. By treating the vegetable tissue in its nascent and still gelatinous state—as in the unimpregnated kernel of the almond or of the apricot, in the membranous matter of the cambium of the cucumber, in the spongioles of radicles, and in leaves, wood, and other substances—with different menstrua, M. Payen obtained the cellular tissue in the state of purity, and having an elementary composition almost identical, from whatever source derived; and this latter fact may be seen from the following table, which gives the composition of cellular tissue from different sources, after having been dried at 352° Fahr.

	Carbon.	Hydrogen.	Oxygen.
Ovules of the almond tree,	43·6	6·1	50·3
„ of the apple and pear,	44·7	6·1	49·2
„ of the helianthus annuus,	44·1	6·2	49·7
Pith of the elder,	43·4	6·0	50·6
Cotton,	44·4	6·1	49·5
Endive,	43·4	6·1	50·5
Banana,	43·2	6·5	50·3
Leaves of the agave,	44·7	6·4	48·9
Cotton of the Virginian poplar,	44·1	6·5	49·4
Heart of oak,	44·5	6·0	49·5
Pine tree,	44·4	7·0	48·6
Perisperm of the phytelaphas,	44·1	6·3	49·6
Mushroom,	44·5	6·7	48·8

The primary tissue, consequently, which constitutes the skeleton of wood, is still isomeric or identical in elementary composition with starch. With mineral acids the cellular tissue further undergoes changes which assimilate it with starch; for on treating it with sulphuric acid, it is changed into dextrine and sugar. Woody fibre, or pure wood, or woody tissue, as it has hitherto been obtained after the action of solvents, and been examined by preceding chemists, differs considerably in composition from the cellular tissue, and consists of the following proportions of elements:—

	Carbon.	Hydrogen.	Oxygen.	Authorities.
Woody tissue of the oak	41·8	5·7	52·5	{Gay Lussac & Thenard.
„ of the beech	42·7	5·8	51·5	Do.
„ of the box	44·4	5·6	50·0	Prout.
„ of the willow	44·6	5·6	49·8	„
„ of the oak	49·7	6·0	44·3	„
„ of the beech	44·3	6·0	49·7	Payen.
„ of the aspen	44·5	6·1	49·4	„
Wood in the natural state:	45·6	6·4	48·0	„
„ of the oak	39·4	6.2	54·4	„
„ of the beech	39·3	6·3	54 4	„
„ of the herminiera	46·9	5·3	47·2	„

From these analyses it appears that wood in the natural state contains more carbon than woody tissue obtained in the way of purification, and that this latter substance is also richer in carbon than the cellular tissue which necessarily forms part of it. In the purified woody tissue, therefore, the cellular tissue is associated with the principle which fills its cells, or which encrusts it,—and it is to this matter that M. Payen has applied the name of encrusting matter; it is wood properly so called; it is that which gives to timber its hardness, its tenacity; it predominates in hard wood and in knots; it corresponds with the duramen of physiologists; it constitutes almost the whole of the hard particles which are met with in woody pears and in cork, and which are hard enough to blunt well-tempered steel instruments. As this incrusting matter is friable in many instances, it may be pulverized and separated from the tissue which surrounds it, this last tearing or yielding in shreds under the pestle. By means of the sieve, the incrusting matter may, in this simple way, be obtained nearly in a state of purity. The analysis of M. Payen shows it to consist of 53·8 per cent. of carbon, 6 of hydrogen, and 40·2 of oxygen."

Timber greatly varies in properties and adaptations, according to the comparative density, resinousness, and other constitutional qualities of the different genera and species of trees; and though in every instance more dense than water, and capable of sinking in the form of either sawdust or dried chips or thoroughly exsiccated billets, it, in most instances, floats in consequence of containing a large quantity of air within its pores. The specific gravity of the white woods, such as those of willow and pine, is about 1·46; that of the heaviest woods, such as those of oak and beech, is about 1·53; and that of a few of the most remarkable species, or of their most remarkable parts, is as follows:—

Pomegranate	1·35
Guaiac, Ebony	1·33
Box	1·32
Oak of 60 years old, the heart	1·17
Medlar	0·94
Olive	0·92
Spanish Mulberry	0·89
Beech	0·85
Ash	0·84
Hornbeam	0·80
Yew	0·80
Apple	0·79
Plum	0·78
Maple	0·75
Cherry	0·75
Orange	0·70
Quince	0·70
Elm, the trunk	0·67
Walnut	0·67
Pear	0·66
Spanish Cypress	0·64
Lime	0·60
Hazel	0·60
Willow	0·58
Arbor Vitæ	0·56
Pine	0·55
Spanish white Poplar	0·52
Pine	0·49
Poplar	0·38
Cork	0·24

The specific gravity of every species, however, is very observably affected by at once age, climate and soil. All timber, when newly cut down, contains a considerable quantity of water. One hundred parts of walnut-tree, dried at 212° Fah-

renheit, lost 37·5 parts by weight; of white oak, 41 parts; of maple, 48. On an average, the quantity of water contained in green wood may be estimated at about 40 per cent.; and the quantity lost by drying or seasoning during eight or ten months, will not amount to more than about 25 per cent. The timber which is used for burning almost always contains about a quarter of its weight of moisture, which not only does not assist in producing heat, but actually absorbs a great deal, to effect conversion into vapour. The composition of woody matter may be represented, on the average, as comprising 52 per cent. of carbon, and 48 per cent. of hydrogen and oxygen, in the proportions which form water; so that the definitive products of its combustion ought to be carbonic acid and water. The heat disengaged during its combustion, necessarily proceeds from the union of its elements with the oxygen of the atmosphere; but, the hydrogen being already present with the proportion of oxygen required for its combustion, may be regarded as already burned, and therefore the heat produced by the wood depends solely on the quantity of carbon which it contains.

The calorific or heat-yielding power of any one kind of wood, used as fuel, suffers deduction correspondingly to the degree of moisture which is present in burning, and can be realized with little of this deduction only when the wood has been dried in stoves or otherwise rendered as dry as possible; and the calorific power of different species, all in the same or similar states, is considerably controlled, not only by their proportional amount of carbon, but by their comparative density, and by the peculiar character of their resinous, saline, and other specific secretions, and, probably on account of conflicting methods of testing or determining it, has been represented by some experimentalists as always essentially different, and by others as virtually or eventually uniform. Assuming that the quantity of heat be designated as unity which is requisite to raise one kilogramme of water one degree of the centigrade thermometer, or 2·2 lb. of water 1° 8′ of Fahrenheit, the following table, by Rumford, shows the calorific power of one kilogramme of each of fourteen kinds of fire-wood, in the several conditions which it specifies; so that one kilogramme of dry lime-tree will raise 3,460 kilogrammes of water one degree of the centigrade thermometer, or 2·2 lb. of it will raise 7,612 lbs. of water 1° 8′ of Fahrenheit's thermometer,—and so of the other instances.

Kinds of wood.	Units of heat evolved.
Lime-tree dry	3460
The same thoroughly stove dried	3960
Beech dry, four years seasoned	3375
The same well dried in a stove	3630
Elm, from four to five years seasoned	3037
Oak, fire-wood	3550
Ash, dry	3075
Wild cherry	3375
Fir, dry	3037
The same well dried in a stove	3750
Poplar, seasoned	3450
The same well dried in a stove	3712
Hornbeam	3187
Oak, dry	3300

From the experiments of Clement, it appears that the heating power of charcoal is equal to 7,050 units; and as dry wood contains 52 per cent. of charcoal, its heating power has been deduced theoretically, as equal to 3,666. Mr. Marcus Bull in America, made a series of experiments to determine the relative quantities of heat given out by different kinds of wood; and from these M. Peclet concludes that the same weight of dry wood of every kind has the same heating power, and that this for a kilogramme, or 2·2 lbs. avoird. of wood dried by artificial means, is equal to 3,500 units, whilst the same quantity of the same wood which has been cut and seasoned during from 10 to 12 months, and which contain from 20 to 25 per cent. of water, is no higher than about 260 units. But though the same quantities of wood, brought to the same degree of dryness, appear to have the same absolute calorific power, all are not alike adapted to the same purposes. Hard woods, for example, burn slowly, and give out less heat in a certain time than the less compact kinds of wood; and hence fir is preferred to oak in furnaces where the object is to obtain the most intense heats.

The different species of trees may be distinguished from one another, and are powerfully modified in their adaptations to the arts, by the size and arrangement of their cellular tissue. One series of white and shining laminæ, called by botanists the medullary rays and by carpenters and other workers in wood the silver grain, radiates from the pith to the bark; and another series of minute cells, called by botanists the concentric layers and by workers in wood the spurious grain, is disposed in circular lines or groups at successive distances around all the intermediate space between the pith and the bark; and both series, when examined in thin horizontal slices of the timber, through a common four-power microscope, are seen to have a different arrangement, and to comprise different sizes of cells or grains, in the different species of wood. The characters of these series, in a few of the most common and diverse kinds of home-grown timber, may be advantageously studied by practical men; and shall here be copied, with slight condensation, from the Useful Knowledge Society's Treatise on Planting, where illustrative diagrams of them may be seen.—The elm has the medullary rays, or silver grain, equal and not crowded. The concentric layers are composed of a series of cells of nearly unequal diameter, arranged in an almost simple curved line. The spaces between the layers are furnished with cells of a smaller diameter, and rather thinly scattered over the surface.—The oak has two

series of medullary rays; the primary ones are large and strongly marked, distant from each other, and are uninterrupted in their course from the pith to the bark; the secondary rays are numerous between the primary, but not crowded. The concentric layers, or circles, are distinguished by the arrangement of the cells; they are grouped in somewhat triangular masses, forming a wavy circular outline. The structure of the concentric layers or annual rings, distinguishes at once with certainty the wood of the oak from that of the chestnut, with which it has often been confounded.—The ash has the places of those rays so prominent on the wood of the oak, supplied by twin rays placed in wide intervals over the surface; and between these double rays are smaller ones, placed in regular order. In the narrow spaces between the individuals which constitute the twin rays are wanting those apparent remains of the cellular texture which are so remarkable in the spaces between the single rays.—The beech has the primary rays dispersed pretty regularly over the surface of a horizontal section of the wood; the secondary rays are not continuous from the pith to the bark, but interrupted, and exhibit a numerous series of fragments of rays, filling up the spaces between the primary ones, obvious to the naked eye, and rendering the silver grain very distinct from that of any other kind of wood.—The Spanish or sweet chestnut agrees with the oak in having the secondary rays equally disposed, almost straight, and, though close to each other, yet not crowded as in the elm and the beech; but it differs, in the primary rays being scarcely to be distinguished from the secondary, whilst in the oak these are prominent and obvious to the naked eye on the slightest inspection,—in the concentric layers being regularly curved, whilst in the oak they are strikingly waved,—and in the mouths of the tubular vessels, which constitute so obvious a part of these annual rings or layers, being in regular order, while in the oak they are disposed in triangular masses.—The hornbeam has the rays nearly equal, but may readily be distinguished from the beech, to which it bears the greatest resemblance, by the simple arrangement of the tubular structure accompanying the concentric layers, which in the hornbeam are distant and oval-shaped, the narrow sides pointing to the pith and to the bark, while in the beech they are circular-shaped, more numerous, and equal-sized.—The birch has all the medullary rays nearly equal, arranged closely, and the concentric circles minute, but marked with a row of equal cells.—The horse chestnut has all the rays very minute, few of them apparently continuous, but interrupted, and in substance varying in breadth. The cells are numerous and minute.—The alder has large primary rays, thinly arranged, but in nearly regular order, and the secondary rays slender, numerous, and interrupted. The cells of the concentric layers are nearly regular. The spaces between the rays are crowded with cells.—The oriental plane has the primary rays regular but closely arranged, and somewhat wavy, and the cellular texture of the concentric layers but slightly marked.—The sycamore in texture approximates to the plane, yet is very distinct in its straight lined rays, which are very minute or slender. The cellular texture is composed of such minute cells as scarcely to be perceptible under a four-power microscope; these cells are, however, very numerous.—The poplar has the wood composed of rays so slender as not to be obvious to the naked eye. The concentric layers are composed of exceedingly minute cells. This wood is extremely porous; the cells of which it is composed are so numerous that a very thin slice of the wood, taken horizontally, exhibits the appearance of the finest possible open network.—The common acacia, or locust, bears some resemblance to the oak; but it wants the distinct primary rays so prominent in the oak, and has its rays nearly all of equal breadth, and as slender as the secondary rays of the oak, and somewhat wavy. The cellular or tubular structure is also very different from that of the oak, the cells being arranged in more regular order where they mark the concentric layers; and the spaces between the rays are furnished with many cells irregularly scattered over, of a size equal to those marking the concentric layers.—The fir is distinguished by very prominent coloured concentric layers, arranged very regularly throughout; and the cellular texture, though composed of cells sufficiently large to be seen with the naked eye, is not to be distinguished without very close observation.—The lime has very slender equal rays, and a minute cellular texture pervading the whole body of the wood. The concentric layers are scarcely perceptible to the naked eye. It may be compared to the poplar; but the network-like arrangement of the cellular texture is not so obvious; and the presence of the rays readily distinguishes it.—The laburnum is distinguished by its minute, regular, uninterrupted medullary rays, and by the broken beaded longitudinal lines of the tubular structure.

Timber trees are conveniently classified, by practical men, into foreign and domestic, or such as will not and such as will grow and prosper in the plantations of Britain; and the latter may be subclassified into deciduous hardwood trees, deciduous aquatic trees, larches, and evergreen trees. Foreign timber-trees yield most of the fancy woods used in cabinet work and for fine or small ornamental purposes; and some of them, notwithstanding their rare beauty and reputed scarceness, attain a great size in the natural forests of the tropics; and among these are the mahogany tree, which sometimes acquires a diameter of upwards of 6 feet,—the wood of St. Martha, which is very hard, and has a deeper colour and a more beautiful appearance than mahogany, and sometimes attains a diameter of

nearly 4½ feet,—the *Cedrela odorata*, which emits an aromatic fragrance, and is never attacked by insects, and sometimes attains a height of 150 feet and a diameter of 6½ feet,—the *Bombax pentandrum*, which, at even 60 years of age, has been known to have a girth of 26¼ feet, and to spread its boughs over a circular area of 120 feet in diameter,—the Zamang, a species of mimosa, which has been known to have a girth of 29 feet, and to spread its boughs over a circular area of about 204 feet in diameter,—and the *Hymenæa courbaril*, which, though as hard as mahogany, and in as great request among cabinet-makers and inlayers, sometimes attains the enormous diameter of 19 feet. The principal deciduous hardwood trees grown in British plantations are the oak, the elm, the ash, the sycamore or plane, the beech, the hornbeam, the Spanish chestnut, the horse chestnut, the walnut, the wild cherry, the maple, the lime, the laburnum, the hawthorn, and the mountain ash; the principal deciduous aquatic trees are the birch, the alder, the abele, the aspen, the black poplar, the Lombardy poplar, the elder, the willow, and the hazel; the only deciduous coniferous tree is the larch; and the principal evergreen trees, whether coniferous or otherwise, are the Scotch pine, the Weymouth pine, the black Austrian pine, the spruce, the common silver fir, the cedar of Lebanon, the yew, the holly, and the box. The peculiar properties and economical adaptations of the several kinds of timber are, in most instances, fully stated in the articles on the several genera or species.

All timber, when in a recently felled state, contains a large proportion of water, and is liable to shrinking, cracking, and eremacausis; and, before it can be profitably or wisely used for almost any purpose in the arts, it requires to be protected against these evils by a process of seasoning. This process, when left wholly or principally to the operation of natural causes, consists merely in the evaporation of the contained moisture of the timber into the atmosphere, and is at first comparatively rapid, and afterwards comparatively slow, and at all times accelerated or retarded by varying degrees of exterior heat and humidity; and, when duly favoured by such a position of the timber as exposes all its sides uniformly and equably to the evaporating action, it either renders the timber perfectly proof against all change dependent in any way on moisture, or permits it to be affected only by prolonged and constant wetness or by the mere hygrometric state of the atmosphere. The removing of the bark twelve months before felling, has been tried as a a method of seasoning oak and larch and perhaps some other species; but, at some seasons, if not in all, it will be found rather to soften the alburnum than to harden it. The subjecting of cut and sawn timber to a strong heat by means of steam has been still more extensively tried; and is regarded, in some departments, as a rapid, economical, and efficient substitute for the tedious method of natural seasoning, but has been abandoned in others as unsuitable or as too expensive. The immersion of logs in water, during a year or two previous to the process of natural drying, has been extensively tried in other departments, and is believed to dissolve out certain deliquescent salts, to bring the timber into the completest possible state of seasoning, and, not only to prevent it from shrinking and decomposing, but to fortify it against the erosions of insects and fungi. "In warm countries especially, it is advantageous to sink fresh-cut timber in water, with a view to prevent it from splitting, apparently in consequence of drying too quickly. The old Venetians sank, for a season in the sea, the oak timber which was destined for the construction of their gallies. Elm and beech, in particular, are said to improve greatly by the process of submersion in salt water, and to dry afterwards perfectly by simple exposure to the air. Mr. John Knowles, who made a particular study of the means most generally employed in seasoning timber, has given an account of a series of experiments undertaken in the arsenals of Deptford and Woolwich, to determine the rate of drying and ultimate degree of dryness attained by timber variously treated,—unprepared and prepared by previous submersion in water. The pieces of timber were placed vertically, now in the position they had occupied in growing, now in that opposed to this; and it was found that, circumstances the same, they dried more quickly in the former than in the latter. The general results of these experiments were, that the pieces of timber were best seasoned by being kept about thirty months in the air, but in the shade and protected from wet,—and that they lost more of their original weight after six months' alternate immersions and dryings, than by being kept under water for six months and then dried. Ship-builders are generally agreed that it is not expedient to make use of timber until three years after it is cut."

Three principal causes produce decay in felled or dead timber, seasoned or unseasoned,—and these are the action of eremacausis, the feeding of insects, and the growth of fungi; and all require the conditions of sufficient warmth, sufficient moisture, and stagnant air in order to their coming into play. The first is a slow and imperceptible combustion, of great power, explained in the article Eremacausis; and the second and the third, though seeming at first sight to be trivial, really possess overwhelming energy, and can speedily reduce the stoutest timber to a mass of mere dust. The rapidity with which wood is, in some circumstances, devoured by insects is almost incredible. Some years ago the thermites, or white ants, spread in such strength through the docks and arsenals of Rochelle and Rochefort, that in a very short space of time serious damage was done. A learned entomologist, M. Audouin,

commissioned by the French ministry to take information on the subject, reported that the ravages committed by these insects had been very considerable. But it is principally in warmer climates, where the temperature is steady throughout the year, and where there is no winter, that the thermites occasion the most alarming injury. At Popayan, for example, it is difficult to meet in a building, even of recent construction, with a piece of wood which is not gnawed and ant-eaten. The hardest and most compact woods do not always resist the attacks of these insects, which, farther, do not spare every kind of odorous wood, cedar for instance. —The dry-rot, which results from the development and growth of cryptogamic plants upon wood, is the curse of navies. Mr. Knowles is of opinion that this disease of timber has been known from the most remote antiquity; he believes that he can even recognise dry-rot in the sore called house-leprosy, mentioned in the 14th chapter of Leviticus. A ship attacked by dry-rot, becomes in a very short space of time unfit for sea. The Foudroyant of 80 guns is often quoted as an instance of its destructive powers; launched in 1798, she had to be taken into dock and almost rebuilt so soon as 1802. The fungi which induce dry-rot have been studied by Sowerby. Mr. Knowles signalizes two species in particular; one of which he describes under the name of *Xylostroma giganteum*, the other under that of *Boletus lacrymans*. The xylostroma does not extend beyond the part where it is developed; but the boletus, on the contrary, is propagated with frightful rapidity, and disorganises deeply and to a great distance around the texture of the wood where it once appears. These fungi are generally found on board ship, between the planking and the ribs, in damp situations, and where the air is scarcely, if ever, changed. See the articles Bostrichidæ, Dry-Rot, and Fungi.

The preservation of timber is a problem of eminent importance to vast multitudes of practical men, and involves great elements of national prosperity, and has been a subject of grave and varied investigation on the part of many distinguished philosophers. One remarkable method, resulting from modern invention, is noticed in our article Kyanizing; and another, that of M. Boucherie, professing to protect timber against both dry-rot and the ordinary wet-rot, to increase its hardness and strength, to preserve its flexibility and elasticity, to counteract its alternate contraction and expansion under varying conditions of the atmosphere, to diminish its inflammability and combustibility, and to give it a variety of permanent colours and odours—may here be explained, historically and descriptively, in the words of Boussingault—"In the whole of his experiments, M. Boucherie set out from this proposition, the truth of which appears indisputable and to require no comment, viz.: That all the changes which wood undergoes proceed or depend upon the soluble matters which it contains. In conformity with this idea, the first step towards giving durability to timber was, either to render these matters insoluble and inert, or to remove them entirely. M. Boucherie, therefore, in his first trials sought to render the matters insoluble by charging the wood with a substance capable of combining chemically and forming a precipitate with the soluble matter left by the sap. To resolve this problem, M. Boucherie investigated the reactions between the soluble matter of wood, which it was his object to precipitate, and a variety of low-priced chemical agents. He found that the pyrolignite of iron combined the greatest number of desirable properties; it is very cheap, the oxide of iron forms stable compounds with the greatest number of the organic substances which are found in the sap of vegetables, and to conclude, the crude pyrolignite contains a notable quantity of creosote. The facts upon which M. Boucherie relies as proving the preservative powers of the pyrolignite of iron flow from numerous experiments performed either on vegetable substances which in themselves readily and rapidly undergo changes, or upon billets of wood of different kinds. A quantity of flour, the pulp of carrots, beet-roots, &c., impregnated with the pyrolignite resist decomposition in a very remarkable manner in contrast with the same substances when they have not been prepared in any way. The wood which was selected for trial, was generally of the most perishable kind. In December 1838, several empty hogsheads and barrels made of the best timber, unimpregnated and impregnated with the pyrolignite, were placed together in the dampest parts of the great cellars of Bourdeaux. In August 1839, it was easy to see that the unimpregnated tubs were already deeply stricken, and after from two to three years they fell to pieces with the slightest force; the casks made of the prepared wood, however, were as sound as on the first day of the experiment. M. Boucherie concluded from his experiments instituted with a view to the settlement of the question, that about $\frac{1}{10}$th of the weight of the wood in its green state of the pyrolignite was adequate to precipitate and render insoluble all the principles obnoxious to change, which were contained in the woody tissue. M. Boucherie, whilst he regards the pyrolignite of iron as at once the most powerful and one of the cheapest preservatives of timber, nevertheless indicates several soluble salts, which are readily available in consequence of their low price, and also very effectual when the wood, which they are to preserve, is not kept constantly wet. Solutions of common salt, of chloride of lime, the mother-water of salt-marshes, &c., were all tried and found useful. Casks, the wood of which had been prepared with the chlorides, after having been long kept in very damp cellars, came out as fresh as those which had

been impregnated with the pyrolignite of iron; the flexibility of the wood preserved with these alkaline and earthy salts was farther as great as at the beginning of the experiment.

"Having now come to a conclusion in regard to the substances most effectual in preserving wood, the next business was to make them penetrate its tissue most intimately. Maceration, M. Boucherie soon found, like his predecessors in the same path, to be insufficient, the substances in solution only penetrating a very little way. He then tried various processes of injection; but all inferior to that imagined by M. Breant, and therefore less effectual. He then bethought him of effecting the needful penetration of the wood in the green state, and before it had been sensibly altered by drying and seasoning; he asked himself if the force which determines the ascent of the sap might not be taken advantage of after the tree was cut down, as a means of determining the entrance of a solution of pyrolignite of iron? And all his trials in this direction answered his expectations fully. M. Boucherie had, in fact, discovered a means of securing the penetration of the minutest pores of the largest log by a substance capable of rendering it incorruptible. No one before M. Boucherie thought of taking advantage of an admitted physiological fact for such a purpose. He announces the principle upon which he proceeds in these terms: 'If a tall tree be cut down at the proper season, and the bottom of the trunk be then immersed in a saline solution, weak or strong, the liquid is powerfully drawn up into the tree, penetrates its most intimate tissues, rises to its smallest branches and even to its terminal leaves.' In the month of September, a poplar, upwards of 90 feet high and nearly 16 inches in diameter, was cut, and the bottom of its bole plunged in a vessel, containing a solution of pyrolignite of iron marking 8° of the areometer of Beaumé; in the course of six days, it had absorbed upwards of 66 gallons of the fluid. In his first experiments, M. Boucherie procured the needful absorption by placing the bottoms of his trees in vessels containing the solution; but this mode of proceeding was obviously full of difficulties and open to many objections. The weight of a green tree of large size, with the whole of its top and branches is often enormous, and to raise a mass of the kind once down again into the perpendicular was no easy task; it implied recurrence to certain mechanical means which are not always at hand, and necessarily expensive. M. Boucherie, therefore, tried other modes of making the trees absorb; he adapted a sac of impermeable material to the bottom of the trunk laid on the ground, and into this sac he poured his solution, and this method answered very well. He next took advantage of one or more of the roots to effect the imbibition. He next bored a hole into the bottom of the trunk, still erect; and having brought the cavity thus made to communicate with a reservoir, he still succeeded. This last plan was still farther simplified in proceeding as follows: the trunk of the tree is pierced by an auger through nearly the whole diameter. Into the auger-hole thus made, a narrow saw is passed, by working which on either side, the trunk is divided internally to a very considerable extent, and the majority of its sap vessels are thus cut across and made accessible. An impervious cloth is then tied round the trunk, below the opening, and this is made to communicate with the reservoir of liquid.—M. Boucherie was almost necessarily led, in the course of his experiments, to inquire whether the absorbing power of trees differed at different seasons or not. He ascertained by trials made in the months of December and February, that though in the oak, the hornbeam, and the plane, the solution of pyrolignite of iron always rises several feet and even several yards, yet that in the colder season of the year, it never rises so high as it does in summer, in spring, and especially in autumn, the season in which the power of ascent is most remarkable. This conclusion is obviously of interest physiologically. It proves that if winter be a season of repose for the sap, it is not so absolutely. There is one remarkable exception to the general fact now announced, and this occurs among the resinous trees that keep their leaves till the spring. It has been ascertained, by direct experiment, that the ascent of the sap continues through the whole course of the winter in the cone-bearing trees, and this to such an extent, that it is always possible to impregnate every part of their trunk by the way of simple absorption at any period of the year. As M. Boucherie remarks, this fact might even have been foreseen from the fresh and green state of the leaves of these trees.—It now became important, in connexion with the practical application of M. Boucherie's views, to ascertain whether or not the penetration was energetic in the ratio of the vigour of the tree itself, in proportion as it was more numerously provided with branches, more thickly covered with leaves. Experiment showed that the penetration still takes place after the removal of the greater number of branches, provided only the leading bough or terminal crown be left. A stem furnished with a number of leafy branches continues, as has been said, to imbibe, though separated from the roots; but for how long a time will it continue to do so? This was a capital point to determine. At the end of September, the bottom of a pine tree about 14 inches in diameter was first put into the solution 48 hours after it had been felled; nevertheless the imbibition was complete. In June, the same success attended the experiment made on a plane that had been cut for thirty-six hours. Still it is certain that the penetration takes place with so much the more energy as it is arranged close upon the time of

the felling. The power by which it is determined declines rapidly after the first day is passed, and by the tenth day it is almost entirely gone. In favourable circumstances these ten days suffice to effect the complete impregnation of the largest stem. In one of his experiments upon a poplar, M. Boucherie saw the absorbed liquid reach the height of about 95 feet in seven days.—In the white woods, it is found that there is an axis of variable diameter in different cases which escapes or rather which resists impregnation. In hard woods, the parts which are not penetrated are the inner or undermost circles of the heart. M. Boucherie, after having ascertained these facts, explains them thus: in the white woods, according to the testimony of the workmen, the central part which resists the penetration is at once the weakest and the most perishable portion of the log; there is no longer any circulation, any life there; it is dead wood interred in the midst of the living woody layers. This absence of penetration of the woody tissue appears on some occasions elsewhere than in the centre of the trunk and branches; it presents itself under the most various forms and in different parts of the trunk; it appears to depend, as has been said, on the presence of wood abstracted from the influence of vital phenomena, and which, impenetrable itself, presents a barrier or an obstacle to the passage of the solution to other parts; it is thus that a knot, or a piece of rotten wood, is generally found as the starting point of the zones that have escaped imbibition. As to the non-penetration of the most central parts of the heart of oak, elm, &c., M. Boucherie views it as affording unquestionable proof of the fact that there the living juices of the tree had long ceased to circulate.

"The distinction generally drawn between the white or soft, and the perfect or hard wood, rests on the differences of colour presented by a transverse section of the trunk. In the oak, for example, the external and nearly white concentric layers are held as the soft and valueless portion of the log, and are commonly hewn away in squaring it; the darker more central portions constitute the heart-wood, the valuable timber. But according to M. Boucherie, the distinction is different when the fact of penetrability is taken as the guide, and all that portion of the trunk which imbibes is considered as alburnum or soft wood, and all that does not imbibe is regarded as hard wood. The alburnum in this way is so much extended that it may be found constituting three-fourths of the whole mass of the trunk. Once introduced, the pyrolignite of iron, according to M. Boucherie, is not only useful in preserving the wood, it also increases the density of the timber. Impregnated with this salt of iron, wood becomes so hard as powerfully to resist the tools of the carpenter and joiner, who even complain of the increased difficulty with which it is worked.—Flexibility and elasticity in timber are qualities in request for certain purposes, particularly for ship-building. The fir timber of the north of Europe is much more prized than that of the south, especially for masting, on account of its greater flexibility and elasticity, qualities which appear to depend in a great measure on the quantity of moisture retained; to increase these qualities M. Boucherie has even introduced by imbibition a deliquescent salt, such as the muriate of lime, which retains moisture powerfully as is well known, and seems to have the power of giving a remarkable degree of suppleness to wood. The experiments, contrived to show the effects of deliquescent salts were made upon deal, which is allowed to be one of the most brittle woods. After having impregnated it with concentrated solutions it was sawed into very thin veneers, some of which I have seen in the possession of M. Boucherie, which after being strongly twisted and bent in various senses, immediately regained their original flatness and evenness when they were left free.—Warping or shrinking is occasioned by alternate shrinking and swelling in consequence of varying hygrometric states of the atmosphere. After having found that this did not begin to take place until the timber was upon the point of losing the last third of the moisture which it contained at the time of being cut, M. Boucherie thought that to prevent all warping and shrinking it would be enough to retain this quantity of water in combination with the woody tissue, in other words, to prevent complete desiccation. Facts have proved the correctness of this view. Pieces of wood kept at a certain unchanging degree of moistness by means of a deliquescent salt infused into their pores, do not change their bulk or form, in spite of extreme variations in the hygrometric state of the air. Such pieces of wood, however, exhibit great differences in point of weight under the influence of different circumstances. Several planks of great breadth and extremely thin were prepared with chloride of lime and joined together; some of them were left unpainted, others were painted on one side, or on both sides; after the lapse of a year these planks were found not to have shrunk or warped, whilst similar planks of the same thickness and kind of wood, but unprepared, were found to have cast in an extraordinary way.—M. Boucherie has done more than this: he has not only had it in view to preserve wood and to prevent it from warping, qualities so desirable, he has made use of the same faculty of imbibition to impregnate the wood with a variety of beautiful colours, and thus to give even the most common kinds tints that will admit of their being used in the construction of costly furniture. The pyrolignite of iron alone gives an agreeable brown tint that harmonizes excellently with the natural colour of the harder parts of so many trees which usually resist penetration. By fol-

lowing up the pyrolignite with an infusion of nutgalls or oak-bark, the mass of the wood is penetrated with ink, which presents a black, blue, or grey colour, according to circumstances; a solution of another salt of iron succeeded by one of prussiate of potash will cause a precipitate of prussian blue in the wood, &c.; in short, by the numerous reactions of this kind with which chemistry is familiar, a great variety of colours may be obtained.—Among the number of useful properties communicated to wood by impregnation with saline solutions, that of being rendered little apt to combustion ought not to be omitted. M. Gay-Lussac was the first who thought of rendering vegetable tissues incombustible by means of saline impregnations. By incombustible, we are not to understand unalterable by a red heat; for every one must see that the protecting power of no salt can extend so far as this; but tissues which take fire very readily, and burn with great rapidity, cease from giving any flame and merely smoulder after they have been impregnated with certain salts; they take fire with difficulty, go out of themselves, become charred, and are incapable of propagating fire. And this is exactly what happens with wood which has been properly charged: it burns, and is reduced to ashes with extreme slowness, so that two huts exactly alike, built one of charged wood, and the other of ordinary wood, having been set fire to at the same moment, the latter was already burned to the ground, when the interior of the former was scarcely charred.

"The ingenious process of impregnating wood by the way of vital inspiration is not without certain objections. In the first place, it can only be performed at those periods of the year when the sap is in motion, and the trees are covered with their leaves. This time, however, is limited to a few months of the year, and the usual practice being to fell timber in the winter, wont and usage are opposed to cutting down trees in the spring and autumn. To meet these objections, M. Boucherie engaged in new experiments, which led him to a means of impregnating timber at all seasons, in winter as well as spring and autumn, and in a very short space of time; this second method is applicable to wood that has already been squared as well as to the round trunk, provided it has been recently felled. To impregnate timber by this process, the logs are placed vertically, and the upper extremities are fitted with an impermeable sack for the reception of the saline solution destined to charge them; the fluid enters from above, and almost at the same moment the sap is seen to begin running out below. There are some woods which include a large quantity of air in their tissues; in this case the flow does not go on until this air has been expelled; once begun, it goes on without interruption. The operation is terminated when the fluid, which drips from the lower part, is of the same nature as that which is entering above. In my opinion this method must be preferable to that by aspiration. In the second mode of proceeding, in fact, we accomplish our object by a true displacement; almost the whole of the sap is expelled, and the saline solution introduced has only to subdue or neutralize the very small quantity of soluble organic matter which may remain adhering to the woody tissue. By accomplishing such a displacement by means of simple water we should undoubtedly obtain results favourable to the preservation of timber, inasmuch as we should have freed it from almost the whole of those matters which are regarded as the most alterable themselves, and the first cause of rotting in timber. The rapidity with which the fluid introduced is substituted for the sap which it displaces, and the quantity of this expelled sap which may be readily collected, exceeds any thing that could have been imagined before making the experiment; thus the trunk of a beech tree about $52\frac{1}{2}$ feet in length by $33\frac{3}{4}$ inches in diameter, and consequently forming a cube of somewhat more than $29\frac{1}{2}$ feet, gave in the course of 25 hours upwards of 330 gallons of sap, which were replaced by about 350 gallons of pyroligneous acid. The liquid which penetrates in this way acts so effectually in displacing the sap, that M. Boucherie says we can readily procure or extract by its means the saccharine, mucilaginous, resinous, and coloured juices contained in trees. It would, perhaps, be possible, and I beg to suggest this idea to colonial planters, to apply the method of displacement to the extraction of the colouring matters of dye-woods. The trade in dye-woods does not extend beyond localities favourably situated for exportation, so that at a certain distance from the shores of the ocean, or the banks of rivers, it is found absolutely impossible to carry on a trade, the material of which is so heavy and bulky as timber. The greater number of the colouring matters found in wood being soluble, it is possible to export them in the state of extract. Various attempts of this kind have already been made; and if they have not been successful, the obvious cause of this lies in the method which has been followed, and which has hitherto consisted in treating the wood reduced to chips by means of boiling water, and then reducing the coloured solution obtained; but it is obvious that in the remote forests of America, or of Africa, where all mechanical means are wanting, nothing but failure could attend upon such a procedure. By the method of M. Boucherie, the main difficulties appear to be got over; there is nothing more to be done, in fact, than to get the trees into the state of logs, and these are generally readily transportable, after which one or more evaporating pans seem all that are further necessary."

The common method of determining the cubic contents of a rough piece of timber, whether stem or branch, is to take the mean of its girth

or circumference beween the butt-end and the top-end, to square the fourth of this mean, to multiply the product by the length, and to deduct an allowance for the bark. But this method does not bring out a result sufficiently near the truth, in cases where the timber is of any considerable value; and a much better one would be to multiply the square of the circumference by the length, and to multiply the product by ·07958. The allowance for bark ought to vary widely in trees of different species, and considerably in different individuals, particularly in the young and the old, of the same species. In England, the customary allowance is one inch for every foot of the quarter of the mean circumference of rough-barked or thick-barked species, such as the oak and elm, and half an inch for every foot of smooth-barked or thin-barked species, such as ash; and in Scotland, it is two inches for every circumference of from 12 to 24 inches, three inches for every circumference of from 24 to 36 inches, four inches for every circumference of from 36 to 48 inches, five inches for every circumference of from 48 to 72 inches, and six inches for every circumference of upwards of 72 inches. The contents of any hewn piece of timber, whose bases are parallel to each other, and whose greatest and least thicknesses are at the ends, may be readily and accurately determined by finding the areas of the two bases and the area of a section parallel to and equidistant from the bases, multiplying this last area by 4, adding to the product the other two areas, and multiplying the same by one-sixth of the length. The measuring of sawn and worked timber in the several departments of carpentry, is noticed in the article Carpenter's Work.

Timber is generally hewn into logs, and sawn into planks and deals, and sold by the load. See the articles Log and Plank. A load of unhewed timber comprises 40 feet, a load of squared timber 50 feet, a load of one-inch plank 600 square feet, a load of 1½-inch plank 400 square feet, a load of 2-inch plank 300 square feet, a load of 2½-inch plank 240 square feet, a load of 3-inch plank 200 square feet, a load of 3½-inch plank 170 square feet, and a load of 4-inch plank 150 square feet.

TIMBER TREE. See Tree, Timber, and Plantation.

TIMOTHY-GRASS. See Phleum.

TIN. One of the metals. It does not occur in many districts of the globe, but is very abundant in a few,—particularly in Cornwall, in part of Bohemia, in Galicia, and in Malacca. The tin mines of Cornwall have been worked from a very remote period, and have sent their produce to very distant parts of the world, and make a conspicuous figure in the constant industry of the south-east of England. The tin of these mines is both extracted from veins in various kinds of matrices, and found in the form of rounded grains among beds of rolled materials which have been deposited by running water; and it occurs both metallically in combination with sulphur and copper under the form of tin pyrites, and oxidizedly in combination with oxide of iron and silex under the forms of tin-stone and wood-tin. The granular ore in the deposits of running water is commonly called stream tin, and contains a very pure oxide, and yields the purest kinds of the tin of commerce; and the veined ore is by far the most abundant, and has a wide diversity of form and character and value, and requires to be subjected to an operose process of metallurgy. The ore, when necessary, is blasted with gunpowder; and, when raised out of the mine, it is divided into as many shares or 'dolls' as there are proprietors and adventurers; and that of each mine is distributed on the adjacent fields. The ore is generally pounded or stamped on the spot, in the pounding-mill; if slimy, it is thrown into a pot, called a buddle, to render the pounding more free, without choking the grates; and if free from slime, it is shovelled into a kind of sloping canal of timber, called 'the pass,' whence it slides by its own weight, and the assistance of a small stream of water, into the box where the 'lifters' work. The lifters are raised by a water-wheel, and are armed at the bottom with large masses of iron of about 1¼ cwt., which pound the ore small enough to allow of its passing through the holes of an iron grate, fixed in one end of the box. It is kept constantly wet by a rill to assist its attrition; and it is carried by a small gutter into the 'fore-pit,' where it makes its first settlement; and the lighter particles run forward with the water into 'the middle-pit,' and thence into the third, where what is called the slime settles. From these pits the ore is carried to 'the keeve,' where it is thoroughly cleansed from its filth, and rendered fit for smelting. It is then carried to works constructed for this operation, and delivered to the smelter, and here it is assayed, to determine its quality, and then fined, and run into moulds of an oblong form; and when cooled, these masses are taken out of the moulds, and under the name of blocks of tin are carried to one of the coinage towns to be coined. A comparatively pure tin—though not so pure as that obtained from the stream ore—is prepared by heating a smelted block from the common ore to very near the point of fusion, and allowing only the most fusible portions of it to melt out,—these being much purer than the less fusible portions. The usual impurities are iron, copper, arsenic, and sulphur; and the worst of these can be dissipated by means of roasting in an intense heat.

Tin has a white colour, and a lustre similar to that of silver; it slowly loses its lustre by exposure to the air, but does not oxidize even under the combined agency of air and moisture; it has a very slight and somewhat disagreeable taste, and emits a peculiar odour when rubbed; it is soft and inelastic, can be easily cut with a

knife, and, when bent backward and forward, produces a peculiar crackling noise; it is inferior to several metals in ductility and tenacity, but possesses a very high degree of malleability; it has a specific gravity of 7·299 after being hammered, and of 7·291 after being melted; and it fuses at 442° Fahrenheit, is not volatilized from a state of fusion, crystallizes in rhombs when allowed to cool, and takes fire and burns with a white flame when heated to a full degree of redness. It forms a protoxide, while in a state of fusion, or under the action of any one of many acids; it passes into peroxide by combustion at a full red heat; and it readily combines in two proportions with both chlorine and sulphur, so as to form chlorides and sulphurets.

Pure or nearly pure melted tin, when briskly agitated in a heated mortar or wooden box till it cools, settles into a powdery form of very little lustre, commonly called tin powder or tin filings; and this substance has a place in the pharmacopœias as a powerful anthelmintic, and as an old and indirect remedy for hysteria and hypochondriasis. Thin plates of iron, coated with tin by means of immersion in it while in a state of fusion, constitute the well-known white-iron or sheet-tin of the arts, so extensively used for making canisters, saucepans, and hundreds of other utensils. Alloys of tin and other metals constitute pewter, solder, bronze, and bell-metal. The peroxide of tin, when melted with glass, forms a white enamel.

TINCAL. See Borates.

TINCTURES. Alcoholic solutions of such proximate principles of organic bodies as are soluble in proof or extra-proof spirit. Those used in medicine are very numerous; and differ from aqueous infusions and decoctions chiefly in the stimulating nature of their menstruum, in the greater number or superior strength of their contained principles, in their freedom from tendency to spontaneous decomposition, and in their comparatively high gratefulness to feeble or squeamish stomachs. A large proportion comprise, in a more or less compound state, such proximate principles as the saccharine, the gummy, the extractive, the resinous, the astringent, the acidulous, and the alkaloidal; and most never require more alcohol than is contained in proof spirit, and will even admit subsequent additions of water without suffering any decomposition or precipitation; while a few either contain such skittish or refractory principles as the essential oils, or require the constant presence of very strong extra-proof spirit in order to the maintenance of their proper character. Tinctures are made by macerating dried and bruised ingredients, chiefly of a vegetable kind, during from six to fourteen days, in a temperature not exceeding 80° Fahrenheit; and are then filtered through bibulous paper, and afterwards kept in well stopped bottles. Few tinctures are suitable remedies in any cases of acute disease; and most, when long or often used in chronic cases, are liable to create an appetite for dram-drinking; and only such as those of digitalis, myrrh, opium, and aloes are serviceable in veterinary medicine, —and then, not for internal administration, but as applications to wounds or inflamed surfaces. See the article Alcohol.

TINE. A large tooth or spike of a harrow, a grubber, or any similar implement.

TINEA. A genus of moths, constituting the type of the family Teneidæ. The moths of this family are great in number, small in size, and very mischievous in habits; and they comprise some species which abound in dwelling-houses, and work some serious and well-known devastations. Their palpi amount to four, and are commonly distinct, and not concealed by hairs or scales; their upper wings are long and narrow, and, when closed, assume the form of a rounded ridge, as if they had been moulded on the body, —and sometimes incline on the sides almost perpendicularly,—and often stand up at the hinder extremity like a cock's tail; and their under wings are proportionally large, and generally plaited. The caterpillars are quite or nearly smooth, and have each sixteen feet, and live in habitations which are generally made of the same substances as their food, and have a curious fabrication, and are in some instances fixed, and in others carried about in the same sort of way as snails carry their shells. Two species are very destructive to bee-hives; and three to respectively corn, clothes, and fur. See the articles Wax-Moth, Corn-Moth, Clothes-Moth, and Fur-Moth.

The genus tinea, as distinguished from the other genera of the Teneidæ, may be known by the inferior palpi scarcely projecting beyond the forehead, by the proboscis being very short, and formed of two small membranous and disjointed threads, and by the head being furnished with a crest. It comprises the corn-moth, the clothes-moth, the fur-moth, the destroying-moth, and about twelve or thirteen other British species, all of which are greater or less pests in granaries and dwelling-houses. Each, in general, lives and feeds on some particular substance in preference to all other substances; yet most can accommodate themselves to a wide variety of circumstances, and may, in a limited sense, be pronounced miscellaneous feeders or general devourers. "They sometimes,"[25] says Mr. Duncan, "appear under circumstances where it is extremely difficult to account for their having obtained access, so as not to render it surprising that the belief should be so general, that they are bred or generated (that is to say, spontaneously) in the substances where they are found. This notion, however, cannot for a moment be entertained; and any object liable to their attacks, such as a piece of fur, if so firmly closed up that the parent moths cannot find entrance, will remain in perfect security, unless

it so happen that the germ of the mischief has been closed up along with it. Exposure to a considerable degree of dry heat, wherever that is practicable, is the easiest and most effectual mode of destroying the eggs and larvæ. Immersion in boiling water is, of course, equally effectual. The objects preserved in museums are protected from moths, as well as other destructive insects, in various ways. Corrosive sublimate, dissolved in spirits of wine, has been a good deal used of late, and is said to be very efficacious. Spirits of turpentine, oil of petroleum and camphor, although, perhaps, they do not actually kill the noxious insects, are yet very useful in driving them away. A preparation which speedily kills them, and which is said to be the best possible preservative, is that called Becœur's soap, which consists of the following ingredients in the proportions indicated:—2 lbs. of arsenic in powder, 2 lbs. of white soap, 12 oz. of salt of tartar, and 4 oz. of lime in powder. Sulphurous fumigations have long been used with advantage, but must be employed with caution, as they are apt to injure the colour of certain objects."

TIPULA. A genus of dipterous insects, belonging to the nemocera family, and constituting the type of a group called Tipulariæ. The species of this group are very numerous, and have singularly long legs and narrow elongated bodies, and are popularly known by many quaint names such as crane-flies, long-legs, tailors, and Jenny-the-spinners. Their antennæ have thirteen joints,—the radical one of which is cylindrical, the second cup-shaped, and the rest cylindrical and bearing each at the base a few verticillate hairs; the palpi are projecting, incurved, cylindrical, and four-jointed, and have the terminal joint elongated; the ocelli are a-wanting; and the wings are lanceolate and spreading. The larvæ and pupæ of some inhabit the water and form vegetable galls; and the larvæ of others live within the soil of meadows and arable land, and frequently make great devastation by loosening and destroying the roots of herbage plants and gramineous crops. Not fewer than at least forty species occur in Britain; and several of them are very common, and often work great havoc. Two of the worst—the one a true tipula, and the other a species of the genus cecidomyia—are noticed in the articles Grub and Wheat-Fly; and these serve as a sufficiently ample specimen of the whole group.

TISSUE, in Botany. All the organs and parts of plants are composed of little cells or vesicles, tubes, and fibres; or, in other words, of cellular, vascular, and woody tissue. The first is of universal occurrence; but the latter are partially or entirely wanting in many plants.

Cellular tissue consists of membranous vesicles, or little bladders, which cohere with each other, more or less perfectly, by their contiguous sides. These are not perforated with holes or visible pores, at least originally: they are at first of extreme tenuity; but are often thickened by the deposition of more solid matter upon their inner surface, either in regular layers, in bands, dots, or otherwise, and which sometimes accumulates so as completely to fill the cell. Their form depends entirely upon the circumstances in which they are placed. When separate they are round or oblong: when equally pressed together, they become twelve-sided, the cross-section being six-sided: when stretched lengthwise, they are rendered prismatical, cylindrical, &c. They contain fluid, and often solid matter, such as starch, the green colouring substance of plants, and sometimes minute crystals, which, when slender, are termed *raphides.* Common cellular tissue, or *parenchyma,* constitutes all the pulpy and succulent parts of plants, the pith, the whole of leaves, excepting the veins, and a portion of the bark, &c. But it is capable of acquiring excessive hardness; as it does in the stone of a peach, and in the bony skin of some seeds. One or more fine spiral lines are sometimes observed on the walls of a cell; forming what is called *fibro-cellular tissue.* See the article Cellular Tissue.

Woody tissue consists of vesicles of cellular tissue drawn out into tubes of extreme tenuity and toughness, their sides being very thick in proportion, each end tapering into a sharp point. These fibres are closely applied to each other by their sides, and form bundles or coarser fibres stretching through the plant lengthwise, affording the necessary degree of strength, and also serving, it is supposed, for the upward conveyance of the sap. This tissue is not confined to the wood, but is also found in the bark; and the veins of leaves, of petals, &c., are chiefly composed of it. In all coniferous trees (pines, firs, &c.), and in a few others with aromatic secretions, the tubes of woody tissue (which are larger than ordinary woody fibre) are marked along their sides with circular gland-like disks, appearing like a row of small holes.

Pitted, or vasiform tissue, consists of large tubes, either composed of ordinary cylindrical cells placed end to end and opening into each other, or often without the appearance of such composition: the walls are marked with pits or dots, produced by the unequal deposition of more solid matter on the inside. They were long considered as true vessels, and have been called *dotted ducts.* The pores conspicuous on the cross section of most kinds of wood, are the large open orifices of these tubes.

Vascular tissue consists of uninterrupted membranous tubes, marked with transverse bars or rings, or with a spiral fibre adherent to their inside. The type of vascular tissue is the *spiral vessel;* in which the closely coiled spiral fibre is capable of unrolling with elasticity. The thin and delicate membrane which confines the fibre being transparent, the latter only is visible, and resembles a slender coil of fine wire. In their

unrolled state, they are readily examined by breaking almost any young shoot or leaf-stalk, and pulling the extremities gently asunder, when the uncoiled fibres appear to the naked eye like a fine cobweb. In stems furnished with pith, the spiral vessels usually occupy a circle immediately around it: thence they proceed to the veins of the leaves, and of all parts which are modifications of leaves. *Ducts* are vessels in which the spiral fibre is incapable of unrolling. The turns of the coil sometimes touch each other, forming what are called *closed ducts*, which are only to be distinguished from spiral vessels by this character: often the turns are distant, or broken into separate rings placed at considerable intervals (*annular ducts*); sometimes they cross each other (*reticulated ducts*), or are broken up into short irregular bands. Occasionally nearly all these varieties may be observed in different portions of a continuous vessel. Ducts occur abundantly among the woody tissue of almost all plants. See the article Vascular Tissue.

Laticiferous tissue consists of a peculiar system of vessels, which have only recently been made known. The vessels of the latex are those in which peculiar products of plants (such as milky juice, &c.) are elaborated and contained. They are distinguished from all other vessels by their numerous anastomosing branches, and also by their irregular contractions and expansions. Their average diameter is said to be one-fourteen hundredth of an inch. Their old trunks are often very much larger; but their ramifications, which proceed to the surface of the organs, and form a most delicate net-work upon the hairs, are so minute that they are only to be discovered with the aid of the most powerful microscopes.—*Gray.*

TIT, or Titmouse,—scientifically *Parus*. A genus of passerinous birds, of the conirostrous family. They have slender, short, conical bills, with little hairs at the base, and with the nostrils concealed among feathers; and they possess exceedingly active powers, and display remarkable agility, and flit constantly from branch to branch, and pass rapidly through a great variety of positions; and they are, in a considerable degree, omnivorous, and tear asunder the seeds on which they feed, and devour all insects whom they can find. and even kill and eat whatever small birds they happen to find sick or are otherwise able to master. Five or six species occur in Britain; and though differing in size, colour, and some other particulars, have a great similarity in habits, feeding, and general character.

The tom-tit, or blue-headed tit, or blue whaup, *Parus cæruleus*, is, in many districts, the most common species, and in almost all a peculiarly interesting one, at once for its pretty appearance, for the erroneous notions which are generally entertained respecting its habits, and for the war of extermination which is often carried on against it. See the article Hedge-Birds. The upper surface of its body has an olive-coloured plumage; the lower surface is yellowish; the top of the head is a fine blue; the forehead is white; and the cheek is white, surrounded with black. He is so knowing a little fellow respecting the nicest morsels of his vegetable diet, and at the same time so prying and impudent and fearless, that one can easily understand how he has acquired a very bad name among the great majority of farmers and gardeners. "He prefers what is delicate as well as nutritive, and is particularly fond of every sort of nuts and the larger seeds, which most resemble nuts in quality, such as the seeds of sunflower, hemp, pease, and the like. It may well be supposed that his small beak, hard though it be, is inadequate to manage such large seeds in the way they are shelled by the linnet or the bullfinch; but the tom-tit is a most ingenious seed-breaker. In the case of a pod of Prussian-blue pease, for example, he will first peck a hole through the shuch or shaup to get at a pea; and this, when he has procured it, he fixes between his claws, while he hammers away at it with his little bill till he gets at the mealy kernel, which he hollows out and devours, leaving the empty shell. He does the same with a hemp seed, and it is surprising to observe how small a hole in the shell will sometimes suffice to enable him to get at the whole contents. Yet he certainly commits very few or trifling depredations on any sort of garden fruit; and, upon the whole, may be considered as producing more benefit than injury to cultivators."

The long-tailed tit, *Parus caudatus*, is a common and well-known species; and remains in Britain throughout the year; and frequents woods, shrubberies, and other places of retreat and shade. His total length is about $5\frac{1}{2}$ inches; the upper surface of his body has black plumage; his wing-coverts are brown; the upper part of his head and all the parts beneath are white; and his tail is longer than his body. The female builds her nest on the branches of small trees, and roofs it over, and lays from 10 to 12 eggs.

The cole-tit, *Parus ater*, and the marsh-tit, *Parus palustris*, have a considerable resemblance to each other, and are distinguished from the tom-tit by the black colour of their head, by the ash colour of the upper part of their body, and by whitishness instead of yellow in the lower part of the body. The cole-tit has a shining glossy black head and throat; and the marsh-tit has a dull non-shining black head and chin. The cole-tit, besides feeding on the same sorts of food as the tom-tit, though not so omnivorously, is very fond of pine seeds, and on this account abounds most in pine and fir forests and plantations; and it is the only species of tit which builds in holes on the ground, in preference to holes in trees and walls. The marsh-tit is perhaps more common in this country than the cole-tit; and a family of them may often be seen in the autumn attacking the ripe seeds of a sun-

flower, which, when they have discovered, they daily visit so long as a single seed remains, holding each seed firmly between their claws till it is neatly unkernelled. During autumn and winter both species come into gardens and orchards, like the tom-tit, in families or small flocks, but do little or no injury.

The greater tit, oxeye, joe-bent, or willow-biter, *Parus major*, has a shining black head and breast like the cole-tit, but is readily distinguished from all the other species by being nearly a third longer, while it is more gaily coloured with yellow, olive, and blue. The greater size and strength of its bill renders it more capable of digging into the crevices of the bark of trees than any of the preceding; and it is also fonder of climbing up the trunks of trees than the tom-tit, in pursuit of lurking grubs and beetles. In this way, it is of essential benefit in orchards and gardens, and ought not to be grudged a walnut or a filbert in reward for its services; and even were all the roots and seeds reckoned up which it may occasionally eat, they would be of such small amount as to be unworthy of consideration.

TITANIUM. One of the rare and recently discovered metals. It was not satisfactorily proved to be a distinct elementary substance till the year 1822. Minute crystals of it are found in the slug of iron works; and have a cubic form, a coppery colour and lustre, a specific gravity of 5·3, and a hardness so great as to scratch a polished surface of rock crystal. Titanium combines with oxygen, chlorine, and sulphur, so as to form oxides, chlorides, and sulphurets.

TITHES. The tenth part of the increase yearly arising from the profits of lands, the stock upon lands, and the industry of the occupants, allotted to the clergy for their maintenance.

The custom of giving and paying tithes is very ancient. In Gen. xiv. 20, Abraham gives Melchizedek the tenth of all the spoils taken from the four kings defeated by him. Tithes were first legally enjoined by Moses. They were not established by Christ. The early Christian ministers lived upon the oblations of the devout. For the first three hundred years after Christ, no mention is made in ecclesiastical history of any such thing as tithes. The first authority produced (setting aside the apostolical constitutions, which few of the advocates of tithes will insist on) is a provincial synod at Cullen, in 356, in which tithes are voted to be God's rent. After the church had enjoyed tithes without disturbance for two or three centuries, the laity in the eighth century obtained possession of part of the tithes, and appropriated them to their own uses. Some time afterwards they restored them, or applied them to the founding of monasteries or chapters. In 1179, the third council of Lateran commanded the laymen to restore to the church all the tithes which they yet held. Upon the first introduction of tithes, though every man was obliged to pay tithes in general, yet he might give them to what ministers he pleased, which were called *arbitrary consecrations of tithes;* or he might pay them into the hands of the bishop, who distributed among his diocesan clergy the revenues of the church, which were then in common. But when dioceses were divided into parishes, the tithes of each parish were allotted to its own particular minister; first by common consent, or the appointments of lords of the manors, and afterwards by the written law of the land. However, arbitrary consecrations of tithes took place again afterwards, and became common in England till the time of King John. This was probably owing to the intrigues of the regular clergy, or monks of the Benedictine and other rules, and will account for the number and riches of the monasteries and religious houses which were founded in those days, and which were frequently endowed with tithes. But, in process of years, the income of the laborious parish-priests being scandalously reduced by these arbitrary consecrations of tithes, it was remedied in England by Pope Innocent III., about the year 1200, in a decretal epistle, sent to the Archbishop of Canterbury, which enjoined the payment of tithes to the parsons of the respective parishes, where every man dwelt, agreeably to what was afterwards directed by the same pope in other countries. This put an effectual stop to all the arbitrary consecrations of tithes, except some traces which still continue in those *portions of tithes*, which the parson of one parish has, though rarely, a right to claim in another; for it is now universally held that tithes are due, of common right, to the parson of the parish, unless there be a special exemption. This parson of the parish may be either the actual incumbent, or else the appropriator of the benefice; appropriations being a method of endowing monasteries, which seems to have been devised by the regular clergy, by way of substitution to arbitrary consecrations of tithes.

Mr. Smith observes that tithes, as well as other similar taxes on the produce of the land, are, in reality, taxes upon the rent, and, under the appearance of equality, are very unequal taxes; a certain portion of the produce being, in different situations, equivalent to a very different portion of the rent. In some very rich lands, the produce is so great, that the one-half of it is fully sufficient to replace to the farmer his capital employed in cultivation, together with the ordinary profits of farming-stock in the neighbourhood. The other half, or, what comes to the same thing, the value of the other half, he could afford to pay as rent to the landlord, if there was no tithe. But, if a tenth of the produce is taken from him in the way of tithe, he must require an abatement of the fifth part of his rent, otherwise he cannot get back his capital with the ordinary profit. In this case, the rent of the landlord, instead of amounting to a half, or five tenths, of the whole produce, will amount only

to four tenths of it. In poorer lands, on the contrary, the produce is sometimes so small, and the expense of cultivation so great, that it requires four fifths of the whole produce to replace to the farmer his capital, with the ordinary profit. In this case, though there were no tithe, the rent of the landlord could amount to no more than one fifth, or two tenths, of the whole produce. But if the farmer pays one tenth of the produce in the way of tithe, he must require an equal abatement of the rent of the landlord, which will thus be reduced to one tenth only of the whole produce. Upon the rent of rich lands, the tithe may sometimes be a tax of no more than one fifth part, or four shillings in the pound; whereas, upon that of poorer lands, it may sometimes be a tax of one half, or of ten shillings in the pound. It is a great discouragement to the improvement of land, that a tenth part of the clear produce, without any deduction for the advanced expense of raising that produce, should be alienated from the cultivator of the land to any other person whatever. The improvements of the landlord and the cultivation of the farmer are both checked by this unequal tax upon the rent. The one cannot venture to make the most important, which are generally the most expensive improvements, nor the other to raise the most valuable, which are generally the most expensive crops, when the church, which contributes no part of the expense, is to share so very largely in the profit. When, instead either of a certain portion of the produce of land, or of the price of a certain portion, a certain sum of money is to be paid in full compensation for all tax or tithe, the tax becomes, in this case, exactly of the same nature with the land tax of England. It neither rises nor falls with the rent of the land. It neither encourages nor discourages improvement. The tithe, in the greater part of those parishes which pay what is called a *modus*, in lieu of all other tithes, is a tax of this kind.

It is well known, and has often been lamented, even by the clergy themselves, that this method of raising a revenue for their subsistence, is a continual source of dispute between the clergy and their parishioners, and contributes to obstruct the usefulness of their ministry.

TITHONIA. An ornamental, tropical, evergreen shrub, of the sunflower division of the composite order. It constitutes a genus of itself, and bears specifically the descriptive name of *tagetiflora* or marigold-flowered. It was introduced to the hothouses of Britain about 30 years ago from Vera Cruz; and it attains a height of about 10 feet, and carries orange-coloured flowers from July till October.

TITMOUSE. See Tit.

TITTMANNIA. A genus of ornamental exotic plants, of the figwort family. Two annual species, the ovate-leaved and the clammy, both small, early-blooming trailers of 2 or 3 inches in height, have been introduced to British collections from Polynesia and India; and 6 or 7 other species are known.

TOAD,—scientifically *Bufo*. A genus of batrachian reptiles, of the frog family. They have a comparatively bulky body, covered with warts or papillæ,—a thick lump situated behind the ear, pierced with pores, and emitting a milky and fœtid humour,—no teeth,—and slightly elongated hind feet; they are bad leapers, and generally avoid the water; they have a hideous and disgusting appearance; and their bite, their saliva, their urine, and even their perspiration are commonly, but erroneously, regarded as poisonous. See the article Frog.

The common toad, called by the old zoologists *Rana bufo*, is a well known frequenter of the moist and shady quarters of kitchen gardens, and of other similar situations, where its presence is most repugnant to the ignorant and the fastidious. Its predominant colour is grey brown or reddish grey, sometimes olive or blackish; its back or upper surface is studded with rounded tubercular warts as large as lentils; its belly or under surface is still more closely set with smaller tubercles; and its hind feet are semi-palmate. It inhabits dark or deeply shaded places in summer, and lies dormant in an excavated hole during winter. It couples in the water in March and April. The female produces innumerable small ova, united by a transparent gelatinous substance in two strings, which are often 20 or 30 feet long; and the male assists with his hind feet in extracting the ova. The tadpole is blackish; and at the time of losing its tail and acquiring legs, is the smallest of the European species. The common toad feeds on flies, ants, and other insects, and therefore does good and no harm in gardens; it has a cry of somewhat similar sound to the barking of a dog; it is preyed upon by buzzards, owls, snakes, and some other animals; and it begins to breed at four years of age, and commonly lives upwards of 15 years, but has been known, in some curious instances, to attain a remarkable longevity.

Most of the other European species of toads are popularly called frogs,—such as the bush frog, the variable frog, and the midwife frog; and one, which has a light brown colour, and is eaten in some places as if it were a fish, *Bufo fuscus*, is popularly called the natter-jack. Some of the species foreign to Europe are remarkably large.

TOADFLAX,—botanically *Linaria*. A diversified genus of plants, of the figwort family. It was included by the old botanists in the genus antirrhinum; and it takes both its botanical and its popular names from the similarity of its leaves —particularly those of the common species—to those of cultivated flax. Six species grow wild in Britain; about 70 have been introduced from other countries; and between 20 and 30 more are known. A few of those in Britain are evergreen undershrubs, a greater number are perennial-rooted herbs, and more than the half are

annuals; a few are more or less tender, and all the rest are quite hardy; a few have a height of from 2 to 5 feet, and most of the others have a height of from 3 to 15 inches; a large number have either white, brown, greenish, blue, or violet flowers, and the rest have either yellow or purple flowers; about a dozen of the herbaceous species have prostrate stems, and either lobed or subentire, angular or toothed leaves, and the rest are erect, and have their lower leaves either opposite, whorled, or scattered.

The common toadflax, *Linaria vulgaris*, called by the old botanists *Antirrhinum linaria*, is a perennial-rooted, annual-stemmed weed of the hedges and field-borders of Britain. Its stem is about a foot high; its leaves are linear-lanceolate, crowded, and irregular; and its flowers grow in terminal spikes, and are scentless, and have a yellow colour, and bloom from June till September.—The creeping-rooted toadflax, *Linaria repens*, is a perennial-rooted but comparatively rare weed of the banks and hills of the calcareous districts of England. Its stem is panicled and about a foot high; its leaves are linear, smooth, glaucous, partly whorled, and partly scattered; and its flowers are sweet-scented, and have a greenish colour, and bloom from July till October. —The ivy-leaved toadflax, *Linaria cymbalaria*, is a perennial-rooted indigen of old walls and similar situations in some parts of England, and possesses sufficient ornamental attractions to hold a place in flower-gardens, and especially on conspicuous walls. Its root is fibrous; its stems are procumbent or trailing, cylindrical, much branched, smooth, and leafy; its foliage is evergreen, and of a deep shining verdure, often tinged with violet, and quite smooth; its leaves are alternate, stalked, and similar in shape and appearance to those of ivy; and its flowers are solitary, and grow on long axillary footstalks, and have a small size, a very elegant form, and a variegatedly blue and violet corolla, and bloom from May till November. The whole plant hangs most beauteously from old walls, and exhibits there the appearance of rich, dense, flowing festoons. One variety of it, *L. c. variegata*, has variegated leaves; and another variety, *L. c. alba*, has white flowers. —The fluellin toadflax, or sharp-pointed fluellin, *Linaria elatine*, is an annual indigen of the corn-fields of some parts of England; and is sometimes very abundant on gravelly and chalky soils. Its stems are procumbent, spreading, and about 6 inches long; its leaves are lobed, halbert-shaped, and comparatively slender; and its flowers have yellow and purple colours, and make a pretty appearance, and bloom from July till November.— The spurious toadflax, or round-leaved fluellin, *Linaria spuria*, is also an annual indigen of the corn-fields of England. Its stems are procumbent; its leaves are subentire and rather larger and less slender than those of the preceding; and its flowers are larger, deeper-coloured, and more conspicuous than those of the preceding, and bloom from July till September. — The small toadflax, *Linaria minor*, is an annual weed of the sandy fields of some parts of England. Its stem is erect and about 6 inches high; its lower leaves are regularly arranged; and its flowers have a violet colour, and bloom from June till November.

TOBACCO,—botanically *Nicotiana*. A genus of cultivated and ornamental plants, of the nightshade family. The corolla is monopetalous and funnel-shaped or bell-shaped; the stigma is emarginate; and the seeds are numerous, and enclosed in a two-celled capsule. Upwards of 30 species, besides a number of varieties, have been introduced to the gardens and the botanical collections of Britain. Two of the species are evergreen shrubs, two are evergreen herbs, one is a biennial, and all the rest are annuals; several have a height of only a few inches, but most have a height of from 3 to 8 feet; nearly all have either pink, white, or herbaceous-coloured flowers, and bloom in the latter part of summer or early part of autumn; a few are so tender as to be cultivable only in the greenhouse or the stove, and the rest are more or less hardy, and may, with proper precautions, be raised from seed in the open ground; a large number, irrespective of varieties, are cultivated for purposes of luxury or economy or medicine, and both these and all the others make either a curious or a very ornate appearance in the flower-garden.

The History of Tobacco.—Six of the species of tobacco now in British collections have been introduced at various periods since about the close of the 17th century from China, Egypt, Persia, Nepaul, and Australia; and all the others have been introduced at various periods, since the latter part of the 16th century, from Yucatan, Vera Cruz, Chili, Peru, Brazil, Columbia, Buenos Ayres, Havannah, and several other parts of America. But the species first known in Europe, and often called par excellence the tobacco plant, and now bearing the botanical name of *Nicotiana tabacum*, was discovered by the Spanish invaders of America under Cortes, in the year 1519, in the province of Tabaco in Yucatan, and is thought by some botanists to have been not very extensively diffused beyond that province at the time of its discovery. The natives made universal use of the plant, and held it in high esteem, and even treated it with veneration. They smoked it as an article of luxury; and employed it as a medicine for all kinds of diseases; and used it to allay the pains of hunger and thirst, in their distant hunting expeditions; and even laid it on the altar as the most acceptable offering which they could make to their gods.

Cortes carefully enquired into all the uses of tobacco, and made himself acquainted with the mode of cultivating and preparing it; and he speedily procured several plants of it, and transmitted them to Spain, accompanied by an accurate account of the virtues, real and imaginary, which it was said to possess. An unhappy disease, which had been imported from America at the first return of Columbus's fleet, raged about this time with fearful virulence in Spain; and the tobacco plant was represented to be an infallible remedy for it, and in consequence received a ready and zealous welcome. But when, after a time, it was found to be no more effectual than the usual remedies, it naturally sank into

a depth of disrepute proportioned to the greatness of the hopes it had excited. It therefore did not at this time come into extensive use in Spain for any medical purpose; it was even slowly, and very sparingly, diffused as an article of luxury; it never became an object of commerce, and, for more than forty years after its first introduction, seems never to have been communicated from Spain to any other nation. Near as it was, we do not learn that even Portugal received the plant from the sister kingdom, but seems to have imported it from one of its own colonies in America; and it was certainly from Portugal, and not from Spain, that its general diffusion over Europe and the East commenced.

About the year 1560, Jean Nicot of Nismes, when acting as French ambassador at the Portuguese court, was presented with a plant of tobacco, as an exotic of great curiosity and rarity, newly imported from the American settlements; and like every one else at that period, he was inquisitive about all the strange productions of the new world, and received it, as Neander says, *lubenti animo*. Accordingly, at his return to France, about the year 1561 or 1562, he took with him a considerable number of tobacco plants, and made his countrymen acquainted with their history and uses. The new exotic was named Nicotiana in honour of its introducer; it was eagerly welcomed by the spirit of inquiry which prevailed even at that time in France; it was carefully and scientifically examined by both naturalists and physicians; its properties and qualities were investigated; such virtues as it possessed were discovered, and many which it did not possess were supposed to be discovered. It was soon received as a valuable and useful addition to the Materia Medica Its introduction seemed to form a new era in the history of physic. Diseases and complaints, which were hitherto thought incurable, were now supposed to have found a remedy. It entered, in the shape of solutions, decoctions, powders and essences, into the composition of almost every drug; and it was applied as a general panacea to almost every human disease. Such an exaggerated idea of it prevailed that Catherine de Medicis thought that her own name would derive additional glory from being connected with it; and she ordered it to be called, no longer Nicotiana, from the name of its introducer, but Herba Reginæ, in honour of herself. But, whether owing to the mode of cultivating it being imperfectly understood, or to some laws of Catherine regarding it, its diffusion for a long time bore no proportion to its fame. So late as the reign of Henry IV., it was raised only in small quantities in gardens, and used only for medical purposes; and not till the reign of Louis XIII. did it begin to come gradually into request as a luxury, and to be taken in the shape of snuff. The laws passed regarding it by Catherine, limited the cultivation of it in several provinces, and altogether prohibited it in others; and these continued in force, more or less modified, for a long series of years.

About the same time that Nicot introduced the tobacco plant into France, St. Croix, then acting as papal legate in Portugal, introduced it into Italy; and here, also, it attained great repute as a medicinal herb,—though, as the temperature of the Italians is too lively, and their climate too genial, to require such adventitious excitement, it was not adopted by them for the purpose of smoking. About this time, too, it was introduced into Russia, by way of Astrachan, from either Portugal or Italy,—into Holland and most parts of Germany, through means of the extensive intercourse between the Hanse towns and the Italians states,—into the countries of the Levant, through the eastward commerce of Venice and Genoa,—and into the vast regions around the Persian gulf and beyond the Indian ocean, in connexion with the vast oriental commerce of Portugal which followed the discovery of the passage round the Cape of Good Hope.

Tobacco was first introduced to England, on a small scale, from France about the year 1570; and was afterwards introduced, on a large scale, from Virginia in 1586. It excited little notice between these two periods, and probably was raised only in small quantities, in physical gardens, for experimental or medicinal purposes; but immediately after its second introduction, it drew the attention of some of the greatest personages in the country, and began to come into extensive use as a luxury. Sir Walter Raleigh saw it smoked by the gentleman who introduced it; and soon acquired a taste for it, and became an easy prey and a willing slave to the pipe. He next commenced to teach the art of smoking to his friends, and was in the habit of giving 'smoking parties' at his house, when the guests were treated with nothing but a pipe, and a mug of ale and nutmeg. The example of so gay and fashionable a man, who might be said to lead the taste of the age, speedily spread its influence at court; the example of the court was soon communicated to the country; and in a few years smoking became pretty general in England. During the reign of Elizabeth, this fashion got into great repute; and some writers hint that she countenanced it by her own example. "It soon became of such vogue at her courte," at all events, "that some of the great ladies, as well as noblemen therein, would not scruple to blow a pipe sociably;" and if it were usual for the ladies to smoke, we may readily imagine how much more it must have been so for the men. In one of Lord Somer's Tracts, entitled "A pleasante invective against Poets, Pipers, Players, Jesuits, and such like catterpillars of the Commonwealth," the practice of ladies smoking is also hinted at; and Mr. William Prynne, in his famous Histriomastrix, mentions, that among the refreshments offered to ladies in his own time, "it was not uncommon to offer them the tobacco-pipe." But the successor of Elizabeth found cause to be fully more zealous in denouncing tobacco than she had been in praising it; and the increase of the consumption of this article during her reign, was only equalled by its decrease during his. His famous "Counterblast to Tobacco" is not more a literary curiosity than a monument of his indignant abhorrence of the odious weed; and a preamble to an act of parliament, passed in 1604, for raising the importation duty upon it from 2d. to 6s. 8d. per pound reveals some mighty public reasons for his opposition to it, and shows how soon and dreadfully it began to desolate its victims. "Whereas tobacco," says that document, "being excessively taken by a number of ryotous and disorderly persons of meane condition, whoe, contrarie to the use which persones of good qualitie do make thereof, do spend most of their time in that evile vanitie, to the evile example and corrupting of others, and also consume that wages which many of them get by their labour, and wherewith their families should be relieved, not caring at what pryce they buy that drugge, but rather divising how to add to it other mixtures, thereby to make it the more delightful to the taste, though so much the more costlie to their purses; by which great and immoderate taking of tobacco, the health of a great number of the people is impayred, and their bodies weakened and made unfit for labour, and the estates of many mean persons so decayed and consumed, as they are thereby driven to unthriftie shifts onlie to meynteyn their gluttonous exercise thereof; besides, that also a great part of the treasure of the lande is consumed by this only drugge so licentiously abused by the meaner sorte; all which enormous inconveniences ensuing therefrom, we do well perceive to proceed principally from the great quantity of to-

bacco daily brought into this Our realme of England and dominions of Wales, from the parts beyond the seas." From that period down to the present day, the history of tobacco in Britain exhibits principally a tissue of mere fiscal regulations respecting the public revenue from it, and an outspread and increasing waste of property and life and morals from the operation of its narcotism.

The Cultivated Species of Tobacco.—The common or Virginia tobacco, *Nicotiana tabacum*, is an annual. Its root is fibrous and large; its stem is erect, cylindrical, villous, slightly viscid, branched, and commonly from 4 to 6 feet high; its leaves are sessile, slightly decurrent, alternate, large, entire, oblong, pointed, strongly midribbed, pale green on the upper surface, and still paler on the under one,—the lowermost about two feet long and four inches broad; its flowers grow in large terminal panicles, and have a bell-shaped calyx and a tubular, cup-mouthed, very viscid corolla, and bloom in July and August; its corolla is twice as long as its calyx, and has a pale greenish colour in the tube and a pale red or pink or rose colour in the mouth; and its fruit is an ovate capsule, containing many small kidney-shaped seeds, and opening at the apex. Nine very distinct varieties are in cultivation,—the Verdan, the lute, the pallescent, the attenuated, the slender-stalked, the wing-stalked, the tongue-leaved, the long-leaved, and the great broad-leaved; and the two last of these commonly attain nearly double the height of any of the others, and even rise on rich moist soils to the height of 10 feet,—and the broad-leaved has large, oval-shaped, roughly glutinous leaves, generally about 18 inches in length and 14 in breadth, and has upright and purplish-coloured flowers. The Virginian tobacco is the species most extensively, or even generally, cultivated in America.

The rustic or green tobacco, *Nicotiana rustica*, is also an annual and a native of America, and is supposed to have been introduced to Britain about the same time as the preceding species. Its stem is upright, and commonly from 3 to 5 feet high; its leaves are stalked, ovate or somewhat heart-shaped, deeply furrowed, of a comparatively dark green colour, from 9 to 12 inches long, and from 5 to 8 inches broad; and its flowers are of a dull yellowish green colour, and have a cylindrically tubular corolla, scarcely longer than the calyx, with short, blunt, recurved segments, and bloom from July till September. This species is the one principally cultivated in the north and centre of Europe, and is hardier and more suited to the climate of Britain than the Virginian species, and, when grown with us in the open ground, is generally ripening to seeds at the time when the Virginian is but beginning to bloom. Its seeds also retain their vitality in the ground during a number of years; so that wherever a crop of it has been grown, seedling plants will spontaneously arise through a series of seasons.

Among the other cultivated tobaccos are the repand, *N. repanda*, a hardy annual of commonly about 2 or 3 feet in height, carrying white flowers in June and July, and introduced from Havannah in 1820; the wave-leaved or sweet-smelling, *N. undulata* or *N. suaveolens*, a greenhouse, evergreen, herbaceous perennial, of commonly about 2 or 3 feet in height, carrying white flowers from May till September, and introduced from Australia in 1800; the shrubby, *N. fruticosa*, an evergreen shrub, of commonly from 4 to 6 feet in height, carrying pink-coloured flowers in July and August, and introduced from China in 1699; and two or three or more hardy annuals, of very similar appearance to the Virginian and the rustic, principally from 3 to 5 feet high, carrying either pink, red, white, or greenish flowers for some time between June and September, and introduced at various periods from America. The kinds most suited to Britain, however, are the Virginian for the garden and the rustic for the field.

The Cultivation of Tobacco.—Tobacco, in some one or other of its hardy varieties, can grow and prosper in all the temperate regions of the world up to a high latitude; and is extensively cultivated in the Low Countries, in Germany, and even in Sweden; and might, beyond all question, be produced to any desirable amount in the British Islands. It was raised in the open ground in England, immediately after being introduced; and was with difficulty driven out of experimental British cultivation by the opposition of King James; and was grown, with the most promising results, on the banks of the Teviot and the Tweed up till the application of the prohibitory laws to Scotland in 1782; and has been successfully raised in the field, in the north of Ireland, in quite recent years. The cultivation of it in Britain, however, even though it were fully permitted by law, would never become extensive, except perhaps for purposes of adulteration; for all tobacco grown here is deficient in the flavour, pungency, and narcotic power which characterise the tobacco grown in hot countries, and which constitute the main value of the plant, whether as a drug or as a popular and debasing luxury.

The methods of cultivation in different climates and countries are widely various; and that practised in France and Belgium, with the tongue-leaved variety of the Virginian species, and detailed in the *Journal d'Agriculture, d'Economie Rurale, et des Manufactures*, by Bailley St. Martin, inspector of tobacco manufactures in France, may be selected as the most instructive and interesting to British readers. The soil most suitable is of a marly, hot, and rather moist nature; and the manures most favourable are the sweepings of streets, the deposits of sewerage, and the ashes of strongly alkaline plants, such as those of artichokes, kidney-beans, ferns, beach, and buckwheat. The seed should be sown

on a slight hotbed in March; and one ounce will furnish plants for a plantation of an acre and a half in extent. The seed should not exceed two years old, and should be sown sufficiently thin to cover the surface of a bed 24 feet long and 4 feet broad. It may be steeped before sowing, and kept moist in a warm place till it begins to swell, in order to hasten its germination. Formerly, the tobacco beds were covered with straw instead of glass frames; but the plants were found to be too much etiolated, and therefore glass sashes and a frame, like that used for growing cucumbers, are recommended as decidedly preferable. Plenty of air is given at all times; and in fine weather, the sashes are removed during the day. About the beginning of May, and sometimes a fortnight earlier, the plants will have attained a sufficient size for transplanting; and a week before this operation commences, the bed should be left night and day without the frame and sashes. The tobacco is nearly as susceptible of injury from frost as the potato. The soil for the plantation should be deeply ploughed, well pulverised, and sufficiently manured. The plants may be placed in rows two feet apart, and two feet distant in the row: they should be watered, and, if convenient, a little litter laid round the root of each plant, to retain the moisture in the soil. It must never be forgotten that tobacco loves the sun and humidity; hence, besides keeping the ground clear of weeds, the plants are watered frequently during the months of June, July and August. After the plants have produced five or six leaves on the stem, they must be prevented from running to flower, by pinching out the heart of the main shoot, and rubbing off all the side shoots which are produced from it. Without this precaution, the principal part of the nourishment drawn up by the plants would go towards the formation of flowers and seeds, and the leaves would become thin and wither off. By shortening the main shoot, the whole of the nourishment is directed to the leaves, which thereby become strong and succulent, without any tendency to decay. Sometimes the plants are earthed up a little; but that operation is by no means essential. It is almost unnecessary to observe that, when seed is required, two or three vigorous plants are allowed to run to flower. When the seed is ripe, the plants are taken up, hung up in a dry airy situation, and afterwards the seed capsules taken off and preserved in paper till wanted. It is found that the seeds preserve much better when kept in the capsules than by any other means.

The following mode of gathering and saving the crop is described in the *Cours d'Agriculture Complet*, as practised in Alsatia and in France. The leaves are known to be fit for cutting when they have attained their full size, a dark green colour, and a brittle succulent texture. The lowest leaves acquire these properties first, and, in gardens or small plantations, are therefore first gathered, by being cut off with a knife close to the stem. Where tobacco is cultivated extensively, however, instead of gathering the leaves separately, the plants are cut over by the surface of the ground, and suspended under an open shed upon lines, so far apart that the leaves may not touch each other. In this state they remain till the leaves are perfectly dry, when they are stripped from the stalks, and tied in small bundles, a leaf serving for the tie. These bundles are laid in heaps in a shed, in order to bring on a similar degree of fermentation to what takes place in new hay. That this fermentation may equally pervade every part, the heaps are covered with a cloth, sometimes blankets, mats, or a layer of straw. These heaps are opened and spread abroad to the air from time to time, in order to prevent their overheating; and when this process has been carried on till no more heat is perceived in the heaps, the tobacco is fit for the manufacturer. But a considerably different mode is practised in America, and is described as follows by a writer in the Quarterly Journal of Agriculture: "The plant may be considered fully ripe when the leaves become corrugated and rough, and mottled with yellow spots on the raised parts, while the cavities between retain their original green colour. At this time they also become thicker, and the footstalks are covered with a downy velvet. If the weather be moderate, it is better to allow the plants to stand, until all these indications are apparent; but should frost come, they must be cut up, whether they are quite ripe or not. When the leaves begin to be corrugated, they must be nearly so. When quite ripe, the gatherer proceeds to the field on the first fine day; and, laying hold of the plant near the top with one hand, he cuts it over, with a large knife or axe, as near the root as possible, with the other. The stalk being severed, it is laid down with great care on the ground. The utmost gentleness must be used, in order to prevent the leaves, which are exceedingly tender and brittle, from being broken. The whole plants on the field being laid down, they are allowed to remain, during the rest of the day, exposed to the rays of the sun; and in the evening, they will be found quite pliant and flexible,—or, as the Americans call it, 'wilted.' Should the weather prove rainy, the operation of wilting must be allowed to go on under cover; but it is much more effectually done in the open air; and, on this account, the gathering ought never to be commenced unless the weather promises to be fine. In the evening, before sunset, when the leaves are completely wilted, and do not run so much risk of being broken, the plants are removed from the field into a large shed or house for the purpose, and laid in large heaps on the floor. When they have been in this situation about 24 hours, they will begin to ferment; and, when this operation is going on, they must be con-

stantly shifted, those on the top of the heap being put into the middle, and those in the middle on the top. During the fermenting, the leaves and stalks will assume a darker colour, and, if allowed to lie too long, will become mouldy, which must by no means be permitted. The process of fermenting may usually be allowed to continue three or four days, after which, the plants must be taken in pairs, and tied together at the roots, or have a peg run through their stalks, close to the bottom, and be suspended, in this way, with their leaves hanging down, with plenty of room between each pair, upon a cross-beam in the same shed. After the leaves are thoroughly dried, which they will in general be, after hanging about a month, the plants may be taken down. A damp day ought to be selected for this purpose, otherwise the leaves are apt, from their extreme dryness, to crumble into dust. But if the atmosphere be damp, their great affinity to moisture will prevent such a casualty. When down, they are again laid in heaps, and pressed together by large logs of wood. Fermentation will again commence, and may be allowed to continue about a week. Great care must be taken, however, to prevent the heat from becoming too great; and, in order to this, the person in attendance must constantly keep inserting his hand into the heap. When the heat exceeds a glowing warmth, it may be considered too powerful, and must be reduced by the removal of some of the wood. This second fermenting process, which in technical language is termed 'the second sweating,' is sometimes omitted; but both Bosc and Carver agree in recommending it, as it tends much to mellow the taste of the tobacco. It is generally allowed to continue for about a week, after which the plants are separated, and the leaves, being stripped off, are tied together in bunches, technically called 'hands.' This is the last operation performed by the planter, who sells the tobacco 'in hands' to the manufacturer."

The farmer who understands how to make good meadow-hay, will be at little loss how to make good tobacco. With regard to growing the plant, it requires very little more care than growing a crop of cabbages: the extra care is in raising the seedlings, pinching *out* the hearts, and *off* the side shoots, and gathering any caterpillars that may appear on the leaves. Any British farmer who contemplates a trial of the tobacco culture, and does not feel himself fully master of the subject, will find his difficulties easiest solved by applying to the nearest intelligent gardener, provided he be a reading gardener. But whoever understands the general principles of culture,—that is, whatever farmer is capable of reasoning on what passes under his notice in the culture of turnips and cabbages, and the making of hay,—is perfectly competent to cultivate tobacco.

The Properties, Uses, and Abuses of Tobacco.—Tobacco, whether applied externally or taken into the stomach, acts as a narcotic, a sedative, an emetic, a diuretic, and a cathartic; and when snuffed into the nostrils, it acts as a powerful errhine,—or when applied hot and in leaf to the skin, it is sufficiently irritating to raise blisters. Its narcotic and sedative actions operate on the heart through the medium of the nerves; and, whenever they are strong or excessive, they produce dreadful sickness, headache, extreme debility, cold sweats, and sometimes even convulsions, delirium, syncope, and death. The leaf is a remedial application for verminal sores; the smoke and the juice, through means of respectively the pipe and the quid, afford some relief from the paroxysms of spasmodic asthma; the powder, in the form of snuff, has the reputation of alleviating the evils of watchfulness and dim vision; the infusion and the smoke—the latter introduced by means of a peculiarly constructed pair of bellows—are sometimes efficacious in cases of ileus, suppression of urine, obstinate constipation, and incarcerated hernia, when other remedies fail; and the infusion, in minute and cautious doses, has occasionally been found serviceable, in cases of dropsy, dysury, and similar diseases, as an emetic and a diuretic,—but, in these capacities, is always a doubtful remedy and sometimes a very dangerous one. In veterinary medicine, enemas of tobacco are eminently serviceable in obstinate constipation, in tetanus, and in some bad spasmodic affections; and infusions of tobacco are common but very improper ingredients in external applications for mange and for destroying parasites.—In all its proper medicinal uses, tobacco ranks at best with such terrifically violent drugs as digitalis, belladonna, and prussic acid; and ought never to be employed by any inexperienced person in any case whatever, nor even by the most skilful practitioner except when feebler remedies are likely to be, or have actually been, inefficient.—Tobacco, in the several forms of smoke, infusion, and powder, is currently and extensively used in horticulture for destroying insects on plants; and, of course, it owes all its value in this way to its deadly power against animal life.

The proximate principle in which the narcotic energy of tobacco resides is an alkaloid called nicotina or nicotia. At thirteen degrees below the freezing-point, it appears as a slightly-tinged pulverulent matter; and above that temperature, it remains in the form of an almost colourless and transparent liquid, with a pricking and burning taste, which is so difficult to get rid of, that it is felt on the tongue for hours. The nicotina gives out, besides, a nauseous and pungent odour. It combines with the acids, with each of which it forms a salt. With a wick, it will burn like oil, diffusing a vivid light. It mixes readily with water in all proportions, and is soluble in alcohol, ether, and oil of almonds, but not in oil of turpentine. This principle of tobacco is so poi-

sonous, that a single drop of it will destroy a large dog. Besides its nicotina, tobacco contains ammonia, sugar, bitter extract, resin, albumen, potash, nitric and muriatic acids, and some other principles, the whole forming different combinations. The free ammonia appears a result of fermentation, and arises from the decomposition of hydrochlorate of ammonia, naturally residing in the plant. If a green tobacco-leaf be crushed between the fingers, it gives out no other than the herbaceous odour common to all plants; but if the same leaf be triturated in a mortar, with a small bit of quicklime, or a few drops of caustic solution of potash, it immediately yields the well-known odour of snuff. The reason of this is, that the lime or the potash decomposes the hydrochlorate of ammonia existing in the leaf, and liberates the ammonia; the hydrochloric acid flies to the lime or potash water, whilst the chlorine and the metal uniting, are converted into chloride of calcium, or chloride of potassium.

For the purposes of use and manufacture, the tobacconist spreads the fermented tobacco-leaves upon a stone pavement, and separates the bad from the good. This being done, the good leaves are watered, by successive layers one over the other, with a solution of common salt. They are then suffered to react upon each other during several days, according to their quality and the temperature to which they are exposed. At this period, a new fermentation arises, and more strongly develops the odorous principle of the leaf. The salt added to the tobacco is supposed to keep the leaf moist, and to temper the fermentative action, which might otherwise run into excess. The maintenance of moisture, however, is better effected by sea-water, which contains other salts besides common salt, or chloride of sodium, some of which have still a greater tendency than it to deliquesce. The leaves, after being thus prepared, are sorted and stripped of their middle stalk; when the larger are set by for making cigars, and the others, together with the stripped stalks, are appropriated for the manufacture of smoking-tobacco, chewing-tobacco, and snuff. "Most of the tobaccos on sale in our shops," observes Dr. Ure, "are mixtures of different growths. One kind of smoking-tobacco, for example, consists of seventy parts of Maryland, and thirty of meagre Virginia; and one kind of snuff consists of eighty parts of Virginia, and thirty parts of either Humesfort or Warwick. The Maryland is a very light tobacco, in thin yellow leaves; that of Virginia is in large brown leaves, unctuous and somewhat gluey on the surface, having a smell somewhat like the figs of Malaga; that of Havannah is in brownish, light leaves, of an agreeable and rather spicy smell,—it forms the best cigars. The Carolina tobacco is less unctuous than the Virginia; but in the United States, it ranks next to Maryland."

Beneficial as, in some cases, tobacco may prove in its character as a medicine, its use as a luxury, in any form, is as injurious as its intoxicating properties are lamentably demoralising. It is generally used in one, yet often in two, of the three forms of smoking tobacco, quid, and snuff. At the commencement, it causes, like opium, intoxication and sickness; but by continued use in moderation, these unpleasant symptoms subside into a sort of fascinating, dreamy state of semi-intoxication, which insidiously attacks the health, making disease and disorganisation creep by silent and stealthy steps into the system, and drink up the spring of life until its fountain is drained. An immoderate use of tobacco produces furious intoxication, and often dangerous delirium, much increased by the strong drinks which its stimulating properties incite the tobacco-consumer to take.

The most general of the three modes of using tobacco as a luxury is smoking. "Some seek in the inhalation of tobacco-smoke," observes Dr. Ure, "a pleasurable narcotism; others imagine it to be beneficial to their health; but, in general, smoking is merely a dreamy resource against ennui, which ere long becomes an indispensable stimulus. The filthiness of this habit, the offensive odour which persons under its influence emit from their mouth and clothes, the stupor it too often occasions, as well as the sallow complexion, black or carious teeth, and impaired digestion, all prove the great consumption of tobacco to be akin in evil influence upon mankind to the use of ardent spirits." Smoking in *any* form, and with *any* kind of tobacco, may, for a time, give ease to the solitary or the sedentary, most of whom are afflicted with dyspepsia; but by degrees it makes an inroad into the system which nothing can repair, and this, of necessity, by the very manner of its action. It maintains, even in its mildest form, the throat and its glands in a state of constant irritation, so as to excite unnatural thirst; it causes an excessive secretion of saliva, which is generally discharged, or, in more polite language, expectorated, and thus deprives the stomach of a fluid necessary to the deglutition and digestion of food, and robs the agents of digestion of a natural and necessary aid; it acts in such a manner on the brain as to produce loss of memory, and general deterioration of intellect; and, lastly, by its general action on the nerves, it generates not only depression of mind, but great infirmity of temper. We may add that, though for a short time it may prove a stimulus to the workings of genius, like the potent alcohol, it excites but to destroy; and many a highly-gifted smoker has survived the loss of that mind which rendered him the delight and ornament of his age and country. Every tobacco-smoker, too, has a tendency to become one of the most selfish and disagreeable of mortals; and though formerly urbane and benevolent, he may soon be a greater nuisance on the street than a hog right

from the sty, and with just as little apparent consciousness of the disgust and pain occasioned by his presence; or he may neglect all the proprieties and many of the highest moral obligations of the domestic circle, and feel utter indifference respecting them, simply that he may squander all the time and money which are due to them upon his own abominable propensity.

The quid is the next form in which tobacco is used as a luxury; and this is put into the mouth between the jaw and the cheek, and there rolled and sucked and turned and chewed. The kind of tobacco used for the quid is the strong leaf, prepared in the manner formerly described, and made first into cords and then into rolls, and popularly called pigtail. The quid in the mouth, like the smoke of tobacco, excites the salivary glands; and the mucus thereby secreted, mixes with the principle of the plant and forms a strong infusion of tobacco. Though this be discharged from the mouth, and little or none of it go into the stomach, the intoxicating and narcotic principle of the tobacco acts upon the brain, and causes the most dreadful intoxication in those unused to it. Like that of smoking, the habit of chewing tobacco is gradually acquired in the same manner as the taking of opium, and the madness of the intoxication gradually ceases; though most chewers of tobacco, unless actively employed, or enduring pain, are always in a state of semi-intoxication, not a few of them displaying an eye which very little would rouse into a glare of ferocious insanity; for it is the intoxication of tobacco that leads to the most cruel acts committed by the idle and the lawless. It is said, and it may be true, that men exposed, as sailors are, to be covered with wet clothes morning, noon, and night, require such a narcotic stimulus as tobacco, to secure them as well against intermittent fever and other distressing and dangerous complaints arising from their pursuits and necessary habits of life, as to keep up their strength and courage during the excessive muscular labour and trying hardships they have to endure. The same kind of stimulus may also be requisite in a low, damp country like Holland, and in climates such as those of the south-eastern coast of Madagascar and of Batavia. But of this we are certain, that, with very few exceptions, men exposed, from these causes or from any other, to the necessity of constantly using tobacco, run out more rapidly than others the thread of their existence,—and that the inveterate tobacco-chewer is as old in constitution at fifty years of age, as he would be at seventy, did he not use this seductive and dangerous plant.

The third form in which tobacco is used as a luxury is snuff. The practice of reducing this plant to a powder and preparing it for introduction into the nostrils, is general throughout Europe. It is said to have originated with the French; and indeed, it is very probable that no other nation in the world would have imagined so singular a mode of using the tobacco plant. As a remedial pretence is often assigned for smoking or chewing tobacco, so also is a similar excuse offered for snuff-taking. Persons who have sore eyes or bad sight are often recommended the use of this tobacco-powder; and it may have happened that inflamed eyes have been cured by such use; from which the takers have inferred that they must ever afterwards continue the practice, or the ophthalmia would return. But the snuff, in effecting such cure, had no peculiar specific virtue; its action was only that of a counter-irritant. The cephalic snuff, Grimstone's eye-snuff, or any other of the quack snuffs, sold as secret remedies for headaches and sore eyes, would have produced the same precise effect, and by the same precise means, but without the same injury to the constitution; for these contain no tobacco; they are composed principally of dried and pulverized sternutatory herbs, such as the leaves of the asarum, those of marjorum, and the flowers of the lily of the valley, combined. These, like the snuff of the tobacco plant, excite and irritate the mucous membrane of the nostrils, and cause an additional secretion of mucus, which accounts for the frequent use of the pocket-handkerchief by snuff-takers. But the tobacco snuff does more; it acts upon the brain, causing intoxication and sickness; and besides this, a large quantity of the powder taken into the nostrils enters the stomach, and there creates a truly distressing disturbance. Almost all snuffs, too, contain other matters besides tobacco; and though some contain nothing deleterious, and are only mixed with substances which improve their flavour, many are said to contain muriate of ammonia, pounded glass, carbonate of potash, and other matters intended to communicate pungency to the powder. To produce a certain ammoniacal flavour peculiar to many strong kinds of snuff, it is affirmed that human urine is sometimes employed; and from the odour of more than one variety, we cannot help thinking this affirmation correct. Pearlash, an impure carbonate of potash, is very frequently made use of by unprincipled dealers, to impart the pungency and flavour obtained in the best snuffs by more costly ingredients. "I was," says Dr. Ure, "employed some years ago by the excise to analyse a quantity of snuff, seized on suspicion of having been adulterated by the manufacturer. I found it to be largely drugged with pearlashes, and to be thereby rendered very pungent and absorbent of moisture,—an economical method of rendering an effete article at the same time active and aqueous." All the damaged or spoiled tobacco is converted into snuff, which, by the aid of adulterating ingredients and sonorous names, is sold at a high price. Thus, in spite of legislative enactments, a snuff-taker receives into his nostrils, and thence into his stomach, matters which, if he were but conscious that they formed component parts of his

favourite powder, would sicken him with disgust. And many of the most recherchés and fashionable snuffs are of this description. It is said that the human senses may be gradually brought to any degree of depravity; and in nothing is this more evident than in snuff-taking. Nauseous odours are considered delicious, and the vilest compounds, have they but a name, eulogised as most exquisite. There is a musty, overpowering, ammoniacal smell arising from snuff in large masses kept for years in close vessels; and this odious exhalation is one of the delights of the snuff-taker. Old snuff is, therefore, prized beyond measure; and what in any other vegetable production would render it only fit for the dunghill, is in snuff deemed its highest excellence.

TOCOCA. A small genus of ornamental, tropical, evergreen shrubs, of the melastoma family. Aublet's species, and the woolly, the former pinkish-flowered and the latter white-flowered, and both about 3 feet high, blooming in autumn, thriving best in a soil of peaty loam, and propagable from cuttings, have been introduced to the hothouses of Britain from respectively Guiana and Trinidad.

TOFIELDIA. A genus of curious and ornamental, evergreen, herbaceous plants, of the melanthium tribe. An indigenous species is noticed in the article Scotch Asphodel; four hardy species of from 2 to 6 inches in height, have been introduced to British collections from North America and Northern Europe; and several other species are known.

TOLPIS. A genus of ornamental, hardy, annual plants, of the succory division of the composite order. Five species, varying in height from 1 foot to 4 feet, and all thriving in any common soil, and carrying either yellow or yellow and purple flowers in June and July, have been introduced to Britain from Continental Europe.

TOLU (Balsam of). See Myroxylon.

TOMATO. See Love Apple.

TOMICUS. A genus of coleopterous insects of the bostrichidæ or wood-eating family. See the article Bostrichidæ. The antennæ of a tomicus cannot be folded under the eyes; the club is distinctly annulated; the head is rounded above and almost globular; the side of the thorax is emarginated; the tibiæ are not striated; the tarsi, at most, are as long as the tibiæ; the eyes are elongated and somewhat emarginated; and the body is cylindrical. Eleven species are known to inhabit Britain; all frequent coniferous trees of the pine and fir family; and some occasionally commit great devastations in other countries; but none are recorded to have done any considerable mischief in Britain. The printing species, *Tomicus typographus*, so called from the letterpress-like traces which are made by its tubular bores or paths, is a rare insect in Britain, but abounds in many continental countries, and has there won a bad fame by its havoc upon forests. It is popularly known in Germany under the name of the Turk; and is recorded to have appeared in prodigious multitudes in the Hartz pine forests in the years 1757, 1769, and 1783,—and to have, in the last of these years, destroyed not fewer than a million and a half of trees, and occasioned a disastrous falling off in the supply of fuel throughout the circumjacent country.

TONGUE. The muscular organ which, in man, forms the principal articulations of speech, and which, both in man and in the inferior animals, disposes the food for mastication between the grinders, collects it after mastication, forms it with the aid of the bars of the palate into pellets for deglutition, and serves as the main instrument and canal for the imbibition of drink. The tongue of some particular groups or orders of animals also performs some additional functions; and that of all co-operates with the palate in exercising the sense of taste. Every tongue is muscular; and that of the higher orders of animals comprises a vast number of fibres, arranged in various forms and directions, interspersed with a considerable quantity of fatty matter, covered with a curious, triplicate, fleshy envelope, and comprising a multitude of minute, comprehensive, and perfect adaptations to its various offices; and that of man, in addition, possesses such ramifications of nerves, such intricacies of mechanism, and such a thousandfold power and nicety and volubility of action in subserviency to the purposes of speech, as render it an absolute museum of most instructive wonders. The tongues of oxen and horses are alike held firm in their places by muscular attachment to the *os hyoides*, a singular bone which connects the whole lingual organ with the larynx; but the ox's tongue needs to collect the herbage in grazing, to roll back the gathered herbage into the mouth, to clean the muzzle from dirt and insects, and to wipe away accumulations of morbid discharge from the nostrils, and therefore has a very loose root of attachment, and possesses very great freedom of motion, and can be far and volubly protruded out of the mouth; while the horse's tongue needs not to perform any such extra functions, and requires capacity to withstand the restraints and abrasions of the bit, and therefore has a very radical attachment, and possesses a sort of pad on which the bit may rest, and is rarely protruded at all from the mouth, except when the vicious habit is acquired of licking the manger. Two bad diseases of the tongue of cattle and sheep are noticed in the articles Blain and Aphthæ. A severe laceration or even disseverment of the tongue of the horse is sometimes occasioned by the awkward manner of administering a ball; but, in general, may soon be alleviated or cured by means of syringing with a solution of alum. A series of purplish vesicles sometimes forms along the under side of the horse's tongue, and occasions enlargement of the whole organ, the copious secretion of a ropy

saliva, and great difficulty or even impossibility of deglutition; and they must be lanced freely and deeply, and a little cooling medicine given to subdue accompanying or resulting symptomatic fever.

TONIC. A medicine which increases the digestive power of an enfeebled stomach, and in consequence improves the general strength of a debilitated body. The best tonic, in any case of sound constitution which has merely been temporarily invaded by an acute disease, is to let the system completely alone after the disease is subdued, or at best to use a little care in the selection of food. Tonic drugs, like cordials, are very good in their way, and often do great and rapid service, but are exceedingly liable to be abused, and sometimes serve as very mischievous tools in the hands of hasty or unskilful practitioners. In veterinary medicine, such mild tonics as chamomile, gentian, and ginger are the most useful, and the least likely to do harm, in all ordinary cases; such stronger tonics as cinchona, quinine, oak-bark, gentian, quassia, cascarilla, and carbonate of iron, require some more caution and discrimination in their use; and such mighty and violent tonics as preparations of copper, zinc, mercury, and arsenic are suitable only in very particular cases, and ought never to be used at all except by the most intelligent practitioner and after the most careful consideration.

TONQUIN BEAN. The seed of *Dipterix odorata*, well known to snuff-takers for the use which is made of it in perfuming their nose-powder. The *Dipterix odorata* is a tropical, purple-flowered, evergreen tree, belonging to the cæsalpinia division of the leguminous order, and naturally attaining a height of about 60 or 70 feet. It was introduced from Guiana to the hothouse collections of Britain about 56 years ago; and it thrives best in a soil of rich peaty loam, and is propagable from cuttings.

TONSELLA. A genus of ornamental tropical plants, of the hippocratea tribe. Two species, the climbing and the pear-shaped, both green-flowered, evergreen climbers of between 5 and 8 feet in height, have been introduced to British hothouses from Guiana; and eight or nine other species are known.

TOOTH. See Teeth.

TOOTHACHE-TREE,—botanically *Zanthoxylum*. A genus of ornamental, ligneous, exotic plants, of the rue family. The Hercules' club species, *Zanthoxylum Clava-Herculis*, is the species best known in Britain, and that which originally received the name of toothache-tree,—a circumstance which it owed to the reputation of its bark as a cure for toothache. See the article Hercules' Club. The height of this shrub is commonly 10 or 12 feet; the bark is rough, and armed with short thick spines; the leaves grow without order on the branches, and are pinnated in form, and of a fine dark green colour on their upper surface, and yellowish underneath, and have a highly ornate appearance, and present a general resemblance to those of the mastic-tree; the folioles of each leaf amount to four or five pairs and a terminating odd one, and have an elongated lanceolate form; and the flowers come out in loose panicles from the ends of the branches, and are small and inconspicuous, and are succeeded by roundish capsules. This plant loves a soil of rich peaty loam, and is propagable from cuttings.—The ash-like, the three-capsuled, and the mild species, *Z. fraxinium*, *Z. tricarpum*, and *Z. mite*, are hardy deciduous shrubs, the first and second about 6 feet high and the third about 10 feet high, introduced from North America at various periods since about the middle of last century; and are best propagated from layers.—Ten or eleven tropical and subtropical evergreen species, varying in natural height from 10 to 25 feet, and mostly loving a soil of rich peaty loam and propagable from cuttings, have been introduced principally from the two Indies; and about thirty other species are known.—A large number of the species, and probably all, possess in a greater or less degree acrid, stimulating, and tonic properties. The Hercules' club and the ash-like—which some persons regard as only very distinct varieties of one species—have the reputation in America of being powerfully sudorific and diaphoretic, and excite copious salivation, not only when made to act directly on the mouth, but when taken internally, and have been found highly efficacious in paralysis of the muscles of the mouth; and the Caribbean species, *Z. caribæum*, is regarded in Guiana as a cleansing vulnerary and a febrifuge.

TOOTH-TONGUE. See Odontoglossum.

TOOTHWORT,—botanically *Lathræa*. A small genus of curious plants, of the orobanche tribe. The scaly species, *Lathræa squamaria*, is a perennial-rooted, epiphytous indigen of dry shady spots, at the root-crowns of elms, beeches, hazels, and other trees, in the woods and thickets of many parts of Britain. It is about a foot high; and has white fleshy scales instead of leaves; and carries herbaceous-coloured flowers in April. It is exceedingly shy of cultivation; but may be brought into a rhododendron quarter by removal of the whole plant, together with as much as possible of the adhering soil, from a spot where it naturally grows; and may afterwards be propagated by a careful division of the roots.

TOP-DRESSING. A manure of any kind spread upon ploughed land without being turned in, or a fine, or comminuted or thoroughly reduced or special manure sown or equally distributed upon grass land. Common kinds of top-dressings are soot, ashes, rape-dust, gypsum, common salt, and the nitrates of soda and potash. See the article Manure.

TORDYLIUM. See Hartwort.

TORE. Rowen or winter-grass. See the article Aftergrass.

TORENIA. A genus of curious and ornamen-

tal exotic plants, of the figwort family. The rough-leaved species, *T. scabra*, is a handsome, evergreen shrub of about 3 feet in height, carrying pale blue flowers from June till August; and was introduced to the greenhouses of Britain from Moreton Bay in 1830; and loves a soil of rich loam, and is propagable from cuttings. The heart-leaved species, *T. cordifolia*, is a curious, late-blooming, pale-lilac-flowered, tender annual, of about 6 inches in height; and was introduced in 1838. Two tropical, purple-flowered, July-blooming, evergreen trailers also occur in British collections; and one of these, *T. asiatica*, is used on the Malabar coast as a medicinal plant.

TORILIS. See HEDGE-PARSLEY.

TORMENTIL. See SEPTFOIL.

TORTRIX. A genus of moths, constituting the type of the family Tortricidæ. The insects of this family are comparatively small and prettily coloured; and possess a bad fame among foresters for the destructive habits of their caterpillars among the foliage of trees. Their proboscis is distinct; their inferior palpi are closely similar to those of the most typal forms of phalenæ; their wings are tectiform, but almost horizontally flattened, and always laid on the body; their upper wings are arcuated at the base of the exterior margin, and then narrowed; and their figure is short and wide, and forms a truncated oval, and gives the insects a very peculiar appearance. The caterpillars have sixteen feet, and a closely shorn or but slightly pilose body; and most twist and roll up the leaves of trees, and connect various points of their surface at different times by layers of silken threads running in one direction, so as to form tubes,—and in these they reside, feeding tranquilly on the parenchyma; but others form a nest by connecting several leaves or flowers with silken threads; and a few inhabit fruits. Some of the species best known in Britain, or most remarkable for their depredations, are the pea-green moth, *Tortrix viridana*, which infests the leaves of the oak-tree,—the rose moth, *Lozotœnia rosana*, which infests the flower-buds of rose and currant bushes,—the narrow-winged red-bar, *Ditula angustiora*, which rolls up the leaves and destroys the nascent fruit-buds of the apricot-tree,—the apple or codling moth, *Carpocapsa pomonella*, which eats into the pulp and devours the pips of growing apples,—the Wœberian moth, *Carpocapsa Wœberiana*, which feeds on the bark of various kinds of fruit trees,—the Bergmann rose moth, *Argyrotoza Bergmanniana*, which devastates the foliage and mutilates the flower-buds of rose plants,—the turpentine moth, *Cnephesia resinella*, which works havoc on the young shoots of fir-trees,—and the bud-tortrix of the pine, *Argyrolepia turionella*, which infests and devastates the buds of young abietinous trees, particularly silver firs.

TOUCH-ME-NOT. See IMPATIENS.

TOURNEFORTIA. A genus of ornamental, evergreen, exotic plants, of the borage family. About a dozen species, principally evergreen shrubs of from 2 to 10 feet in height, have been introduced to the conservatories, greenhouses, and hothouses of Britain; and about 30 other species are known. One of the earliest introduced is described as follows by Miller, and may serve as a sufficient specimen of the whole. "It grows naturally in Jamaica and in some other islands in the West Indies. It rises with shrubby stalks 8 or 10 feet high, sending out many branches, closely garnished with oval spear-shaped leaves placed alternately round the stalks. These are 5 inches long, and 2½ broad in the middle, hairy on their under side, and stand on short footstalks. The branches are terminated by long branching spikes of flowers, ranged on one side the footstalks in the same manner as those of the heliotrope. Some of the footstalks sustain two, others three, and some four spikes of flowers, which are near 5 inches long, and are reflexed like a scorpion's tail at the top. The flowers are of a dirty white colour, and are small and closely ranged on one side of the spike; and are succeeded by small succulent fruit, enclosing four oblong seeds in each." Nearly all the introduced species thrive best in a soil of peaty loam, and are propagated from cuttings.

TOWER-MUSTARD,—botanically *Turritis*. A small genus of white-flowered herbaceous plants, of the cruciferous order. The smooth or long-podded tower-mustard, *Turritis glabra*, called by some botanists *Arabis perfoliata*, is an annual indigen of grassy-banks, road-sides, and pasture fields, with a dry gravelly soil, in various parts of England. Its root is tapering; its stem is erect, slender, leafy, and from 15 to 36 inches high; its radical leaves are numerous, spreading, toothed, and rough; its cauline leaves are sheathing, oblong, arrow-shaped, entire, glaucous, and smooth, and are so disposed on the stem as to present a pyramidal or tower-like appearance, which is alluded to in both the popular and the botanical names of the genus; the flowers are numerous, and grow in close corymbs, and bloom in May and June; and the pods stand on short footstalks, and are very long and slender, and contain about sixty very small seeds in each cell.

TOWER-MUSTARD (WALL-CRESS),—botanically *Arabis turrita*. An indigenous biennial plant, of the wall-cress genus and cruciferous order. It grows on walls and similar situations in some parts of England; and has a general appearance similar to that of the smooth tower-mustard. Its stem is commonly about 18 or 20 inches high; its cauline leaves are clasping; its flowers are sulphur-coloured, and bloom in April and May; and its seeds are marginate. Two varieties of it, called the shady and the pendulous, have been introduced to British botanical collections from Continental Europe.

TOXICODENDRON. See SUMACH.

TRACES. See DRAUGHT, PLOUGH, CART, and TRACTION.

TRACHEA. See WINDPIPE.

TRACHELIUM. See THROATWORT.

TRACHEOTOMY. The formation of an artificial opening into the windpipe. It is sometimes required, in horses, in cases of strangles, of throat-tumours, and of excessive tumefaction of the mouth and nostrils, arising from the effects of severe accidents,—in cattle, in cases of blain, of inflammation of the parotid gland, and peculiar tumours arising from fever,—and both in horses and cattle, in cases of threatened suffocation from the pressure of some large piece of food or other substance sticking fast in the œsophagus. "The operation," says Delabere Blaine, with special reference to horses, "is a very simple one, and may consist either in a longitudinal section made through two or three of the rings; or a portion, occupying about an inch square, may be excised from the anterior cartilaginous substance, and which latter is by far the best method. The integuments should be first divided in front of the neck three or four inches below the obstruction; and the integumental section should be sufficiently long to allow of their being retained back by a hook to each side, to which tape should be attached and tied on the crest of the neck above. This is however only to be pursued when the obstruction is likely to remain but a few days. When a more lengthened one is probable, a tube adapted to the size of the trachea must be introduced, having an acute turn and a projecting rim, which must furnish holes for the adaptation of tapes to secure it around the neck."

TRACHYMENE. A genus of curious and ornamental, exotic, evergreen shrubs and undershrubs of the umbelliferous order. Four or five species have been introduced to the gardens of Britain, principally from Australia; and all love a soil of sandy peat, and are propagated from cuttings. The name trachymene signifies 'a rough membrane,' and alludes to the involucrum.

TRADESCANTIA. See SPIDERWORT.

TRAGACANTH. A medicinal gum, supposed to be produced by the great goat's thorn, *Astragalus tragacantha*, a hardy evergreen undershrub, belonging to the lotus division of leguminosæ, and introduced to the gardens of Britain from the Levant in the year 1640. The stem of this plant is about an inch thick, very much branched, and about 2 or 3 feet high; the branches are closely crowded together, and have an armature of scales and spikes, formed from the petioles of the preceding year; the leaves are pinnate, each comprising six, seven, or eight pairs of leaflets, and scarcely half an inch in length, and terminating at the end of the midrib in a sharp yellowish point; the leaflets are opposite, villous, stiff, and pointed; and the flowers grow from the axils of the leaves, and are small, pale yellow, and papilionaceous, and bloom from May till July. The gum exudes in tortuous filaments during the heat of summer, and is allowed to dry on the plants before it is gathered; and it is produced principally in Persia, and sent thence to Britain by way of Aleppo. It is whitish, semi-transparent, brittle, difficult of pulverisation, inodorous, and very slightly bitter. It swells and softens in water, but cannot without special management be reduced in even a small degree to the state of mucilage; and it is insoluble also in alcohol and ether. It possesses demulcent properties; and is employed, in a compounded or pharmacised form, in cases of catarrh, hectic fever, strangury, and dysentery.

TRAGIA. A genus of exotic, green-flowered plants, of the spurge family. Nearly a dozen species—comprising annuals, perennials, twiners, creepers, and erect plants, varying in height from 1 foot to 6 feet, some hardy, others very tender, and most capable of thriving in any common soil—have been introduced to the botanical collections of Britain; and about as many more are known.

TRAGIUM. A genus of exotic, white-flowered, herbaceous plants, of the umbelliferous order. The anise plant, *Pimpinella anisum* or *Sison anisum*, is assigned in the most modern botanical rearrangements to this genus. See the article ANISE. Six other species, principally perennial-rooted, annual-stemmed, and about two feet high, have been introduced to Britain; and three or four more are known. The name tragium is formed from a word signifying a goat, and alludes to the hircine odour of the oldest-known species.

TRAGOPOGON. See GOAT'S BEARD.

TRAGOPYRUM. See GOAT'S WHEAT.

TRAINING. See BREAKING and MANEGE.

TRAINING, IN GARDENING. Towards the end of March, young trees that have been planted out since October of the former year are headed down, or have their shoots shortened back to three, five, or six buds, according to their strength, and the purpose for which they are intended. When the trees have stood two, three, or more years in the nursery after grafting or budding, the heading down is of course confined to the last year's shoots, and its extent, as well as the thinning out of superfluous shoots, must be left to the judgment of the experienced gardener, it being impossible to lay down rules where the circumstances must be perpetually varying.

Wall-trees.—The two principal methods of training wall-trees which are followed in this country, are called the *fan* and the *horizontal* modes. In the former, the branches are arranged like the spokes of a fan, or like the hand opened and the fingers spread. In the other way, a principal stem is carried upright, and branches are led from it horizontally on either side. The Dutch style consists in taking a young tree with two branches, and leading these horizontally to the right and left, to the extent perhaps of

twelve feet each way, and in then training the shoots from these perfectly upright to the top of the wall. This is now seldom practised here, excepting perhaps with fig-trees or white currants. In some places, a few of the wall-trees are trained in a stellate form, the stem being led upright for about six feet, and then some branches trained downwards, others laterally, and others upwards. When walls exceed seven feet in height, the best gardeners seem to concur in giving the preference to the fan training, variously modified: in this way they find that a tree can much sooner be brought to fill its allotted space, and the loss of a branch can much more easily be supplied at any time. For lower walls, the horizontal method is preferred; and the same plan is adopted almost universally on espalier rails. Mr. Hitt strongly recommends this mode for most sorts of wall-trees; and for pears he adopts what is called the *screw* stem, or training the stem in a serpentine manner, the branches going off horizontally as in the ordinary straight stem.

In the first volume of the Transactions of the London Horticultural Society, Mr. Knight has made some ingenious and excellent remarks on the training and pruning of fruit-trees. His year-old plants are headed down as usual, early in the spring, and two shoots only are trained from each stem in opposite directions, and to an elevation of about 5°. To procure the shoots to be of equal lengths, the stronger is depressed, or the weaker elevated. All lateral shoots are destroyed. Thus far, it may be remarked, Mr. Knight's method agrees very much with Hitt's, described in his treatise on fruit-trees. This shape, Mr. Knight observes, ought to be given to young trees in the nursery, and is perhaps the only one that can be given to them without the risk of subsequent injury. Next season, as many branches are suffered to spring from each plant as can be conveniently trained, without shading each other; and by selecting the strongest and earliest buds towards the points of the year-old branches, to be trained lowest, and the weakest and latest near their bases, to be trained inclining upwards, each annual shoot will be nearly equal in vigour. In the following winter, the shoots are alternately shortened and left at full length. In the course of the third year, if the tree be a peach, the central part consists of bearing wood: and, upon the whole, the size and general health of the trees trained in this way, afford evidence of a more regular distribution of the sap than Mr. Knight has witnessed in any other mode.

The distance at which the branches are laid in, in all the different modes, varies from eight to ten inches, according to the nature of the tree, or the size of its foliage or fruit. While fan-trained trees are still in progress, a few more shoots are preserved at the summer pruning, than are likely to be ultimately laid in; this is for fear of accidents. Trees that have filled the spaces allotted to them, are disbudded of most of the wood-buds that appear. Wood-buds on old spurs are always displaced. Trees which are in training for the horizontal method require different management. The leading stem is constantly to be attended to; all the buds that appear on it are carefully preserved, till enough be procured to lay right and left, and form the tree. All wood-buds on the horizontal branches, excepting the leading one, are displaced. The fan-training is considered as best for apricots, cherries, and plums, placed against walls, even though the walls be low. None of these kinds of fruit answer well for espaliers; cherries or plums succeed better as half standards or dwarf standards.

The wall-trees which have now been spoken of are called *dwarfs* by the gardeners. It is a very common practice to train high standards on the intermediate spaces between the dwarf trees; such trees are in Scotland termed *riders*. Plants four or five years old are preferred, because they are but temporary, and the object is to get fruit as soon as possible. Some good judges have condemned this plan of temporary trees as hurtful; being calculated to deprive the permanent trees of a proportion of the nourishment which they would otherwise draw from the border; but if the border be tolerably rich, and be only slightly cropped with herbaceous plants, it does not seem likely that the temporary trees can do much injury.

Espalier Trees.—Some horticulturists have proposed to banish espalier-trees altogether, alleging that they injure the kitchen-garden quarters, by depriving them of sun and air. But though they are sometimes injurious by depriving the plants of air, they are at other times very useful, acting as a hedge in protecting the young crops from the violence of strong winds. Espalier-trees generally produce excellent fruit, the sun and air having access to both sides of the tree; they commonly afford abundant crops, and the fruit is not apt to be shaken by high winds. Further, they tend to hide the crops of culinary vegetables from the eye, and to render the walk of the kitchen garden as pleasant as an avenue in the shrubbery. Apples and pears are the fruits best suited for espaliers. The apples are generally grafted on crab stocks, to keep them of moderate size; or, if the tree be wished still smaller, on Dutch paradise stocks. The distance allowed between the former is from 30 to 40 feet; between the latter, 25 is found sufficient. These may seem large spaces at first; and, to take away the naked appearance, a small cherry-tree, or white currant bush, is sometimes planted in each interval. It is to be studied that, in the same line of rail, trees of similar growth be planted; so that the whole may be nearly equally filled. The trees, when planted, should be of one year's growth, or at most of two years. If the rail be not previously erected, so that the branches can be tied

to it, a stake is necessary, to prevent wind-waving. Very often, the permanent rails are not put up till the trees have been two or three years trained on temporary stakes. Simple ash-poles firmly stuck in the ground, and either charred or smeared with tar at the bottom, to retard rotting, form a very efficient substitute for a rail; for it is to be observed, that during summer, when the leaves are expanded, they equally hide the roughest poles, or the most finished rail. Mr. Nicol, however, recommends sinking hewn stones in the earth, and fixing a wooden rail in them; and a writer in the Scottish Horticultural Memoirs, vol. i., has described a kind of cast-iron espalier rail, which of course must be highly durable, and, what is remarkable, is cheaper at the first than a wooden one. Some gardeners shorten the head of the tree in the usual way; others preserve the original branches at full length, never cutting a branch unless where there is a real deficiency of wood for filling the rail. The pruning is chiefly done by disbudding in the summer season. The distance at which the branches are laid in depends on the size of the fruit and leaves; when these are large, seven or eight inches are required; when small, four or five may be sufficient. See the article ESPALIER.

Dwarf Standards.—Dwarf trees were formerly much in vogue; and, strange as it may appear, the prospect of fruit was generally sacrificed to a fine shape. It was thought necessary that the lower branches should spread horizontally near the ground, and should decrease in width upwards, so that the tree should have a conical form. Now, it is well known that the fruit-buds of pears and apples in general, and of many sorts of plums and cherries, are produced at the end of the former year's shoots, which therefore should remain at full length; yet these were necessarily shortened, in order to preserve the desired shape, and it may easily be conceived that trees so dressed could not prove fruitful. For these reasons, the training to espalier-rails has generally been preferred. A few dwarf trees, however, prove ornamental, and they sometimes afford a great deal of fruit. The kinds of dwarf fruit-trees now in request are chiefly pears and apples. The pears must be of the summer and autumn sorts, the later fruits requiring a wall in our climate. Dwarf pears are chiefly budded on quince stocks. The trees are planted out, at two or three years old, where they are to remain, and they are placed from 20 to 25 feet asunder. A few stakes are driven into the ground, and, by means of tying down, the lower branches may soon be made to acquire a horizontal direction. No branches must cross each other, and no central upright shoots are permitted. The only other particular to be attended to is, when the trees are to be trained in a concave form, that, in shortening the shoots, the uppermost eye or bud is to be left *outwards*, as in this way the hollowness in the middle of the tree is better preserved. Sometimes the branches are trained round a hoop, which is supported by three or four small poles. Dwarf standard apple-trees on paradise stocks may be planted very closely, as they occupy but little room: they do not require more than 10 or 15 feet; on crab stocks they need at least 25. Plums are now seldom planted as dwarf standards; cherries more frequently; apricots scarcely ever.

TRAMMEL. An artificial hindrance to the free motion of an animal's limbs,—particularly an implement of leather or of ropes, fitted to a horse's legs to restrain his natural paces, and to aid the purposes of the manege.

TRANSPLANTING. The removal of a living plant from one site to another. This must be done without any material damage to the roots; else the plant will suffer in health, or even may die. Generally speaking, there is no difficulty in removing plants when young; and if they were removed every season, they would hardly be the worse for it. When, however, we attempt to remove trees, plants, or shrubs, that have been many years undisturbed, the greatest care must be used to prevent injury from the loss of fibres, which, with all our attention, will be broken. Two facts may be relied upon in the consideration of this subject,—first, the growth of a tree is always in proportion to the under-growth of its roots, and the head maintained grows as large as the roots will allow it; and second, any damage the roots sustain checks the growth of the tree or plant. From these two facts all the art of removing trees and plants should be learned; and upon these two facts all the art is founded. In transplanting seedlings of almost any kind, there is no difficulty, because the roots being easily removed whole, the plants suffer nothing. In seedlings of all kinds, there is a strong disposition to make new roots; and, if the fibres are damaged, but little mischief accrues. It is when plants have stood some time, and their roots have made considerable progress, that the difficulty of removal begins to arise. Here, then, we have two particular duties to perform; the first is, by carefully removing the earth to the very end of the root, to get the plant up with as little damage as possible; and the second is to curtail the head sufficiently to allow for the damaged powers of the root. In taking up nursery plants, where despatch governs every thing, the roots lose considerably, and the ends of all the main spreading portions are invariably chopped off with the spade. In this case two other operations become necessary,—first, to cut smooth all the bruised ends, and, second, to prune off a considerable portion of the branches, in order to diminish the evaporation and consumption of moisture. Some trees, indeed, are so much inclined to grow and strike root, that they would live almost if the roots were chopped off; but others are extremely impatient of damage at the

roots, and, if not very carefully removed, will fail. Again, there are many trees that cannot be pruned; for instance, cedars, firs, arborvitæ, and trees of that description, must not lose a branch, or they lose their beauty. Hence the necessity of removing every fibre of the root with it, if the tree is to live. But the more valuable kinds are generally kept in pots a few years, that they may suffer nothing by removal. As they advance in growth, the pots are changed; but at length they are turned out into the ground,—and for one year, or even two, they might be moved well and easily, because their roots have not had time to spread; but, after that, the difficulty increases every year, and it is a tedious as well as troublesome task to follow out the direction of the roots, and extricate them from the ground without damage.

The only conditions required on removing a tree of any age or kind are, first, to release all the root from the ground, without bruising; secondly, to remove the tree whole, as it is, and undamaged, from where it was to where it is to be; thirdly, to preserve all the fibres thoroughly moist, from the time it is released from the ground until it is replaced; fourthly, to support it in such way, on replanting, as that the earth may be all among the fibres and roots, solid and proper, as it was when it was moved; and, lastly, so to tread and press the earth about it that the fibres shall not be pressed together, nor the roots bent out of their places. It is next to impossible, however, to comply with all these conditions with very large trees; and therefore large trees are seldom removed, and rarely live after removal. Many contrivances have been resorted to; but there ought to be two years' preparation before it is attempted. This preparation consists of digging a circle round the tree, and cutting off the roots that extend beyond; and as even this may be too much check, if all done at once, it is necessary to do it at two different periods, by opening four opposite places, and at each place cutting away an eighth of the circle, building a wall within a foot of the remaining roots, and filling up that foot with the soil again, as well as the hole outside the bricks. New fibres and roots will spring out, and almost fill the space to the bricks. The next season the other four spaces may be opened, and the roots cut off at the same distance. At this time there must be some undermining, to examine whether there be any roots running very deep or downwards, like a tap-root; and if there be any, they must be severed before you build walling to complete the circle of bricks. If these operations be well conducted, there will, by the next moving time, be a mass of roots within the brick wall capable of sustaining the tree; and the removal, without damage, will be accomplished with little risk. The only thing then required is power; for by clearing all round the outer part of the brick wall first, and then pulling it down, the roots will be undamaged, and the ball of earth entire. But too much importance is attached to the mere ball of earth in all cases. Thousands of trees have been moved with balls of earth to them five times the weight of the trees themselves, while the roots have been dreadfully shortened all round, and the principal nourishing portions removed. In removing very large specimens, some nicety is required in reducing the head enough to make allowance for the decreased power of the roots, without injuring the general figure and appearance. Even in adopting the plan we have suggested, which is too troublesome for anything but a really valuable and large specimen, the head of the tree should lose something, and it will require some ingenuity to remove those portions whose removal will not injure the appearance of the specimen. But the same principles that govern us in the case of a large tree should be observed in transplanting all things.

One certain fact is, that whatever the root suffers checks the tree, and unless the subject be the better for checking, the plant must be reduced, and therefore care must be taken to prevent the root from suffering. But many subjects are the better for the check,—that is to say, they would be too luxuriant without such check; hence the practice of root-pruning, to check fruit-trees,—a practice that hastens maturity and brings on fruit-bearing. This was the inducement to disroot pines, which some people have complained of as unnatural culture. The pruning of roots checks the flow of raw sap, which induces rank growth, and allows that already in the tree to elaborate and adapt itself to the fruiting process; and if roots are not pruned, or a check given artificially, the tree must push on with vigour, forming leaves and branches, but no fruit, until the tree attains its mature size, and the roots have settled down the supply by lessening it sufficiently, when that sap which is supplied will properly elaborate, and fruit is the consequence. Confine the roots of a tree in a pot, and stunted growth is a certain consequence. Cut away the parts of a root which wander farthest, and a more sudden check takes place; yet it so lessens the quantity of nourishment taken up, that, if it be not too violent, it hastens the blooming and fruiting. Carry this operation too far, and the check is too great; yet a little further, and the tree dies, because the leaves give off more moisture than can be taken up. The only chance, therefore, of saving trees of which the roots have been too much damaged, is to lessen the work which the roots have to perform, when the life will be saved. Plant unchanged such trees or shrubs as have accidentally or otherwise been deprived of one half or so of their roots in the process of taking them up, and they die; lessen the head a good deal, and they live, but are sickly; cut a very large portion down, and the remainder will not

lose a leaf. Hence it is that plants of all kinds which are inclined to grow too vigorously receive a wholesome check when they are young; that fruit-trees are root-pruned, and bear the earlier for it; that pine-apples are disrooted to hasten their fruiting; and that many plants which are apt to run away and grow too fast are frequently removed, and each time with the loss of some of their roots. See the article PLANTING.

TRAP. See the articles MOUSE, RAT, and VERMIN.

TRAPA. See CALTROPS (WATER).

TRAP-ROCKS. An important class of rocks in geology, which derive their name from the Swedish word *trappa*, a stair, because they frequently divide into regular forms, resembling the steps of stairs.

These rocks vary in texture, from an apparently simple rock to a confusedly crystalline compound, in which crystals of felspar are disseminated. The predominant substance in the members of the family is a simple rock, of which indurated clay (wacke) may be placed at one extreme, and compact felspar at the other, the intermediate members being claystone or clinkstone. In some cases, it forms the whole mass; in others, it is mixed with other materials in various proportions, producing great diversities of aspect, without any material variations in the fundamental character. It often appears as if quartz, felspar, and hornblende composed the mass, and various circumstances determined their union in such a manner as to produce a large proportion of the different compounds known as trap-rocks, sometimes the hornblende being in mass, at others the felspar, while the quartz rarely predominates. In other situations, confusedly crystalline compounds have been the result. Quartz, felspar, and hornblende united form *sienite;* or felspar and hornblende, without the quartz, constitute *greenstone.* The compounds occasionally contain disseminated crystals of felspar, and thus become what are called *greenstone porphyries* (*diabase porphyroide,* French; *Grunstein Porphyr,* German). A paste of green hornblende, containing crystals of felspar, constitutes the *antique green porphyry* (the *ophite* of the French). Some of the trappean rocks are often vesicular, in the manner of modern lavas; the vesicles, however, being generally filled up by some mineral substances, which have been infiltrated into them subsequent to their formation. Such substances are either agates, calcareous spar, or some of the zeolitic minerals. From these cavities frequently being of an almond shape, or rather from the appearance of their solid contents resembling almonds in form, the term *amygdaloid* has been applied to rocks of this description. It must be understood that the base, or paste of the amygdaloids, is not constantly the same, but is liable to vary materially. A trap-rock is sometimes both amygdaloidal and porphyritic at the same time. Other minerals besides those above enumerated occur in the trappean rocks, but cannot be considered as forming an essential part of them, with the exception of augite and hypersthene, which, with the mixture of either common compact or glassy felspar, constitute the *augite* and *hypersthene rocks.*

It would be inappropriate to the present article to attempt a notice of the various aspects under which these rocks present themselves. It should, however, be remarked, that the term *basalt* is applied to substances which are not precisely the same, being sometimes given to a fine compound of augite and compact felspar; at others, to a minute mixture of hornblende and compact felspar; sometimes to dark, indurated claystones, and finally to a compound of felspar, augite, and titaniferous iron. The last mixture seems that now most commonly termed *basalt.* Basalt is possessed of a greenish, or brownish, and sometimes of an iron-black, colour. It is difficult to break, and possesses a considerable degree of hardness. It is fusible into a black glass, and is magnetic. The iron which it contains, as is the fact also with greenstone, passes, when exposed to the air, into a further state of oxygenation; and they are consequently generally covered with a reddish-brown incrustation. —The whole family of trap-rocks have, on the one hand, a close alliance with volcanic rocks, and, on the other, with the more ancient rocks of porphyry and granite. The gradation of trap-rock, having in some parts a volcanic character, into true granite, has been observed in a mountain near Christiania, in Norway. The lower rocks are gneiss, over which occurs dark slate, in which are beds of blackish limestone, containing organic remains. These beds are covered by an enormous mass of porphyry, varying in thickness from 1,600 to 2,000 feet. In the lower part of the bed, the porphyry becomes vesicular, and changes into an amygdaloidal basalt, containing crystals of augite. Basalt, associated with porphyry in enormous masses, often covers the primary mountains of the Andes. They are arranged in regular columns, which strike the eye of the traveller like immense castles in the sky. Porphyritic rocks may, in general, be regarded as more ancient than basaltic rocks, as porphyry most frequently occurs intermixed with, or covering, transition rocks, and basalt is most commonly associated with the secondary strata, which it either cuts through in the form of dikes, or covers unconformably. Sometimes it appears to have broken the strata confusedly, and to have enveloped large portions of other rocks. All the trappean rocks give decisive indications of an igneous origin, not only in the shapes of their masses, but in their action on the adjacent rocks. Where basalt is in contact with gneiss, it becomes nearly compact, and approaches to the character of hornstone; and where greenstone rests on sandstone or clay, these rocks have a red and

burnt appearance, and a hardness superior to what they possess in other places. Where they cross the coal strata, and come in contact with the seams of coal, the substance of the coal is, for several feet, converted into soot. At a greater distance from the trap, the coal is reduced to a coke or cinder, which burns without smoke, and with a clear and durable heat. At the distance of fifty feet from the dike, the coal is found in its natural, unaltered state. The thickness of trap dikes varies from a few inches to twenty or thirty yards. The extent to which they reach across a country has seldom been explored beyond the mining districts. The longest in England extends from the western side of Durham to Berwick, in Yorkshire. These dikes are generally harder than the rocks they intersect, and, when the latter are partly decomposed, often remain, forming vast walls of stone that rise above the surface of the ground. They also extend into the sea, and give rise to reefs of rocks; and, when they cross the beds of rivers, they form fords, and sometimes hold up the water and occasion cascades, of which there are frequent instances on the river Tees. From these circumstances, it seems conclusive that basalt and greenstone (and the same may be affirmed of the other varieties of trap-rocks) were thrown out in a melted state, like lava, and poured over the surface of the ground. The frequent occurrence of trap-rocks forming isolated caps on distant mountains, was for a long time considered as opposing the hypothesis of the igneous origin of basaltic rocks; but a more attentive observation of such districts has established the fact, that these isolated caps are parts of continuous beds, which have, in remote ages, been excavated by valleys, in the same manner as the beds of other rocks, which frequently form isolated caps on detached mountains.

The occurrence of thick beds of basalt, divided into regular pentagonal or hexagonal columns, and disposed in ranges of vast extent and height, early attracted the attention of mankind, and gave rise to various theories respecting their formation. Few countries in the world present more magnificent deposits of columnar basalt than the north part of Ireland and some of the Hebrides. The Giant's causeway, in the county of Antrim, constitutes a small part of a range of this description. The promontories of Fairhead and Borge, in the same range, are situated eight miles from each other. These capes consist of various ranges of pillars and horizontal strata, which rise from the sea to the height of 500 feet. From their abruptness they are conspicuous, and form a pile of natural architecture, in which the regularity and symmetry of art appear to be united with the wild grandeur and magnificence of nature. Many of the columns in the ranges at Fairhead are 150 feet in height and five feet in breadth. At the base along the shore is a wild waste of rocky fragments which have fallen from the cliffs, resembling the ruins of enormous castles. At the Giant's causeway, the columns rarely exceed one foot in breadth and thirty in height. They are sharply defined, and the columns are divided into smaller blocks, or prisms, of one foot or more in length, which fit neatly into each other, like a ball and socket. The basalt is close-grained, excepting the upper joint of the column, which is often cellular. The columns usually have five or six sides; but some have seven or eight, and others only three. Beds of basalt that are not columnar, in some places lie over and also under the columns. The basalt of the beds is amygdaloidal. The columns at Fairhead are not articulated like those of the Giant's causeway; but blocks, which are of great length, lie flat on each other.

TRAVELLER'S JOY. See CLEMATIS.

TREACLE. See MOLASSES.

TREACLE-MUSTARD,—botanically *Clypeola*. A genus of handsome, hardy, annual plants, of the cruciferous order. The violet-thlaspi species, *Clypeola ion-thlaspi*, was introduced to Britain from the south of Europe, in the early part of the 18th century. It has commonly a height of only 3 or 4 inches; its branches rise from every side of the root, and are slender and leafy, and generally lie prostrate on the ground; its leaves are small, narrow at the base, and obtuse and broader at the end; its flowers grow in short close spikes at the extremity of the branches, and are small, yellow, and cruciform, and bloom from May till July; and its silicles are compressed, orbicular, buckler-like, one-celled, and one-seeded. —The wool-bearing species, *Clypeola eriophora*, is white-flowered and about the same height as the preceding; and was introduced about 30 years ago from Spain.—The name treacle-mustard is sometimes given also to some species of erysimums and alyssums.

TREAD. A bruise of the coronet of the hind foot of a horse, inflicted by a blow either from the foot of another horse behind him, or from the calkin of his own other hind foot. It is sometimes so slight as to be easily cured by first carefully cleaning it, and next applying a pledget of tow dipped in Friar's balsam or in tincture of myrrh; but in other instances it is so severe as to involve considerable inflammation and to require poulticing for a few days, followed by the use of Friar's balsam, digestive ointment, or a solution of alum or of white vitriol. In no case must it be neglected; for if not promptly and duly attended to, it may give rise to quittor. See the articles QUITTOR and OVER-REACH.

TREADING. The compressing of sown seed into the soil with the feet of man or of some of the domesticated animals. It serves the same purpose as rolling; and is thought, in some respects, to serve it much better, at least when only common cylindrical rollers are used. "In Flanders, where the minutiæ of agriculture are so much attended to," says Sir John Sinclair,

"it is not unusual to tread fields of a moderate size by the human feet; but this plan cannot be carried to any great extent. The superior sample obtained from the dibble, compared to the drill, is by some attributed to the additional solidity the land receives from the treading of the children employed in the operation. In some districts of England, it is usual either to fold the sheep on the ground sown with wheat, between the sowing and the coming up of the crop, or to drive the flock repeatedly over it at that juncture, in order to give firmness to the soil and greater stability to the crop. By this means, wheat may be raised on land which is naturally too loose in its texture for the profitable production of wheat. Some farmers, on light soils, prefer pigs for that purpose, as better calculated for the process than any other animal, from their great weight, compared to the size of their feet. But in West Sussex, the lighter soils, in dry seasons, are trod by the plough-horses, when turning the seed-furrow. Three plough-horses, instead of going at length, draw the last-made plough-furrow abreast, and thereby tread or compress the line of soil they are turning. The advantages of treading, as more effectual than even rolling, in destroying the larvæ of insects, and preventing the harbouring of vermin in the soil, cannot be questioned. It may likewise contribute to check the vegetation of weeds: it prevents evaporation;—and it is found, that the crops on land thus trod, are not liable to be rusted. It is certainly more applicable to dry light soils; but even in wet ones, when it is impossible to roll the land after it is sown, owing to the wetness of the season, it may be trod afterwards by sheep."

TREE. Almost all subjects of any value or interest respecting trees are discussed in our articles Timber, Alburnum, Duramen, Bark, Ascent of Sap, Lignin, Coppice, Plantation, Forest, Planting, Germination, Growth, Decay, Age of Plants, Wood, Transplanting, Pruning, Barking, Felling, and Landscape-Gardening, and in the articles on the several kinds of trees, both indigenous and exotic; and nothing is left to be done in this place except to note a few general facts respecting the size, growth, maturity, and indigenousness of trees.

On ordinary soil and in ordinary circumstances, the average height and diameter of the spruce fir, at the period of full growth or of full fitness for felling, is from 26 to 100 feet and 47·1 inches; of the larch, from 26 to 100 feet and 30·3 inches; of the pine, from 16 to 65 feet and 34·1 inches; of the poplar, from 19 to 65 feet and 31·8 inches; of the plane, from 16 to 48 feet and 36·1 inches; of the oak and the elm, from 16 to 48 feet and 31·4 inches; of the birch, from 16 to 48 feet and 29·4 inches; of the beech, from 16 to 48 feet and 28·2 inches; of the lime, from 16 to 48 feet and 25·9 inches; of the ash, from 16 to 48 feet and 23·5 inches; of the willow, from 16 to 48 feet and 11·7 inches; of the chestnut, from 13 to 48 feet and 36·1 inches; of the maple, from 10 to 48 feet and 28·2 inches; of the service, from 13 to 39 feet and 17·6 inches; of the acacia-tree, from 13 to 26 feet and 19·2 inches; of the hornbeam, from 10 to 23 feet and 21·2 inches; of the mulberry, from 10 to 23 feet and 16·5 inches; of the wild pear, from 10 to 23 feet and 14·1 inches; of the crab, from 6 to 20 feet and 12·9 inches; and of the walnut, from 6 to 16 feet and 36·1 inches. All trees, however, are greatly controlled in their size by soil, position, exposure, elevation, and climate; and some individuals of almost every species, as compared with all ordinary individuals of the same species, acquire very large dimensions.

Young trees, in all favourable circumstances, manifestly grow with great rapidity; while all old ones appear to common observers to be quite stationary, or, like adult animals, to have entirely ceased to grow; and yet trees of every age, on till the actual commencement of decay, maintain a comparatively steady progress of growth, and acquire seasonal or yearly increments to their bulk. Dicotyledonous trees, in particular, comprising all the kinds which thrive in the open air in Great Britain, make, all their life long, periodical additions to their substance in the form of concentric or superimposed layers of woody tissue; and not a few of them, variously influenced by the intrinsic powers of their constitution and by the extrinsic ones of their situation, make these additions much more bulkily when they are at a somewhat advanced age than when they are young. "With a view to ascertain the amount of increase in the woody layers at different periods, De Candolle measured their thickness, and found that if the annual increase presented a certain regularity, it was still very far from being absolute even in the case of a single species. The oak especially offered striking anomalies; thus a trunk which had grown slowly in diameter was found to have increased more rapidly as it got older. He found young trees of the same species, the growth of which, very slow at first, by and bye became accelerated, and then fell off in a third period of their existence. From the whole of his observations, De Candolle concludes that the growth of our common European trees, having gone on with a certain rapidity to the age of from about 50 to 70 years, then became slower, but continued regular to extreme age. The inequalities of growth, conspicuous in the different thickness of different rings, he thinks are mainly due to the kind of soil which the mass of the roots encountered in their progress, or the removal of other trees which grew in the vicinity. The diminished thickness of the rings after trees have passed a certain age, he ascribes to the depth to which the roots have now penetrated, and their consequent remoteness from the air; and farther, to the resistance opposed

to the expansion of the trunk by the bark, which has now become thick, hard, and unyielding. Mr. Knight found that old pear-trees, relieved of their outer bark, formed more wood in a couple of summers afterwards, than they had made in the 20 years that preceded the operation." "However essential to a tree," says Mr. Dovaston, "are all the skyey influences of air, which cannot be kept from it, light is the grand and indispensable agent of vegetation. A tree deprived of this will soon sicken, and so die. I have very repeatedly seen, when a tree has been cut down near the edge of a thick wood, having the boughs all on the light side, the annual rings, instead of being concentric, have gone off round the place of the pith in vast parabolic curves, like the orbit of a comet on a planetary diagram, the layers being exactly equally numerous on both sides, but vastly wider on the side of the light. Two trees of equal organisation, were it possible, and in equal soils, the one incommoded and the other not, would in a very few years tell utterly distant in the scale of growth; though a tree may be too much exposed, and I have occasionally seen even a sycamore show a weather-side to the storm."

The maturity of trees, or the period at which they begin to lose their vigour, or have reached the extreme verge of maximum fitness for felling, does not depend on mere age or bulk, but is largely determined by the aggregate of the circumstances of growth, especially by those of soil, situation, and exposure. Very old living timber always perishes first in those parts which constitute the most interior ligneous layers; so that to suffer any timber-tree to stand till it begins to give slight exterior indications of decay is, in general, to allow it to lose some of the most valuable portions of its wood. Too young a tree has not all the excellence of timber which it would gain if it were permitted to grow to a higher maturity; and too old an one commonly has the timber of its centre lighter and less valuable than that of its circumference; and every tree is in its prime, as to both the quality and the homogeneity of its timber just at the moment which immediately precedes the decay of its heart or innermost layer. And though the commencement of this decay is so entirely interior as to be profoundly beyond the reach of observation, yet it soon communicates its influence to the whole tree, and rapidly produces external symptomatic indications of its existence. A tree whose top forms one uniformly rounded mass—particularly if it naturally possess a somewhat straggling and freely-branching habit—is in a weak condition; one which comes prematurely into leaf in spring—particularly if it prematurely suffer discoloration and fall of foliage in autumn—is also in a weak condition; one which begins to shrink or die at the extremities of any of its principal shoots or branches has begun to decay in the innermost woody layers of its trunk; one whose bark is here and there cracked or fissured or fallen-off, has undergone a considerable degree of decay in the innermost parts of its trunk; one whose bark is marked with red or black spots, or infested with mosses, lichens, and fungi, is in a suspicious condition, and may possibly be somewhat far-gone in heart-decay; and one whose sap may be observed to ooze through crevices of the bark, is thoroughly diseased, and may already be half-dead.

The upland regions of Britain, and most of all the mountain fastnesses of the Scottish Highlands, afford the best evidence as to the species of trees which are truly indigenous in our country, and which may be grown in it with the highest degree of advantage. The original and natural vegetation of nearly all parts of the globe, excepting such as are covered by shifting soil or perennial snows, consists chiefly of trees and shrubs, differing according to the climate. If, after the revolutions and catastrophes which geology so clearly indicates, the surfaces consisted partly of bare rock, and partly of debris, gravel, sand, and clay, whatever may have been the first vegetation by which these surfaces were covered, it is at least apparent that trees were abundant upon them at a period antecedent to the formation of peat and other soils of vegetable origin; for the decayed stumps and roots of the oldest trees which we meet with may generally be traced to the subsoil, and in few cases occur in soil that is evidently of posterior origin. A considerable portion of Scotland can hardly be supposed to have been covered with trees for many ages back; for in the soil and subsoil the operations of the agriculturist disclose no roots, which, had they once existed, could scarcely have been so entirely decomposed as to leave no traces behind. But the sides of all the Highland mountains, the glens and ravines, the margins of the rivers and lakes, and very extensive tracts of the low grounds, have at some period been covered by wood. Beyond the mere fact, however, that, at a former period, Scotland exhibited extensive ranges of uninhabited forest, where corn-fields and pastures now surround the habitations of a crowded population, little respecting the species is to be learned from the pages of our historians. They can only tell us at random of 'noble forests of oak, ash, beech, and other hard timber;' and in order to discover the real species, we must have recourse to our peat bogs, and to the remnants of the ancient woods which still grace many parts of the country. Yet from the former of even these sources, little information is to be obtained. When trunks, branches, or roots are found in peat, they are generally so altered that the species to which they belong can in only few cases be discovered. The pine, the birch, the alder, and the oak, are all that can be made out with certainty, to which may be added the hazel, upon the occasional evidence of its nuts. In an insular situation like ours,

it is evident, that, unless new species spring up spontaneously, no addition can by natural means be made to the original stock. Shrubs or young trees wafted from the European or American continents, would necessarily perish before arriving upon our coasts; and the seeds of none of our present species of trees are fitted for long aerial voyages, and could scarcely arrive from the nearest point of Europe, even if whirled thence by a hurricane. As to the dissemination of trees by birds, no seeds of any kind, perhaps, have ever been found entire in the intestines, and the hardest are shattered by the least muscular gizzards. The present indigenous trees of the country are, therefore, very probably the species of which its ancient forests consisted. The principal, both in number of individuals and in economical value, are the Scotch pine, the common oak, the white birch, the dwarf birch, the alder, the aspen, the yew, the common ash, the wych elm, the bird cherry, the wild cherry or gean, the crab, the hawthorn, the blackthorn, the common mountain ash, the bastard mountain ash, the whitebeam, and the holly; and a few of either the rarest as to individuals or the most doubtful as to true indigenousness, are the common elm, the beech, the white poplar, the black poplar, the common elder, the dwarf elder, the wayfaring tree, and the bullace-tree.

TREE-CABBAGE. See CABBAGE.

TREE-MALLOW. See LAVATERA.

TREE-OF-HEAVEN. See AILANTHUS.

TREE-OF-SADNESS. See NYCTANTHES.

TREE-ONION,—botanically *Allium proliferum*. A curious, hardy, bulbous-rooted, white-flowered, perennial, herbaceous plant, of the garlic genus and asphodel family. It has commonly a height of about 3 feet, and blooms from July till October, and is propagated from offsets.

TREFALLOW. Ploughing land the third time before sowing.

TREFOIL,—botanically *Trifolium*. A genus of herbaceous plants, constituting the type of a sub-tribe of the lotus division of the leguminous order. Twelve genera are comprised in this sub-tribe; and the chief of these are trifolium, medicago, lotus, melilotus, and trigonella. The flowers of the true trefoils are crowded in an elongated or globular spike or head; the petals generally remain attached when dry or withered; the stamens amount to nine united and one solitary; and the pods in general are shorter than the calyx, and are either one or few seeded. Sixteen species grow wild in Britain; upwards of an hundred have been introduced from other countries; and about thirty unintroduced exotic species are known. All the species in Britain, exotic as well as indigenous, are hardy; about twenty are agricultural, and many of the others are ornamental; about forty-eight are perennials, two are biennials, and all the rest are annuals; several have a height of from 2 to 5 feet, a few have a height of only 3 or 4 inches, and most have a height of from 6 to 15 inches; a considerable number of both the perennials and the annuals are creeping or procumbent, and all the rest are erect. In one subgenus, consisting principally of annuals, and comprising one indigenous species and about twenty introduced species, the flowers are spiked, the spikes have an oblong form and are ebracteate at the base, and the calyx is villous and is not inflated after blooming; in a second subgenus, consisting partly of biennials, much more of perennials, and still more of annuals, and comprising seven indigenous species, and somewhat upwards of forty introduced species, the flowers are capitate, the heads are ovate and often bracteate, and the calyx is villous and not inflated; in a third subgenus, consisting partly of perennials and partly of annuals, and comprising three indigens and about sixteen introduced species, the flowers are capitate and often deflexed, the heads are globose, and the calyx is not inflated; in a fourth subgenus, consisting partly of perennials and partly of annuals, and comprising two indigens and six or seven introduced species, the flowers are densely capitate, and the upper lip of the calyx after the period of blooming rises up in an inflated and arched manner and covers the legume; in a fifth subgenus, consisting principally of perennials, and comprising at least nine introduced species, the flowers are large, the petals are coriaceous and persistent, and the segments of the calyx are subulate or erect; and in a sixth subgenus, consisting principally of annuals, and comprising three indigens and about ten introduced species, the flowers are capitate, the heads are pedunculated and ovate, and the petals are scarious, yellow, deflexed, and persistent. The principal agricultural species are fully noticed in the article CLOVER; the species of the fifth subgenus are briefly noticed in the article LUPINASTER; and the subject of the trifoliate plant which forms the national emblem of Ireland is discussed in the article SHAMROCK.

The indigenous species of the first subgenus is the field hare's-foot, *T. arvense*, an erect weedy annual of sandy fields, about a foot high, carrying flesh-coloured flowers in July and August. The seven indigens of the second subgenus are the striated trefoil, *T. striatum*, an erect weedy annual of barren grounds, about 5 or 6 inches high, carrying purple flowers in June; the rough trefoil, *T. scabrum*, a creeping handsome annual of sandy fields, about 5 or 6 inches high, carrying white flowers in May and June; the starry trefoil, *T. stellatum*, a creeping handsome annual of the southern coasts of England, about 6 or 8 inches high, carrying purple flowers in July; the sea trefoil, *T. maritimum*, an erect handsome annual of salt marshes, about 6 inches high, carrying pale purple flowers in

June and July; and the yellowish-white clover, *T. ochroleucum*, the cow-grass clover, *T. medium*, and the common red clover, *T. pratense*, described in the article Clover. The three indigens of the third subgenus are the suffocated trefoil, *T. suffocatum*, a trailing weedy annual of the seashores of England, about 6 inches in height, carrying white flowers in June and July; the cluster-headed trefoil, *T. glomeratum*, a trailing weedy annual of the pastures of England, about 6 inches in height, carrying pink flowers in June; and the common white clover, *T. repens*, described in the article Clover. The two indigens of the fourth subgenus are the strawberry-bearing trefoil, *T. fragiferum*, a creeping and somewhat agricultural perennial of moist pastures in England, about 3 or 4 inches high, carrying flesh-coloured flowers in July and August; and the subterraneous trefoil, *T. subterraneum*, an erect handsome annual of the barren heaths of England, about 6 inches high, carrying white flowers in May. And the three indigens of the sixth subgenus are the procumbent hop trefoil, *T. procumbens*, the lesser yellow trefoil, *T. minus*, and the thread-shaped trefoil, *T. filiforme*, all described in the article Clover.

TREFOIL (Bird's-Foot). See Bird's-Foot Trefoil.

TREFOIL (Marsh). See Buckbean.

TREFOIL-SHRUB. See Ptelea.

TREFOIL-TREE. See Cytisus.

TRELLIS. A contrivance of the nature of a lattice for supporting the branches of fruit-trees, or for training and supporting the stem and ramifications of ornamental climbing plants. The old-fashioned trellis for fruit-trees, or common wall-fruit trellis, is constructed upon a piered wall, and extends from the inside of one pier to the nearest inside of the next, and is closely similar in at once form, uses, and management to an espalier, and may be diversified, in its aggregate size and outline, and in the materials, dimensions, and arrangement of its rails, to suit the wants of different kinds of trees. See the article Espalier. The ornamental trellis of the flower-garden, particularly in its newest forms and applications, is endlessly diversified in shape and size, and admits of a considerable choice of material, and may be worked into great complexity of compound form, and affords a very wide scope for the combined exercise and display of ingenuity, fancy, caprice, and both good and bad taste. Some kinds of it are mimic and belong only to the greenhouse, while others are gigantic and belong to the open ground; and some are chaste and elegant, and serve only to exhibit the plants upon them to the best advantage, while others are stalking and fantastic, and fix enlightened attention only on their own absurdity. Ornamental trellises, on the whole, give gardens an excessively artificial or downright harlequin appearance; and would have formed a far fitter accompaniment to the clipping and figuring horticulture of a former period than to the natural and flowing style of the present day. "The more we look on the present unnatural-looking shields for our climbing plants, the greater appears the necessity of an alteration. Whatever is unnatural in plant-growing, must have some great advantage to enable us to tolerate it at all. This may be said against plants growing in pots instead of the ground, for nothing but the necessity of doing so justifies it. Plants must be moved about, and therefore something to grow in is necessary, and that something is a pot or tub, or some receptacle for the soil they require. But in all cases, the nearer we can approach to familiar objects in our mode of training the better. There can hardly be a better guide than nature in all this. Where do we find climbing plants? Twining up and round pillars, insinuating themselves into all the crevices of a ruin, festooning the Gothic arch and the glassless window, enfolding the aged tree, and clinging to the ancient gateway. All these things can, more or less, be imitated. A pillar, whether broken or perfect, is not only an appropriate, but a handsome design for a climbing plant. An ancient arched window is well adapted for one of the larger kinds of plants; and there is one great advantage in such subjects, if well made they look better for not being entirely covered."

TREMANDREÆ. See Tetratheca.

TRENCH. A long cut in the ground,—either a single spade-cut in the process of spade-tillage, or a mere furrow-cut for the purpose of draining, or a deep and wide ditch for the purpose of military defence.

TRENCHING. Digging up the subsoil in the process of garden tillage or of spade husbandry. It admits of many degrees and variations; and comprises any depth and amount of interference with the subsoil, from the simple stirring of it and bringing up merely an inch or two, to the complete upturning of a considerable stratum of it and bringing up the whole of this to the surface. It serves, in all its varieties, to renovate the soil, to imperviate the subsoil, to deepen the range and scope of roots, to improve the drainage, to increase the interior circulation of air and moisture, and to promote all the digestional chemical processes which prepare the mineral and gaseous food within the soil for absorption by plants; and it must be adapted, in its particular depth and manner, to the character and circumstances of the particular ground on which it is performed, and by no means done everywhere and indiscriminately in the ordinary manner of making the top-spit and the bottom-spit of land simply interchange places,—a manner which is suited chiefly to a very deep homogeneous garden soil which has been long in cultivation. The trenching of all land whose subsoil differs materially from its soil—and especially of

all land whose subsoil is compact, stiff, and almost wholly destitute of humus—requires to be done with judgment and caution; and yet, when thus done, is proportionally more beneficial than even the complete, mechanical turning upside down of very deep loamy mould. "Let us take the worst possible state of ground for the trenching operation,—bad, poor, sour land which, in its present state, will grow nothing well. A little of it might be brought to the top every time the earth is dug, because exposing even bad soil to the atmosphere will improve it; and if good ground reached only ten or a dozen inches down, this, when we begin to dig, must be removed one trench wide for the first operation, for the purpose of filling in the last left trench. This being removed for a start, in ordinary digging, the next spit dug all along would fill it up, and the ground would be merely turned over; but before we go at the second spit, it would be wise to dig up the bottom and leave it there; for next to bringing it to the top, loosening it at the bottom is best; but taking out about two inches, to put on the top of the good soil, will be found an excellent mode of improving the ground permanently. Then dig the second spit along the space to be trenched, and throw it into the trench; loosen the bottom again, and throw two inches of the stuff on the top of the good soil; continue this all through, one trench after another, until it is all finished, and the result will be, that this small quantity of worthless stuff will become, by the dressing and the exposure, workable and useful. In time two more inches might be brought up, and when it has become well mixed and amalgamated with the better soil, and the dung which is from time to time put on it, the soil which has been for years called shallow and unprofitable, will be far better than the owner could anticipate. In gravelly soil, the ground would soon become stony, but excellent produce will come off stony ground; and by picking the largest off from time to time, even the gravel brought up will be anything but unprofitable in the culture. The worse the ground is in its subsoil, the less must be brought up from time to time; but whether clay, gravel, or chalk, attention to these matters will be repaid by a deeper cultivable soil; and by proper dressings according to its nature, additional produce will be obtained." See the article Spade-Husbandry.

TRENCH-PLOUGHING. See Subsoil-Ploughing.

TREPANNING. See Hydatid.

TREVERINA. A splendid, tropical, scarlet-flowered, evergreen, herbaceous plant, of the fig-wort family. It constitutes a genus of itself, and bears the specific name of *coccinea*, or 'the scarlet;' but it is called by some botanists *Cyrilla pulchella*. It was introduced to Britain from Jamaica in 1778; and has long been a favourite with amateur florists. It has a height of about 20 inches, and blooms in September; and it loves a soil of loamy peat, and is propagated by division of the roots.

TRIANDRIA. See Botany.

TRIANTHEMA. A genus of curious, exotic, green-flowered plants, of the purslane tribe. The monogynous species, *T. monogyna*, is a native of both Indies, and was introduced to Britain from Jamaica in 1820. It is an annual, of about a foot in height, and blooms in May and June. Its root is bitter and slightly nauseous, and is used in India in combination with ginger as a cathartic; its branches lie flat on the ground; and its general appearance is similar to that of common purslane. Some other specimens have been introduced to British collections.

TRIAS. A genus of ornamental, tropical, epiphytous plants, of the malaxis division of the orchis family. The name alludes to the triangular form of the open flower. The oblong species, *T. oblonga*, is a very handsome plant, with dingy green and purple flowers, blooming in November; and was introduced to the orchideous collections of Britain a number of years ago from India.

TRIBES. See Classification.

TRIBRACHYA. A curious, tropical, green-flowered epiphyte, of the orchis family. It was introduced to British gardens from Sierra Leone in 1823; it has a height of only three or four inches, and blooms from midsummer till November; and it constitutes a genus of itself, and is specifically called the pendulous. Its generic name signifies 'three-armed,' and alludes to its spikes.

TRIBULUS. See Caltrops.

TRICHÆTA. A hardy perennial grass, of the oat tribe. It constitutes a genus of itself, and is specifically called the ovate; it was introduced to Britain from the South of Europe about 25 years ago; and it blooms from midsummer till August; but it possesses little or no economical interest.

TRICHILIA. A genus of ornamental, exotic, white-flowered, evergreen tall shrubs and small trees, of the bead-tree tribe. Five or six species, varying in height from 15 to 25 feet, and all blooming in June and July, and propagable from cuttings, have been introduced to British collections from the West Indies and Australia; and upwards of a dozen other species are known. The name trichilia is formed from a word signifying 'ternary,' and alludes to the triple cell and triple valve of the capsule. A warm oil, prepared from the fruit of the thorny species, *T. spinosa*, is regarded in India as a valuable application in cases of paralysis and of chronic rheumatism.

TRICHOCENTRUM. A genus of curious, exotic, epiphytous plants of the orchis family. Several species have been introduced to British gardens since 1834; and one of the first-flower-

ing of these is a small and easily cultivated one called *T. iridifolium*.

TRICHOCHLOA. A genus of exotic grasses, of the agrostis tribe. The name signifies 'hair-grass,' and is descriptive. Five perennial species, and an annual one, all hardy, and mostly about a foot high and blooming in June and July, have been introduced to British collections from various parts of North America; and upwards of 20 more are known. All the introduced species are interesting to naturalists; and four are assigned by some botanists to the genus agrostis; but none possess any agricultural value.

TRICHODESMA. A genus of exotic annual plants, of the borage family. The Indian species, *T. indicum*, called by Linnæus *Borago indica*, is a handsome blue-flowered annual, of about a foot in height, blooming from midsummer till late in autumn, and capable of cultivation in the open ground; and it was introduced to Britain from India in 1759.

TRICHODIUM. See Agrostis.

TRICHOLÆNA. A handsome, exotic, perennial grass, of the sugar-cane tribe. It constitutes a genus of itself, and bears the specific name of *micrantha* or 'small-flowered;' but was regarded by Linnæus as a true sugar-cane, and by Sprengel as a panic-grass. It is a native of Teneriffe, and was introduced to Britain in 1825. It has a height of about a foot, and blooms in June and July; and it forms an interesting object in the greenhouse, but does not possess any economical importance.

TRICHOMANES. A genus of ornamental ferns, of the polypody tribe. The short-bristled species, *T. brevisetum*, called by some botanists *Hymenophyllum alatum*, is a very handsome evergreen indigen of the moist rocks of Britain, about 4 inches high, and blooming in May and June. Nearly 50 exotic species are known. The name trichomanes is given also to a beautiful indigenous species of the spleenwort genus. See the article Maiden-Hair.

TRICHONEMA. A genus of ornamental, bulbous-rooted plants, of the iris order. The bulbocodium species, *T. bulbocodium*, is a native of the Channel Islands and of the South of Europe; and was introduced to Britain in 1739; and is so hardy as to be freely cultivable in the open ground. Its bulb is ovate and esculent, and has two membranous coats; its leaves are spreading and 3 or 4 inches long; its flower-stalks are either simple or branched, and commonly about 6 inches high; and its flowers have a reddish or purplish colour, and bloom in March and April. About twenty species have been introduced, principally from the Cape of Good Hope and the South of Europe; and have variously blue, purple, red, pink, rose-coloured, yellow, and greenish-white flowers; and have for the most part a height of about 6 inches; and love a mixed soil of sand and peat and loam; and must be grown either in the greenhouse or in a pit or frame; and are propagated from offsets. All are beautiful; and several are nearly allied to the ixias.

TRICHOSANTHES. See Snake Gourd.

TRICHOSTEMA. A small genus of hardy, ornamental, blue-flowered, North-American, annual plants, of the labiate order. The dichotomous and the linear-leaved species were introduced to Britain about 90 years ago, and have a height of about a foot, and naturally bloom in June and July.

TRICORYNE. A genus of ornamental, Australian, herbaceous plants, of the asphodel tribe. Two evergreen perennials and one biennial, varying in height from 10 to 25 inches, have been introduced to the gardens of Britain; and they love a soil of rich mould, and are propagated by radical division.

TRICUSPIS. A small genus of exotic grasses of the glyceria tribe. The five-cleft species, *Tricuspis quinquefida*, called by Michaux *Poa cærulescens*, is a native of North America, and was introduced about 30 years ago to Britain. It is a perennial, and has commonly a height of about 2 feet, and blooms in June and July; it thrives best in a soil of rich mould; and it possesses some claims to rank as an agricultural plant.

TRIDENTEA. A genus of Cape-of-Good-Hope, curious, small, evergreen undershrubs, of the swallow-wort family. The name alludes to the fancied resemblance of the flowers to a trident. Seven species, all about 6 or 7 inches high, and mostly carrying dark purple or brown purple flowers, but blooming at very different periods, have been introduced to Britain; and they love a soil of sandy loam, and require the heat of the dry stove, and are propagated from cuttings.

TRIENTALIS. See Winter Green.

TRIFOLIUM. See Trefoil and Clover.

TRIGLOCHIN. See Arrow-Grass.

TRIGONELLA. See Fenugreek.

TRIGONIA. A small genus of ornamental, tropical, evergreen shrubs, of the hippocratea tribe. The name alludes to the three-corneredness of the fruit. Two species, the villous and the soft, have been introduced to British collections from Cayenne and Brazil.

TRIGONIDIUM. A genus of beautiful, tropical, epiphytous plants, of the orchis family. The blunt-petaled species, *T. obtusum*, was introduced to Britain in 1834 from Demerara, and is about a foot high, and carries white and red flowers in autumn; and Egerton's species, *T. Egertonianum*, was introduced in 1837 from Honduras, and is about 20 inches high, and carries yellow and brown flowers throughout a great part of the year.

TRILLIUM. A genus of ornamental, hardy, perennial, tuberous-rooted, herbaceous plants, of the melanthium family. Fifteen species have been introduced to Britain from Canada and the United States of America. Most grow wild in

the American woods, and thrive only in shaded situations, and have a height of from 5 to 10 inches, and carry either red, brown, white, green, or pale purple flowers; and all love a soil of sandy peat, and may be propagated by division of the root. One of the earliest introduced is described as follows by Miller; and may be taken as a fair specimen of the whole. "The root is tuberous, and sends out many fibres. The stalk is single, naked, and rises 5 or 6 inches high, with three oval leaves placed at the top on short footstalks, which spread out in a triangle, and are 2 inches long and 1½ inch broad, smooth, and of a deep green colour. From the centre of the footstalks of the three leaves comes out one flower on a short footstalk, which nods downward. This has a three-leaved green empalement which spreads open; and within are three petals about the size of the empalement, of a whitish green on their outside, and purple within, having 6 stamina in the centre, surrounding the style, which have oblong summits. The flowers appear in April, and are succeeded by roundish succulent berries, having 3 cells filled with roundish seeds, which ripen in June." The ternate exfoliations, particularly those of the calyx, are alluded to in the name trillium. The two-coloured species, *T. discolor*, a green-flowered plant of about 9 inches in height, introduced in 1831 from Georgia, is fragrant.

TRINIA. A small genus of hardy biennial plants, of the umbelliferous order. It is nearly allied to the burnet-saxifrage genus. Hoffman's species, *T. Hoffmanni*, called by some botanists *Pimpinella dioica*, is a weed of rocky places in some parts of England; and has a height of about 10 inches, and carries white flowers in May and June.

TRIODIA. A genus of grasses of the oat tribe. The decumbent species, or heath-grass, *T. decumbens*, called by Linnæus *Poa decumbens*, is a perennial indigen of the spongy bogs and barren heathy mountains of Britain. Its root is very slightly creeping, and has strong fibres; its stem is hard, harsh, rigid, jointed, bent, leafy, and from 4 to 15 inches long, and lies close to the ground, except during the period of bloom; its leaves are linear, striated, rigid, somewhat glaucous, smooth throughout the body, and very rough in the rib and edges toward the point; and the inflorescence is panicled, and blooms in July and August. Eight or nine exotic species are known.

TRIOPTERIS. A genus of ornamental tropical plants, of the Barbadoes cherry tribe. Two species, the silky and the Jamaica, both evergreen climbers of between 5 and 12 feet in height, loving a soil of peaty loam, and propagable from cuttings, have been introduced to the hothouse collections of Britain; and 6 or 7 more are known. The name triopteris signifies 'three winged,' and alludes to the capsule.

TRIOSTEUM. See Feverwort.

TRIPHÆNA,—popularly *Yellow Underwing*. A genus of destructive insects, of the moth tribe. Their caterpillars are subterranean, and therefore root-eaters; and can in general be attacked by the cultivator only by the methods which are used against grubs. The great yellow underwing, or bride's-maid moth, *Triphæna pronuba*, is very common, and does a great deal of mischief both in the garden and in the field. "The expansion of the wings is upwards of two inches. The upper pair are brownish-grey, dark-liver coloured, or some shade intermediate between these two, each with two kidney-shaped marks towards the centre. The under wings are orange-yellow, with a narrow black band at the hinder extremity, but not reaching the margin, and continued along the anterior margin, emitting a narrow streak towards the centre of the wing. The head and thorax are of the same colour as the anterior wings; and the abdomen is like the hinder wings. The eggs are, in all probability, laid in the earth; at all events the caterpillars penetrate into the soil, and pass the greater part of their lives beneath the surface. Their skin is tough and resisting, to fit them for such a mode of life; the colour brown, or dull-livid, with a slight tinge of green, and two interrupted black lines on the back. They pass the winter under the surface of the ground, and are capable of enduring a great degree of cold. Mr. Curtis states that he has known them to be embedded in a sheet of ice and yet recover. They come to the surface early in spring, and prepare to undergo their metamorphosis to a chrysalis, which takes place in April, the moth appearing early in summer. It flies only for a short distance at a time, and chiefly in the afternoon and evening. During the day it may be found lurking at the sides of stones and among grass; and when an attempt is made to seize it, it seldom takes wing, but endeavours to escape by gliding rapidly away among the herbage. It appears to be plentiful in all parts of the country. The caterpillar seems to be a very general feeder, and destroys the roots of many kinds of useful plants. It has been known to commit extensive injury to the turnip crop by eating away the rootlets, and even penetrating into the bulb."

TRIPHASIA. A Chinese evergreen, fruit-shrub, of the orange-tree family. It constitutes a genus of itself, and bears the specific name of *aurantiola* or 'the little orange;' but is called by Willdenow *Limonium trifoliata*. It was introduced to the greenhouses of Britain in 1798. It has commonly a height of about 2 feet, and carries white flowers in June and July; and it requires a soil of rich mould, and is propagated from cuttings.

TRIPLARIS. A small genus of exotic ligneous plants, of the polygonum tribe. The American species, *T. americana*, is an evergreen timber-tree, of naturally about 40 or 50 feet in height, inhabiting the tropical parts of South America, and introduced to the botanical col-

lections of Britain in 1824. The name triplaris alludes to the triplicate arrangement of the parts of fructification.

TRIPOLY,—botanically *Aster Tripolium*. An ornamental, blue-flowered, perennial-rooted, annual-stemmed, herbaceous indigen of the seashores of Britain. It has a height of about 2 feet, and blooms in August and September.

TRIPSACUM. A small genus of exotic grasses, of the maize tribe. Two hardy perennial species, the single-spiked and the dactylus-like, the former about 2 feet high, the latter about 4 feet high, and both blooming in August, have been introduced to Britain from North America; but, though taking their name of tripsacum from the grinding of their grain into flour, they possess very little interest.

TRIPTILION. A genus of ornamental, exotic, herbaceous plants, of the labiate order. Two very handsome species, the spiny and the cordate-leaved, the former blue-flowered, the latter white-flowered, and both blooming from May till August, and capable of being treated in the manner of common hardy annuals, were introduced to Britain about 25 years ago from Chili. The spiny is very abundant in its native country, and bears there the name of Sempreviva on account of the permanence of its deep azure flowers; and it produces these in corymbs, and may be so managed as to bloom throughout a great part of the year. Its root is fleshy, and somewhat like that of a dahlia in miniature; and its radical leaves spring up in autumn as soon as the flowering stems are cut off.

TRISETUM. A genus of grasses of the oat tribe. Three species grow wild in Britain, nearly twenty have been introduced from other countries, and a good many more are known. All the indigenous species were formerly ranked as true oats, and are described in the article Avena. All the introduced species are hardy, and the majority are annuals, varying in height from 1 foot to 6 feet; but none possess any noticeable economical interest.

TRISTANIA. A genus of ornamental, Australian, evergreen, ligneous plants, of the myrtle family. The name signifies 'to stand by threes,' and alludes to the disposition of the leaves and flowers. Seven or eight shrubby species, varying in height from 6 to 12 feet, and two dendritic species of respectively about 50 and 80 feet in ordinary natural height, have been introduced to the greenhouses and conservatories of Britain; and all love a somewhat peaty soil, and are propagable from cuttings. The two trees have white flowers, and bloom in June and July, and require a loamier soil than the shrubs; and the taller one, *Tristania albicans*, popularly bears among the colonists the name of the turpentine-tree.

TRISTEGIS. A small, curious, hardy, perennial grass of the subbiflorous suborder. It takes its name from the circumstance of having three glumes; it constitutes a genus of itself, with the specific name of *glutinosa* or 'clammy;' and it differs widely in character from all the other subbiflorous genera. It has a height of only 6 or 7 inches, and blooms in June and July.

TRITICUM. See Wheat.

TRITOMA. A genus of ornamental, evergreen, Cape-of-Good-Hope, herbaceous plants, of the day-lily family. Four species, varying in height from 12 to 25 inches, and mostly carrying orange-coloured flowers, and blooming at an advanced period in the year, have been introduced to British gardens; and they love a soil of peaty loam, and require frame-protection, and are propagated by division of the root.

TRITONIA. A genus of ornamental, South-African, bulbous-rooted plants, of the iris family. About 25 species, varying in height from 4 or 5 inches to 2 feet, have been introduced to the greenhouses of Britain. Some bloom in spring, some in summer, and some in autumn; most have yellow or fulvous or rufous or brownish or white or orange coloured flowers; and all love a mixed soil of sand and loam and peat, and are propagated from offsets. The name tritonia is formed from a word signifying 'a weathercock,' and alludes to the stamens.

TRIUMFETTA. A genus of tropical, yellow-flowered plants, of the lime-tree tribe. Three annual species of 2 or 3 feet in height, and upwards of a dozen evergreen ligneous species, principally about 3 feet in height, have been introduced to British collections, chiefly from the two Indies; but they possess little interest.

TRIXIS. A genus of ornamental, exotic plants, of the labiate-flowered division of the composite order. A handsome, annual, Chilian species is noticed in the article Leuceria; a beautiful, small, evergreen, ligneous species, of about a foot in height, carrying white flowers in autumn, *Trixis auriculata*, was introduced to the hothouses of Britain about 22 years ago from Brazil; and 6 or 7 other species are known.

TROCHAR. A surgical instrument, used for piercing the rumen of cattle in order to let the gas escape in hoove. See the article Hoove. The trochar closely resembles the instrument used in human surgery in tapping for dropsy; it consists of a short strong stilett, terminating in three cutting edges which converge to a point, mounted on a handle which admits of being forcibly grasped, and having fitted to it a silver tube which reaches from the point to the handle; and when used, the whole is plunged into the flank, the stilett is then withdrawn, and the tube remains as long as the operator judges necessary, and may be secured in the place by means of tapes attached to rings at its base and tied round the body of the animal. It is an useful instrument on any farm of the mixed husbandry, or wherever hoove is of more than very rare occurrence.

TROCHOCARPA. A small genus of orna-

mental, Australian, evergreen, ligneous plants, of the epacris tribe. The laurel-leaved species, *T. laurina*, is a tree of about 25 feet in height, and carries white flowers from April till August; it was introduced to British collections about 26 years ago; and it loves a soil of sandy peat, and is propagated from cuttings.

TROGOSITA. A genus of beetles of the bostrichidæ family. The mandibles are shorter than the head, and crossed; the ligula is almost square, and is not prolonged between the palpi; and the maxillæ have but a single lobe. The Mauritanian species, or the cadelle, *Trogosita Mauritanicus*, is very extensively known for the depredations of its larvæ upon various kinds of field and forest produce. It is a native of the north of Africa; but has been so profusely propagated thence, partly by natural immigration and partly in attachment to articles of importation, that it now occurs in America, and is very common throughout a great part of Europe. It is about four lines long, blackish above, and light brown beneath, and its elytra are striated. The beetle itself is carnivorous, and makes some amends for the mischief done by its larva by destroying the *Tinea granella*. How or where the female deposits her eggs is not yet known; but the larva has been bred by an experimentalist in a Spanish almond, and was found to live there during 15 months, and the beetle which arose from it afterwards lived during 21 months,—so that the entire period of the creature is believed to be not less than 3 years. The larva, when full grown, is about 8 lines long and 1 line broad; its body is whitish, and comprises 12 segments, distinct enough, and rough with short scattered hairs; its head is hard, scaly, and black, and has two sharp, curved, horny jaws; each of the three thoracic segments has a pair of short scaly legs and a pair of obscure spots; and the anal segment is terminated by two very horny hooks. The larva makes very great havoc among grain locked up in granaries, eating the outside of it, and passing so freely from one seed to another as to injure more than it consumes; and it also attacks dead trees, and even bread and nuts, and is very commonly found beneath the bark of trees; and when it has completed its period, it buries itself in the ground, and there undergoes transformation into a pupa.

TROLLIUS. See Globe Flower.

TROMOTRICHE. A genus of curious, South-African, evergreen undershrubs, of the swallow-wort tribe. Five genera, varying in height from 6 to 25 inches, and carrying dark-coloured flowers, principally purplish, in June and succeeding months, have been introduced to British gardens; and they require the heat of the dry stove, and love a soil of sandy loam, and are propagated from cuttings.

TRONA. The native sesquicarbonate of soda. It occurs on the banks of the alkaline lakes of Sukenah in Africa, and is imported thence to Britain.

TROPÆOLUM. See Indian Cress.

TROPHIS. See Ramoon Tree.

TROT. The medium one of the three natural paces of the horse. See the articles Manege and Pace. It comprises two varieties,—the slow and the swift; yet has been very generally described in terms which exclude the latter. In the slow trot—or what most persons regard as the only trot—the off fore leg and the near hind leg are simultaneously elevated and replaced, while the near fore leg and the off hind leg are on the ground, sustaining the whole weight and making ready for action, and *vice versa*. But in the swift trot, all the four feet, though moving in the same order as in the slow trot, or in diagonal pairs, are kept in such rapid action as to be all simultaneously in the air, each sustaining pair being off the ground before the alternate pair alight. "In the slow trot," remarks Delabere Blaine, "the near fore and off hind legs are preparing for elevation only, while the off fore leg and near hind are yet in action, and these raised legs are, in this instance, first set down before the near fore foot and off hind are actually removed from the ground. But in a fast trot these same feet are completely lifted from the ground, while the off fore and the near hind are yet in full progress. At this moment, it must be clear that the horse is all in air; and it is this complete elevation from the earth which forms the essential difference between the slow and the extended trot. To pursue the description, the animal still acting on the impulse derived from the near fore and off hind, they become carried across the off fore and near hind at the moment these latter meet the ground. The off fore and near hind having met the ground, immediately prepare to rebound from it, and to give a fresh impetus to the motion before the near fore and off hind legs again come down; which then forms the second period when the horse is all in air, or, in other words, is again aërially elevated, and as totally detached from the ground as a bird when flying, or as the horse is understood to be when either leaping or galloping. If it should still not be readily comprehended how the horse should be without support at any time during the trot, let us draw a parallel between the progression of a biped and that of the horse. In the walking of a man, one foot becoming elevated is carried forward, and set down,—during which the body is likewise carried forward, and the centre of gravity takes a new line through the moving mass; the contrary foot is now elevated also in its turn, and repeats all the phenomena of its fellow. In running, so essential a difference may be observed, that let running be conducted ever so slowly, and walking ever so fast, so that the speed shall be greatly in favour of walking, yet the paces will remain totally distinct. In the running of man, as well as in the extended trot of the horse, there is a period when all the supports are completely removed from the

ground; for by means of the flexion and extension of the angles of one of the lower extremities of the man, a spring is made, which displaces and elevates the body, inclining it forwards, and taking the first elevated leg with it, which, before it meets the ground, is crossed by the other. The body, losing its impetus, waits for fresh impulse to be gained by the rebound of the limb which was last elevated, and is by that means again propelled forward; the contrary leg once more passes, to be ready to receive the propelled weight thrown on it, and again, by flexing and extending its angles to relieve itself, it renews the action. Exactly the same happens in the extended trot of the horse as in the running of the man, for here the fore and hind diagonal extremities of the horse, acting in unison, form themselves, as it were, into a single support, as one leg, the centre of motion being placed diagonally across it; by which the superincumbent weight, although moving on two distinct members, yet these members, acting in perfect accordance, produce one effect. The principles of the trot, therefore, are illustrated by the running of a biped, and correspond with it in the mechanism of its action."

TROTTELS. See Comfrey.

TROUGH. An oblong vessel, for holding any kind of liquid; — or, figuratively, any kind of oblong depression, such as the hollow between two waves in a stormy sea, or a hollow surrounded by heights or hills in an undulated country.

TROUT. Several species, and many varieties, of abdominal malacopterygian fish, of the salmon genus.

The great trout of the Lake of Geneva and of some neighbouring lakes, *Salmo lemanus*, sometimes weighs from 40 to 50 pounds. Its flesh is white, and its head and back have a whitish ground-colour, and are sprinkled with small round blackish spots.—The dotted alpine trout, found in the lakes of Lombardy and of all the Alpine Countries, *Salmo punctatus*, is dotted with small black and red points, and has delicious flesh.—The marbled trout of the lakes of Lombardy, *Salmo marmoratus*, is closely and irregularly streaked and spotted with brown somewhat in the manner of some kinds of marble, and possesses a not very remote affinity to the *Salmo salvelinus* or English char.

The salmon trout, *Salmo trutta*, occurs in rivers and rivulets at all moderate heights above sea-level, and far in the interior of countries; but is best in streams of clear water which empty themselves directly into the sea. It is marked with ocellated or X-shaped spots, and has sometimes around the upper ones circles of a lighter colour, and displays many of the spots on the opercula and adipose fin; and its flesh is reddish.

The common trout, *Salmo fario*, occurs in almost every stream, both small and great, whose waters are clear and rapid; and is generally smaller than the salmon trout, and often so small as to weigh only 5 or 6 ounces, but comprises some varieties of ordinarily about 4 pounds in weight, and is, in some instances, so large as to weigh even 30 pounds or upwards; its hues and markings vary infinitely in both tint and character, but, in the most abundant instances, comprise ash-colour on the back, some ground-colour on the sides between white or golden yellow and a deep brown, and spots or sprinklings of brown on the back,—and of red on the flanks, surrounded by a lighter-tinted circle; its head is short and roundish, — its nose blunt, — its mouth wide and filled with teeth, not only in the jaws, but also on the palate and tongue,—its scales small,—and its tail broad; and its flesh is commonly white,—but, in all the best specimens when dressed, is either yellow or red. The general shape of trouts is rather long than broad; and in several of the Scotch and Irish lakes and rivers, they grow so much thicker than in those of England, that a fish from 18 to 22 inches will often weigh from 3 to 5 pounds. The female fish has a smaller head and deeper body than the male, and is of superior flavour.

In Llyndivi, a lake in South Wales, are trout called coch-y-dail, with red and black spots as big as sixpences; and others unmarked, and of a reddish hue, which sometimes weigh nearly 10 pounds, but are ill-tasted. In Lough Neagh in Ireland, are trout called buddaghs, which rise to 30 pounds, and some are taken in Ulles-Water, in Cumberland, of still greater weight; and both these are supposed to be similar to the large trout of the Lake of Geneva. In many points the trout taken out of the same river, or of the same pool, agree, and in some they vary; but they are supposed to spawn promiscuously, and all are similar in shape, and in the number and disposition of the fins. A very experienced angler records that in several of the northern rivers of England, he has taken trouts as red and as well tasted as any char, and whose bones, when potted, have dissolved like those of the char,—that about Michaelmas he has caught trouts of a copperish hue without spots, whose flesh, when dressed, was like bees'-wax, and well tasted,—that likewise in April he has taken one of these trouts 28 inches long, and thick in proportion, which boiled yellow, but was equally good,—and this he thinks was the bull trout mentioned by Walton and several authors, as extraordinary both for its size and goodness, and to be found nowhere but in Northumberland. Walton mentions the Fordwich trout, taken in the river Stour, of which only one instance was ever known to be caught by the angle. It is said to be delicious eating; and one weighing 26 pounds, and of a most beautiful colour, was taken with a net in December 1797. The gillaroo trout, found in Loughs Corrib and Mask in the west of Ireland, is highly esteemed for its fine flavour, and has the reputation of being more acceptable to gourmands than any other kind of trout. It com-

monly weighs from 12 to 18 pounds, but sometimes rises so high as 30 pounds. It has a similar appearance to the common trout, but is thicker in proportion to the length, and has a redder hue of flesh both before and after being dressed, and possesses the remarkable peculiarity of having a gizzard somewhat similar to that of a large fowl or a turkey,—and this gizzard, when dressed, is a very favourite morsel. Some supposed varieties of trout, in many of the waters of Britain, or rather peculiar salmonic individuals which anglers regard as curious or remarkable trouts, are probably salmon smelts.

In the end of September trouts leave their hot-weather retreats, and go in search of suitable spawning ground; in October in some rivers, but chiefly in November in most rivers, they spawn; in the following months, they are feeble and wasted,—though some barren females may sometimes be found who continue plump and strong during all the winter; and in February in mild open seasons, or in March in more severe years, they begin to leave their winter quarters, and approach the shallows and tails of streams, and there cleanse themselves and seek restoration to health and vigour. As they acquire strength, they advance still higher up the rivers, until they find summer residences, and for these they generally choose eddies, behind a stone, a log, or bank that projects forward into the water, and against which the current drives, —whirlpools and holes into which sharps and shallows fall, under roots of trees, and in places shaded by boughs and bushes. In small rivers, they frequently lie under sedges and weeds, especially in the beginning of the year, before their perfect strength is recovered; but when in their prime, they feed in the swiftest streams, and are often found at the upper end of mill-pools, at locks, flood-gates, and rivers, also under bridges, or between two streams running from under their arches, and likewise in the returns of streams, where the water seems to boil; and in the decline of summer, they lie at mill-tails, or end of other streams, and in the deep water. Trouts may be said to be in season from March to September, but are fattest during the five or six weeks succeeding the middle of August.

TROWEL. A mason's hand implement for applying mortar. A narrow one of 7 inches long in the blade, 5 inches long in the handle, and $1\frac{1}{2}$ inch high in the vertical connexion of the blade with the handle, is serviceable in various operations of the farm and the garden, and will be found indispensable in laying the sole-tiles of some kinds of subsoil drains.

TROXIMON. A small genus of ornamental, hardy, perennial-rooted, herbaceous, North-American plants, of the succory division of the composite order. The glaucous species, *T. glaucum*, was introduced to Britain from Missouri in 1811. It is about a foot high, and carries yellow flowers from June till August; and it comprises two distinct varieties,—the one with spreading and hirsutely tomentose scape and leaflets of the involucre, and the other with these organs erect and perfectly glabrous. Two other yellow-flowered kinds, the cuspidate and the marginate, both about the same height as the glaucous, and regarded by some botanists as varieties of it, and by others as separate species, were introduced several years later from Louisiana. The name troximon signifies "eatable;" and points at the supposed useful qualities of the plants.

TRUFFLE,—botanically *Tuber*. A genus of fungi of the gasteromycetous tribe. The esculent species, *Tuber cibarium*, is one of the most wholesome and nutritive of the eatable fungi; it grows under ground, and has neither roots nor leafy appendages, but consists of globular vesicles, and absorbs nutriment at every point of its surface; it abounds in some situations in a wild state, and is also raised artificially in beds so formed as to contain suitable niduses for its spores; it is discovered in its natural habitats by means of dogs, who are taught to scent it, and who, on finding it, bark and scratch it up: and it is served up as a rare luxury at the tables of the wealthy, either roasted in a fresh state somewhat like potatoes, or dried, shred, and dressed as an ingredient in soups and ragouts. The form of it is rugosely tubercular, more or less approaching the form of a sphere, or of an egg, or of a kidney, with a somewhat warty roughness. The colour of the surface, in the young state, is whitish, but, in the full-grown state, either blackish or a deep black. The colour of the inside is whitish, with dark blue and white, grey, reddish, light brown, or dark brown veins, of the thickness of a horse-hair, which are usually variously entangled, and which form a kind of network or mat. Between the veins are numerous cavities filled with a great deal of mucilage and small solid grains; and these scarcely visible glands were formerly said to be the seeds or germs of the young truffles. The less the inside of the truffle is coloured by dark veins, the more tender and delicious is its flesh. The blackish external rind is hard, and very rough, by means of fine fissures, grains, and protuberances; and forms with its small facets, which are almost hexagonal, an appearance by which it somewhat resembles the fir apples of the larch. Whilst the truffle is young, its smell resembles that of putrid plants, or of moist vegetable earth. When it first approaches the period of full growth, it diffuses an agreeable smell which is peculiar to it, resembling that of musk, but which lasts only a few days; this smell then becomes stronger, and the nearer the fungus is to its death and its dissolution, which speedily ensues, so much the more unpleasant and urinous is the smell, till at last it is quite disagreeable and putrid. Whilst young, the flesh is watery, and insipid; but when fully formed, it is firm like the kernel of the almond and the nut, and

has an extremely aromatic and delicious taste. As soon, however, as the fungus begins to decay, and worms and putrescence to attack it, its taste is bitter and disagreeable. Wherever truffles are produced, they are to be found from the beginning of spring till late in autumn; but in the greatest plenty from towards the end of August till the end of October. They thrive extremely, like all fungi, in warm moist autumns, and are then most delicious. After warm continuous showers, they are found nearer the surface of the soil, sometimes so high that they form little hemispherical mounds of earth, in which small clefts are produced by the sun's rays. If the soil is loose, and dry weather succeeds, the earth which was raised up falls down, and the truffle is seen half uncovered. Truffles in this state, however, are of small value, as they are generally either dead or worm-eaten. The favourite habitat of truffles is a somewhat moist light wood soil, which is defended from the immediate effect of the burning rays of the sun by large oak trees, standing at a distance from each other, but is not deprived, by thick bushes, of the free access of currents of air. Where, in woods, there are places bare of timber-trees, and with but few bushes, or covered with pollarded wood that does not stand thick, they thrive under an oak, beech, whitethorn, and even under a fruit tree, and sometimes attain the weight of from a pound to a pound and a half. This unusual size, however, is only met with in warm moist grounds. Here they lie nearer the surface of the soil. The drier the soil is, the deeper they are produced in it; but except in the vicinity of springs, they are usually so much the smaller.

Some kinds of truffles differ in the greater or less degree of roughness of the external rind, in a stronger smell, resembling that of garlic, and in a lighter or darker colour. Amongst all truffles, the white is of most value, and in highest request. It grows in Upper Italy, chiefly in Piedmont. Its surface is of a yellowish brown, or pale grey yellow, covered with protuberances resembling warts. The veins in the inside are more delicate than in the black kind, and are of a reddish yellow colour. Between the veins, the flesh of truffles that are fully formed, and their sap vessels and glands, are of a reddish colour. The smell and taste of the white truffle are much superior to those of the black; and on that account, it is more deserving of cultivation. Only the first plantation requires to be circumstantially attended to, as living pieces can seldom be procured; and to plant dead ones in new plantations is useless. Since this white truffle never degenerates to the black, but constantly produces the same, it appears to be not a variety, but a particular species. It is also found in vineyards, meadows, and even in ploughed fields; but the black ones are found only near to forest trees.

The hog-truffle, swine-truffle, or wild truffle, *Tuber suillum*, is generally kidney-shaped, usually reaches the size of a bean, and only under very favourable circumstances that of a small hen's egg. It has a thin leather-like rind, which is covered with many small round warts, without any flat interstices. By means of these, it is distinguished from the kidney-shaped varieties of the esculent truffle. The flesh is juicy, and traversed by coarse veins, which are not very crooked. The smell is disagreeably sour, and is like that of swine's dung, on which account it has received its name. Its taste is unpleasant and insipid. On account of its disagreeable taste and smell, it is not used as food; and none but avaricious truffle-hunters mix it among the edible truffles, along with which it is often found. There are, nevertheless, districts in which none but swine-truffles are to be met with. They are usually found in abundance in such tracts of land as are not mellow, but inclined to sourness. Young plantations of truffles may easily be spoiled, and all labour and expense be useless, if, through inattention or want of knowledge, the swine-truffle is transferred from its old place of growth into the new. As the real truffle prefers the oak, so the swine-truffle seems to prefer the whitethorn; and the real truffle usually occurs singly and in small numbers, while the swine-truffle grows under the whitethorn in groups of from twenty to thirty.

The small truffle, *Tuber minimum*, lives in much society, or always occurs in great numbers together. It attains only the size of a pea, and is of an irregular form, approaching to that of a sphere. Formerly it was thought to be the young progeny of the edible truffle. The stag truffle, *Tuber cervinum*, is the largest kind. It has a globular form and a loose spongy flesh, which, in the midst of its body, has so little coherence, that it forms a dusty core or heart. It is not used by man; but red-deer scrape it. All truffles receive their nourishment by means of absorbing vessels, which cover their whole superficies, in the form, generally, of small warts; and for this reason, they can thrive in none but moist situations, which offer them, in sufficient quantity, matter dissolved in water. In proportion as the earth about them dries up, the fungi must wither away. They have indeed, in their interior, vessels which contain water, to enable them for a time to do without external moisture; but if the drought continues, their internal provision is exhausted, and they become unhealthy, and must at length perish from thirst. Yet too much moisture is also injurious and even destructive to them. Acids are generated, mould and numerous other parasitic plants get a footing upon the surface of the tubes, and by degrees obstruct the absorbing vessels, and cause the truffle to consume or putrify; the mould also allures many small worms, which establish themselves upon the truffle, and live upon its

flesh. Upon the first production of the esculent truffle, its size is scarcely perceptible. As it proceeds in its growth, the earth that is around it is pressed together and pushed off, and on this account the truffle can prosper in none but a loose soil. If the soil is everywhere equally loose, the truffle assumes a globular form; but this is changed, if there is on one side a greater opposition than on the other, as, for instance, by a root or a stone. Where the soil is most moist, whether above or under the truffle, there it will either rise up or sink deeper. The degree of power of attraction of the moisture in the earth, to that in the truffle, necessitates such a change of place. In moist summers and in wet winters, truffles are found near the surface, and even projecting above it, while in dry summers, upon poor dry places in woods, they have often to be dug from a depth of more than half a foot. Here is imposed upon them a greater pressure of superincumbent soil. If the earth is not very light, they cannot be fully developed, and therefore remain small. The largest are, consequently, in general, found not deep under the earth, and in shaded light soil that is somewhat moist. These, however, are not so well tasted as those of middling size; they are also usually injured, and therefore of a bitter taste; for the access of their enemies, worms, snails, and quadrupeds, is much facilitated when no deep stratum of earth protects them against these attacks.

Of all species of trees, an oak standing aloof from other trees with its branches widely extended, collects about it the greatest number of edible truffles. It keeps off the burning rays of the sun, but at the same time permits the free co-operation of the air and of warmth. Under it, truffles acquire the most delicious flavour, and sometimes are so large as to be three or four inches in diameter and to weigh from a pound to a pound and a half. Truffles are also dug up, in woods that are not crowded, under hornbeams, elms, maples, and other deciduous trees; but less plentifully, not so well-flavoured, and less in size. In close pine woods they entirely fail, and are rare in woods of mixed kinds of trees. Hence vegetable mould from oak-leaves and decayed oak appears to contribute to the production and the growth of truffles, as advantageously as the dung of horses and asses does to the production of mushrooms. In the one case, a peculiar animal matter produces the effect, in the other a peculiar vegetable matter,—perhaps the tannin, or some other yet undiscovered product of the oak-tree. The more of this matter any species of tree contains, with the greater facility are truffles produced in its vicinity, and in greater numbers. He, therefore, who wishes to lay out truffle-beds, must endeavour to accumulate this matter in the soil where he intends them to be, and to introduce those circumstances under which the production and thriving of this fungus are promoted.

TRUG. A hod for mortar.

TRUMPET-FLOWER,—botanically *Bignonia*. A genus of ornamental, exotic, corolliflorous, ligneous plants, constituting the type of the natural order Bignoniaceæ. See the article Bignonia. A number of species formerly belonging to it are now assigned to seven other genera; and some of the best known and most magnificent of these are noticed in the articles Catalpa, Tecoma, Spathodea, and Gelsemium. But about 60 species which occur in British gardens still belong to it; and at least 20 more are known. Upwards of a dozen of the introduced species are tropical, erect, evergreen shrubs and small trees; two are respectively hardy and half-hardy deciduous climbing shrubs, from 10 to 30 feet in height; and most of the others are hothouse evergreen climbers, varying in height from 4 to about 50 feet. Upwards of one-third have binate, tendrilled leaves and one or few flowered peduncles,—some carrying their flowers racemosely, and others paniculately; about a dozen have ternate tendrilled leaves; a few have digitate leaves; one has simple, cordate, fine-nerved leaves; and about ten or a dozen have either simply pinnate, bipinnate, or compoundly pinnate leaves. About one-third have flowers of some shade or combination of yellow; and the rest have variously scarlet, orange, pink, purple, white, green, or variegated flowers.

The capriolate or tendrilled trumpet-flower, *Bignonia capriolata*, is a native of North America, and was introduced to Britain in 1710. It is one of the hardy deciduous climbers, and makes a fine show in shrubberies and upon large trellises. It rises by the assistance of tendrils or claspers, and has commonly a height of about 15 feet; its leaves sometimes come out singly, but generally in pairs, oppositely, at the joints, and are oblong, and continue so long in winter as to make the plant really a subevergreen; the flowers come out from the wings of the leaves, and are monopetalous and bell-shaped, and have a very large tube, with an outspread and divided rim, and are large and of a yellow colour, and bloom in June and July, and are succeeded by short pods.

The claw or quadrifoliate trumpet-flower, *Bignonia unguis*, is a native of the West Indies, and was introduced to Britain in 1759. It is the half-hardy deciduous climber; and makes fully as fine a show as the preceding. Its branches are very weak and slender, yet wind about every thing near them, and sometimes rise so high as to overtop trees of from 20 to 30 feet in height, —and they are very tough, and have a smooth surface, and are often of a reddish colour, particularly on the side next the sun; its tendrils grow from the joints, and are curved and tripartite, and have a claw-like form; its leaves grow in pairs at the joints, and are four in number at each, and have an oblong form, an elegantly green colour, and a very ornamental

aggregate appearance; and its flowers come out from the wings of the leaves, and commonly grow two together at each joint, and are similar in shape and size and colour to those of the capreolate species, and bloom in July and August.

Some of the most beautiful or interesting of the other species are the equinoctial and Chamberlayne's, *B. æquinoctialis*, and *B. Chamberlaynii*, two yellow-flowered, binate-leaved, evergreen climbers, from Guiana and Brazil, commonly about 40 feet in height, and blooming from April till October; the lovely, *B. venusta*, an orange-flowered, ternate-leaved, evergreen climber, from tropical South America, commonly about 4 feet in height, and blooming from September till December; the milk-flowered, *B. lactiflora*, a white-flowered, binate-leaved, evergreen climber, from Santa Cruz, commonly about 20 feet in height, and blooming in June and July; the jasmine-like, *B. jasminoides*, a purple-flowered, greenhouse, evergreen climber, from Moreton Bay, commonly about 30 feet in height; and the white-wooded, *B. leucoxylon*, a pink-flowered, digitate-leaved, evergreen erect shrub, from the West Indies, commonly about 12 feet in height, and blooming in June and July. Most of the species thrive best in a soil of loamy peat; two or three, particularly *B. unguis* and *B. crucigera*, are most readily propagated from layers; and all the rest, with only one or two exceptions, are most readily propagated from cuttings.

TRUNDLE. A low, coarse carriage, with small wheels, for carrying heavy and cumbrous loads.

TRUNK. The stem of a tree,—principally the part between the ground and the commencement of the ramification.

TRUSS. A bundle of hay, straw, or other dried forage. A truss of straw weighs 36 lbs., a truss of hay weighs 56 lbs., and 36 trusses make a load; but in June, July, and August, a truss of new hay ought to weigh 60 lbs. See the articles Straw and Hay.

TRUSS OF FLOWERS. Any kind of inflorescence which carries many ornamental blossoms on one peduncle or common footstalk,—and particularly such as has the individual flowers well free from one another, so that each is as distinct an object as the whole.

TUBER. The peculiar subterraneous development of a tuberous-rooted plant. It is popularly regarded as a root, and has been called by some botanists a subterranean stem; but differs widely in structure and functions from both a root and a stem, and comprises a complicated system of contrivances and secretions for achieving propagation, quite independently of the propagational organisms which its plants possess in common with more fibrous-rooted species. Its peculiar structure and uses, as exemplified in potato tubers, are noticed in the article Potato; and its affinities of character and function to a bulb may be learned from the article Bulb. The tuber of some plants is single and quite solid, as in the case of *Bunium bulbocastanum;* the tubers of others are in pairs, comprising an old, exhausted, or light one which has ministered to the present year's growth, and a young, plump, and heavy one which will minister to the growth of next year, as in the case of *Orchis mascula;* and those of other plants generally amount to more than two, and may be pretty numerous according to circumstances of prolificity, and contain large supplies of germs and nourishment whence great annual crops may be raised, as in the cases of the potato, the dahlia, and the Jerusalem artichoke.

TUBER. A genus of fungi. See the article Truffle.

TUBEROSE,—botanically *Polianthes*. A small genus of exotic, ornamental, tuberous-rooted plants, of the day-lily family. The common or tuberous species, *Polianthes tuberosa*, is a native of India, and was introduced to Britain in 1629, and has very long been cultivated in Italy, for the exportation of its tubers to other countries, in the same manner in which tulips, oriental hyacinths, and other bulbous-rooted beauties are cultivated in Holland. It has a flower somewhat like the narcissus, but far more powerfully fragrant, and was called by the old gardeners the tuberous Indian hyacinth. Its stem is commonly about 3 feet high; its flowers are white, and bloom in August and September; its corolla is monopetalous and funnel-shaped, with an oblong incurved tube and an outspread six-segmented brim; and its fruit is an obtuse, roundish, three-cornered, three-celled capsule, full of plain half-round seeds disposed in a double range. One variety has a weaker and shorter stem, and a smaller flower, than the normal plant; another has striped leaves; and another—now the universal favourite of cultivators, and often spoken of as if it were the only tuberose—has double flowers. Yet this last variety, though at present so common, originated not much upwards of a century ago in a garden in Holland, and was for many years prevented by the proprietor from passing beyond the limits of his own grounds, in order that he might have the silly boast of being the only owner of this flower in Europe. The tubers may be purchased from seedsmen in the same way as "Dutch roots;" and they should be potted in sandy loam, and brought forward in a frame with a little bottom heat; and when the plants are coming into flower, they may be removed to the greenhouse or the sitting-room, provided their powerful fragrance should not be felt inconvenient in the latter. The cultivation is very easy; but the tubers do not succeed in the second year, unless the plants are repotted in heat, and kept close to the glass till the leaves decay. Tuberoses are planted in the public gardens of Paris at distances of 50 or 60 yards from one another; and they diffuse a delightful odour in the mornings and evenings when the dew is on, or after a shower of rain.—The slender tu-

berose, *Polianthes gracilis*, was introduced to Britain in 1822 from Brazil. It has pale yellow flowers, and a similar height and time of blooming to the common tuberose; and is also propagated from offsets, and loves the same kind of soil; but requires a considerably greater degree of heat.

TUBEROUS ROOTS. See TUBER and POTATO.

TULBAGHIA. A genus of ornamental, bulbous-rooted, herbaceous, South-African plants, of the day-lily family. Three brown-flowered species, of from 6 to 15 inches in height,—the onion-scented, the garlic-scented, and the allied,—were introduced to Britain between 1773 and 1821; and another and much more beautiful species, the violet-flowered, was introduced at a considerably later period. The leaves of this last are several, sheathing at the base, linear-sword-shaped, 6 or 8 inches long, ¼ of an inch broad, obtuse, quadrifarious, glabrous, coriaceous, rigid, and bright green; the footstalk is erect, slender, filiform, glabrous, and a foot or more high; the inflorescence is an umbel, whose flowers amount to 8 or 9 and open in succession; and the flowers are erect, patent, purple, bright, and shining, and emit a powerful alliaceous fragrance. The three brown-flowered species bloom in spring or the early part of summer; the violet-flowered species blooms in October; and all love a soil of rich mould, and are propagated from offsets.

TULIP,—botanically *Tulipa*. A genus of ornamental, bulbous-rooted, monocotyledonous, herbaceous plants, constituting the type of the natural order Tulipaceæ. This order will probably be so revised by future botanists as to comprise many of the numerous genera which have hitherto been included in the asphodel group, the day-lily group, the amaryllis group, and some cognate families,—and will then be the most superb for floral glory within the whole range of vegetable existence; and even in its present very restricted condition, though comprising but eight or nine genera, it presents to view a vast and dazzling collection of combined beauty and brilliance, and contributes to the parterre a large proportion of its most gorgeous ornaments, and claims, in the estimation of the ablest critics, to comprise the chief objects of allusion in the saying of Infinite Wisdom,—"Consider the lilies of the field, how they grow; they toil not, neither do they spin; and yet I say unto you that Solomon in all his glory was not arrayed like one of these." The principal tulipaceous genera are lilium, tulipa, fritillaria, yucca, erythronium, and gloriosa; and these strike all eyes, from the child to the philosopher, as magnificently beautiful. Only about 120 species, irrespective of varieties, occur in British gardens,—and of these 3 or 4 require hothouse culture, 12 or 14 are suited to the greenhouse, and all the rest thrive well in the open ground.

The tulip genus comprises one indigenous species, about twenty-five introduced exotic species, and an innumerable multitude of varieties. The roots of all its plants are bulbous; the leaves are few and grow from the root-crown, or from the basal part of the flower-stem; the flowers are chiefly solitary, and sit on long, naked footstalks; the perianth consists of six fleshy, coloured, large sepals; the stamens are six in number, subulate, and shorter than the sepals, and terminate in oblong four-cornered summits; the stigma is three-lobed, triangular, sessile, and persistent; and the fruit is a triangular three-celled capsule, full of smooth compressed seeds. The name tulip is corrupted from a Persian word which both designates the garden tulip and signifies a turban. One or two of the species require a little frame protection; and all the others are perfectly hardy.

The wild or indigenous tulip, *T. sylvestris*, occurs on calcareous grounds, and especially in chalk pits, in Middlesex, Hertfordshire, Suffolk, and Norfolk; and has also been found in Scotland; and is more or less plentiful in many parts of France, Switzerland, Italy, and Southern Germany. It naturally propagates itself by sending out a long strong fibre from its root, and developing at the end of this a new bulb; so that the offspring arises at a considerable distance from the parent. The stem is about a foot high, one-flowered, and somewhat drooping; the flower is sweet-scented, and has a bright yellow colour, and blooms in April and May; the sepals of the perianth have an ovate-acuminate form, and are hairy at the extremity; and the stamens are hairy at the base.

The small yellow or Cels's tulip, *T. Celsiana*, is a native of the Levant, of Southern Europe, and of the basin of the Wolga. It was known to Clusius, Tournefort, and some other early European botanists as a distinct species; but was confounded by Linnæus with the wild tulip, though differing greatly from it in size; and was restored to the rank of a separate species by Redouté, the author of the huge French work *Les Liliacées*. Its leaves are lanceolate; its stem is one-flowered, and commonly about 18 inches high; its flower is mostly erect, and has a greenish yellow colour, and blooms in June and July; its sepals are lanceolate; and its stamens are slightly hairy above the base.

Clusius's tulip, or the white and red Italian tulip, *T. Clusiana*, is a native of Sicily, Italy, and the South of France; and was introduced to Britain from the first of these countries in 1636. It was confounded by Linnæus with the common garden tulip; and, like Cels's, was restored to the rank of a separate species by Redouté. Its size is similar to that of the wild tulip; its leaves are linear-lanceolate; its stem is smooth, one-flowered, and about a foot high; its flower has a white and red or white and purple colour, and blooms in June; and its sepals are acute.

The two-flowered yellow tulip, *T. biflora*, is a native of the salt deserts in the basin of the

Wolga, and often occurs in company with the small yellow tulip, and was introduced to Britain in 1806. Its leaves are lanceolate and spreading; its stem is two-flowered or three-flowered, and commonly about 6 inches high; and its flowers are yellow and fragrant, and bloom in April.

The sun's-eye or Agen tulip, *T. oculus solis*, is a native of Italy, France, Germany, and other parts of Europe; and was introduced to Britain from the first of these countries in 1816. It was unknown to Linnæus; and was first described by St. Amans, who found it at Agen in France. Its leaves are oblong-lanceolate; its stem is one-flowered, glabrous, and about a foot high; its flower is large, bell-shaped, and of a fine scarlet-crimson colour, with a broad, black, yellow-edged spot at the base of each sepal, and blooms in April and May; its exterior sepals are acuminate, and the interior ones obtuse; and its stamens are smooth.

The sweet-scented or early dwarf or Duc Van Thol tulip, *T. suaveolens*, is a native of the South of Europe, and was introduced thence to Britain in 1603. Its leaves are ovate-lanceolate; its stem is one-flowered, downy, and about 6 inches high; its sepals are obtuse and smooth; and its flowers are sweetly fragrant, and have a scarlet colour edged with yellow, and are valued far more for their odour and their earliness than for their form or appearance, and naturally bloom in March and April, but when grown in a room in either sandy soil or water, may be made to bloom as early as January.

The creeping Russian tulip, *T. repens*, was introduced to Britain from Russia in 1819, and is a foot high and yellow-flowered, and blooms in April and May. The horned tulip, *T. cornuta*, was introduced from the Levant in 1816, and is two feet high and striped-flowered, and blooms in May. The starred tulip, *T. stellata*, was introduced from Kumana in 1827, and requires frame protection, and has a height of between 30 and 36 inches, and carries white flowers, and blooms in March and April. The rock tulip, *T. saxatilis*, was introduced from Crete in 1827, and is a foot high and yellow-flowered, and blooms in April and May. Bieberstein's tulip, *T. Bieberstieniana*, was introduced from Siberia in 1820, and is a foot high and yellow and purple flowered, and blooms in June and July. The bad-smelling tulip, *T. maleolens*, was introduced from Italy in 1827, and is a foot high and red and yellow-flowered, and comprises a variety with red and variegated flowers, and blooms in May. The Altaian tulip, *T. altaica*, was introduced from the Altai Mountains previous to 1830, and is a foot high and yellow-flowered, and blooms in April and May. The rough-stemmed tulip, *T. scabriscapa*, was introduced from Italy in 1827, and is two feet high and red and yellow-flowered, and blooms in April and May. The middle tulip, *T. media*, was introduced about 1830, and is a foot high and scarlet and white flowered, and blooms in May and June. Bonarota's tulip, *T. Bonarotiana*, was introduced from Italy in 1827, and is about 18 inches high, and has red and variegated flowers, and blooms in April and May. The three-coloured tulip, *T. tricolor*, was introduced from Russia in 1817, and is a foot high and scarlet-flowered, and blooms in April and May. The pubescent species, *T. pubescens*, was introduced in 1824, and is a foot high and red-flowered, and blooms in April and May. The Turkish tulip, *T. turcica*, was introduced at a considerably distant but uncertain period, and is two feet high and striped-flowered, and blooms in April and May. The early-flowering tulip, *T. præcox*, was introduced from Italy in 1825, and is a foot high and scarlet-flowered, and blooms in April and May. The mountain tulip, *T. montana*, was introduced from Persia in 1826, and is a foot high and scarlet-flowered, and blooms in July. The choked tulip, *T. strangulata*, was introduced about 1830, and is about 18 inches high, and blooms in April. The spreading tulip, *T. patens*, was introduced from Siberia in 1829, and is about a foot high, and has white and grey flowers, and blooms in April and May.

Gesner's tulip or the common garden tulip, *T. Gesneriana*, was the earliest known of all the species; and has probably received more attention from florists than any other plant in existence; and is diffused throughout almost all the gardens of Europe, small and great; and often monopolizes the entire name, and usually concentrates in itself the main interest, of the whole tulip genus. Its leaves are ovate-lanceolate, glaucous, and smooth; its stem is one-flowered, smooth, and commonly from 10 to 30 inches high, varying widely in different varieties; its flowers are normally striped, but sport into multitudinous and highly diversified colourings, and bloom in April and May; its sepals and filaments are smooth; and the lobes of its stigma are decurrent and deeply divided. There are five very distinct varieties of it, serving as types or representatives of so many groups of innumerable subvarieties;—the normal, *T. Gesneriana*, from 20 to 30 inches high, with striped flowers; the yellow, *T. G. lutea*, from 15 to 24 inches high, with yellow flowers; the double, *T. G. plena*, from 10 to 16 inches high, with variegated flowers; the party-coloured, *T. G. versicolor*, from 15 to 24 inches high, with variegated flowers; and the cut-sepaled, *T. G. laciniata*, from 20 to 30 inches high, with variegated flowers.

The garden tulip grows wild in Syria and in other countries near the eastern parts of the Mediterranean; it was cultivated by the Turks, from an early period, in their gardens; it was introduced to Western Europe from Constantinople in 1554, and was first described, in a systematic way, by Conrad Gesner in 1559; and it was introduced to Britain in a general way about 1577, and re-introduced in its finer forms in 1603. When it was introduced to Holland is not pre-

cisely known, but it early made a profound impression in that country, and began to be cultivated with an enthusiasm, which speedily rose into the famous tulipomania. This was originally a violent and spendthrift passion for the newest and finest varieties of the tulip; and it eventually became, and for some time continued, a system of gambling speculation, in which tulip-bulbs were sold at enormous prices, somewhat in the manner of the transactions of the Stock-Exchange; and it rose to its greatest height in the four years succeeding 1633. The bulbs were sold by weight, in perits or grains; and some brought prices which would have purchased a small estate. "The variety called Semper Augustus," Beckman tells us, "was often sold for 2,000 florins; and it once happened that there were only two roots of it to be had, the one at Amsterdam, the other at Haarlem. For a root of this variety one agreed to give 4,600 florins, together with a new carriage, two grey horses, and a complete harness. Another agreed to give twelve acres of land for a root. Those who had not ready money promised their moveable and immoveable goods, house and lands, cattle and clothes." The traffic in tulip-bulbs engaged men of all ranks, and absorbed more attention than any department of useful commerce, and organized itself into a regular system, and occasionally worked out for some of its votaries prodigious profits, and terminated in such general, rabid, and destructive gambling that the Dutch government felt obliged to interfere with it and put it down. In one instance, it brought a profit of more than 60,000 florins to one dealer in four months; and in multitudes, it was pursued with such reckless disregard of principle and decency, that a bulb was sold several times or even many times over without being seen or possessed by any of its purchasers. "It was followed," says Beckman, "not only by mercantile people, but also by the first noblemen, citizens of every description, mechanics, seamen, farmers, turf-diggers, chimney-sweeps, footmen, maid-servants, and old clothes-women. At first, every one won, and no one lost. Some of the poorest people gained in a few months houses, coaches, and horses, and figured away like the first characters in the land. In every town some tavern was selected which served as a Change, where high and low traded in flowers, and confirmed their bargains with the most sumptuous entertainments. They formed laws for themselves, and had notaries and clerks. During the time of the tulipomania, a speculator often offered and paid large sums for a root which he never received, and never wished to receive. Another sold roots which he never possessed or delivered. Oft did a nobleman purchase of a chimney-sweep tulips to the amount of 2,000 florins, and sold them at the same time to a farmer; and neither the nobleman, chimney-sweep, nor farmer had roots in their possession, or wished to possess them. Before the tulip season was over, more roots were sold and purchased, bespoke and promised to be delivered, than in all probability were to be found in the gardens of Holland; and when Semper Augustus was not to be had, which happened twice, no species perhaps was oftener purchased and sold. In the space of three years, as Munting tells us, more than 10,000,000 florins were expended in this trade, in only one town of Holland." The tulipomania was ridiculed and despised by calm observers in other lands, and has ever since been proverbially quoted as a marked instance of the epidemic folly which sometimes assails a whole community; and when it passed away, it afforded ignorant pretenders and indolent aristocrats a feasible pretence for neglecting or deriding all floriculture, and especially tulip-culture, as undignified and foolish. Another mania, therefore, arose, more gross and irrational than even the tulipomania, calmer indeed and clothed with more trappings of worldly rank, yet incomparably more grovelling and brutal,—the mania of treating with indifference or contempt, or of denouncing as suitable for only the uneducated and the vulgar, one of the most beautiful and heaven-proclaiming objects in the vegetable world. But this mania also is becoming obsolete; and the tulip—probably both the superbest and the truest "lily of the field"—is now very generally allowed to occupy its just place as a meek and lowly yet most magnificent instance of the beauty which pervades all God's works,—more gorgeous than "Solomon in all his glory," challenging the admiration of all eyes, and directing to heaven the kindlings of all hearts.

The innumerable varieties of the garden tulip are usually classified by British florists into selfs, bizarres, byblomens, roses, and tricolours. A self is all white or all yellow, or at least has a predominant ground-colour of white or yellow, without any distinct markings. A bizarre has a yellow ground colour, marked with any one of many different shades of purple or scarlet; and may be either a feathered bizarre or a flamed bizarre, according as the colours are in filaments and pencillings or in a broad central stripe. A byblomen has a white ground colour, marked with lines, stripes, or variegations of any one of various shades of purple or violet; and it also may be either feathered or flamed. A rose has a white ground colour, marked with lines, stripes, or variegations of any one of various shades of rose, scarlet, cherry-colour, or crimson; and, like each of the two preceding, it may be either feathered or flamed. Tricolours do not properly constitute a separate class; but comprise all tulips, but especially all bizarres, which have three colours.—The tulips of the old British gardeners were classified sometimes into early-bloomers and late-bloomers, and sometimes into early-bloomers, middle-bloomers, and late-bloomers; but they comprised rather species than varieties, — or rather, the early bloomers were principally iden-

tical with *Tulipa suaveolens*, and the late bloomers with *Tulipa Gesneriana*.

During the time of the tulipomania, and even in a considerable degree in the succeeding times down to the present day, a prime or a good tulip was not necessarily a very beautiful one, but simply a very rare one; but, in all the sober schools of modern floriculture, it is essentially and even eminently beautiful in both form and colour, whether it be rare or common,—and according to general consent, it must possess the following characters:—"The stem should be strong, elastic, and erect, and about 30 inches above the surface of the bed. The flowers should be large, and composed of 6 sepals or petals; these should proceed a little horizontally at first, and then turn upwards, forming almost a perfect cup, with a round bottom, rather widest at the top. The three exterior petals should be rather larger than the three interior ones, and broader at their base; all the petals should have perfectly entire edges, free from notch or serrature, the top of each should be broad and well rounded; the ground colour of the flower, at the bottom of the cup, should be clear white or yellow, and the various rich-coloured stripes, which are the principal ornament of a fine tulip, should be regular, bold, and distinct on the margin, and terminate in fine broken points elegantly feathered or pencilled. The centre of each leaf or petal should contain one or more bold blotches or stripes, intermixed with small portions of the original or breeder colour, abruptly broken into many irregular obtuse points."

A self-tulip is always raised from seed; and under suitable circumstances of soil and age and management, may give rise to one or more fine varieties of either bizarre, byblomen, or rose. A breeder is a choice self, from five to nine years of age, from the seed, still vigorous, tall, and elastic in the stem, beautifully formed in cup and sepal, of an uniform colour on both surfaces, of a pure white or bright yellow in the bottom, and either black or dark in the anthers and stigmas; and if it be properly grown, and judiciously treated, and perseveringly cared for, it will sooner or later "break" into a bizarre, or a byblomen, or a rose,—or in other words, develop the colours and markings of one of a variegated and richly tinted variety. But a breeder of any of the three classes is not a breeder of either of the other two; some breeders break in the very earliest years of blooming, and others not till after a number of years, perhaps so many as twelve or even twenty; and the variegated offspring of some have a tendency to revert to the breeder characters, while the variegated offspring of others are absolutely or comparatively permanent, and have been known to transmit their acquired characters, through the medium of their offset-bulbs, with very little variation, for nearly half a century. The influences most favourable to the sure and brilliant breaking of breeders are not well understood in Britain, and have been the topic of much conjecture and discussion among florists, and may best be studied by careful enquiry into the practices of the most successful tulip-growers of Holland.

An easy and efficient method of obtaining valuable breeders, and even some splendid broken flowers, from 150 or 200 seeds, in a period of from 5 to 7 years, is detailed as follows by a writer in the Gardener's Gazette:—"In November, take a common twelve-sized pot; put about 1 inch or 1½ inch layer of crocks, and fill up the pot with a rich light compost, tolerably free from stones, such as would be used for carnations; shake it down a little, and level the top even with the edge of the pot. Spread the seed on this; plunge it in the ground up to the rim of the pot, as the earth settles down, by watering, and sift the same kind of compost on the seeds, covering them to half an inch in depth and not more. When they come up, sift the same kind of light rich earth upon them; for, without doubling down the grass, it will raise the soil above the embryo bulbs. The heat of the sun and the extreme of the frost must be kept from the plants, no matter how; the one or the other would stint the growth, if not kill them; nor must they ever be dry. When the grass has turned yellow, sift the mould through a small sieve, and collect your bulbs; or if they be not very near together, you may allow them to stand a second year; but they grow larger when taken up, and kept out of the ground a short time. In October plant them again in pots, an inch apart, and sink them as before. Take them up as before. The third year plant them again in October, two inches apart in the row, and two inches deep, in a properly prepared bed of rich earth, and let the rows be six inches apart. Here they must have a foot, at least, of good soil, free from large stones, and be kept very clear from weeds. When they die down, they must be taken up again. The fourth year they must be planted three inches apart in the row, and three inches deep, and be taken up as before, when the foliage is decayed. The fifth year, plant the bulbs four inches apart, in good compost, as before, and in October. This year many will bloom, of a self colour. If they have thin petals, pointed petals, foul bottoms, or are of a bad form, throw them away before they have done blooming—it prevents mistakes—and throw away all their offsets at the same time. If they have thick petals, round at the ends, forming a good cup, and having a clean yellow or white bottom, mark them to be kept separate from that season onwards, and place them, on taking up, in separate bags or boxes with their increase; so that, when any one breaks into colours, the whole of that variety may be either saved or destroyed, as they may deserve."

The matured bulbs of selfs, and all bulbs of bizarres, byblomens, and roses, succeed best, and

produce the most showy results, in specially prepared beds. The situation must be open and airy; the ground should be dug out to the depth of about 20 inches; the excavated space should be filled with a compost of about one part of well rotted cow's dung and about two parts of rich, fresh, loamy, somewhat sandy soil; and the bulbs should be deposited at distances of about seven inches from one another, and at a depth of four inches or less according to their size. A sprinkling of fine dry sand may be put on the site of each bulb; and as much of the same material may be sprinkled over the bulb as might prevent the coherence to it of moistened soil. The best time for planting is from the first till the tenth day of November. The collocation of different classes of flowers may be done to suit the cultivator's personal taste; but that of different heights of stem should be in the successive rows,—the shortest in the front, and the tallest in the rear; and in order to facilitate this arrangement, all fine varieties, previously not known to the cultivator, ought to be described to him as of the row, whether first, second, third, or fourth, to which they are suited. An awning may be erected over the bed in spring, after the nascent flowers begin to show colours; but should be so constructed as to permit the free play of light and air during all the morning and the evening, between the extremes of midnight cold and mid-day sunshine. No artificial watering ought ever to be given. As soon as the petals fall, the incipient fructification ought to be cut away; when the leaves become embrowned, and the top of the stem begins to wither, the bulbs should be unearthed, and placed in a dry situation; and in August or September, the bulbs may be freed from their fibres, loose skins, and young offsets, and stowed away in drawers.

The fine varieties of garden tulip at present in cultivation are exceedingly numerous, and amount at least to five or six hundred; yet some of the most common bear a number of different names, and falsely pass in many catalogues for as many kinds as they have names,—and some of the least common are eminently beautiful, and owe their uncommonness rather to want of fashion than to real scarceness. A brief notice of a few of the principal varieties, therefore, may serve the double purpose of acting somewhat as a check upon the market catalogues, and of guiding novices in amateur culture to the making of a pre-eminently good small collection.

Polyphemus, a very common but first-rate bizarre, suitable for the second and the third rows, bears many names, and is sold under most or all at different prices. The ground colour of it is rather pale yellow, the markings are dark and good, but often too heavy; the form pretty nearly the best; the petals lying so close as to form a whole cup; in general the purest of the bizarres, but ugly in its breeder state, and when it has gone nearly back. The bottom, however, is never stained, but the colour of the anthers occasionally runs a little down the stamens. This would be a blemish if compared with one which was not so; but coloured stamens is not a disqualification like a stained bottom.—Captain White, Sanzoe, Captain Black, or Admiral Black, is one of the most beautiful bizarres, in several respects the best, and belongs to the second row. The yellow is exceedingly rich; and the marking greatly varied in style, but nearly always splendid. This flower is above the average in form, though not equal to Polyphemus in compactness and neatness of construction; yet it very rarely occurs without three very slight stains at the base of three of the petals, so slight that hundreds would overlook them.—Surpass Catafalque is a bizarre of great pretensions as to form, and probably excels in that respect all our present varieties. It belongs to the second and third rows. The yellow is not so fine, and the marking not so dark as in many others; but, well grown, it is a fine show flower, quite pure, often very neatly and perfectly feathered. It is also very plentiful and cheap.—Charbonnier Noir is a very pure bizarre, with very bad marking; that is to say, there is great uncertainty. It is very apt to come with portions of the breeder colour, so much so, as to scarcely afford one showable or well-marked bloom in twenty; but, when perfect, it is a most splendid bizarre, with fine, but pale yellow, splendid bottom, and not a bad form. It so rarely comes in perfection that good specimens of it have borne other names as if they were distinct varieties.—Pompe Funebre is a bizarre of great price and pretensions, but of quite second-rate, if not worse, form. The yellow is brilliant, and the marking generally pretty and always effective. The flower is in repute, but is a very unsafe one to show in a stand, if the judges go in earnest at the properties; for it must lose every point in regard to form.—Brown's Polyphemus is as compact as the original Polyphemus, but higher on the sides, so as to form a rather longer cup. The yellow is deep and rich; the marking darker than in any other,—in fact, as nearly black as it can be when in good order. It appears rather a constant flower; and rises well up to the fourth row when full grown, and the third when comparatively undersized; and it is at present one of the dearest varieties in the market.—Thomas Brown is a bizarre of the fourth row, fully as noble as the last mentioned, but different. The flame is large; the yellow a good gold colour; the marking very striking; feather and flower too; and generally the colour outside better than that of many others. The size is above the average, and remarkably showy in a bed; a half-grown root will reach the third row.—Lawrence's Duke of Clarence comes in twenty different characters, and has had as many names. It is one of those indistinct and eccentric flowers which, besides changing character, actually change colour; sometimes a bright yellow and dark markings, but the outside always dull, and a struggle between a dirty white and a straw colour; and the markings not half defined, even when the inside is tolerable. The inside is sometimes a good, though not a brilliant yellow; but the outside is never bright. It is, however, a bold middle-row variety; and possesses a medium character between a bizarre and a tricolor.—Leonatus Posthumus is singular but not splendid, curious but not beautiful. It has almost always a flame without feather, a brown and yellow, with nothing strikingly good to recommend it; and its chief merit is that of differing in colour and character from all the old bizarres. It grows, according to the size of the root, in the first, second, or third row; and is quite clean, but not of very good form.—Solon is a first, or, at the most, second-row bizarre, of better form than the preceding, showy, with good yellow, and very often highly uniform marking; frequently flame without much feather,—sometimes without any. It makes a striking flower in the first row, because the flower is large in proportion to the height. The yellow is palish, but very pretty and bright.—Lord Colling-

wood is a very tall bizarre, which has been held in very high estimation. It has a singular colour and character about it, unlike any other bizarre,—a singular purple cast in the marking; and always brings a high price. It is in most good beds. It is tall even for the fourth row, mostly topping all others. The flower, however, is small for the height of the stem, and it is not very certain as to the marking.

Rose Emily is a showy, clean, middle-row flower, of tolerably certain character; always pretty, sometimes very fine; with a tolerably thick petal, clear white, and frequently well-defined marking. It is not plentiful, and therefore pretty high in price. Smaller roots do for the third row: but it should never be had in the second, for it will run up.—Rosa Blanca is a beautiful flower, and curiously sports into two very distinct subvarieties. One of these is beautifully and regularly feathered, and without any flame; and the other is richly feathered and flamed. The two are the same flower in different characters; and any body who grows the feathered kind will find in time that he will obtain the other, though the feathered and flamed kind does not go back to the lighter character. The flower is a showy subject in a bed; yet it blooms too early for the rest of the bed, —and after it has been out some days, its beautiful rose colour goes off to a light purple, and so distinct as to enable a stranger to pronounce one a byblomen, the other a rose. It is a good third-row flower, and is occasionally used as a fourth-row flower; but is very apt to split and form two roots instead of blooming; on which account two bulbs of it may be planted in the same hole.—Madame Vestris, in its best state, is a feather only, and one of the most rich and beautiful roses; but it more frequently comes full of flame and feather, in which state the colours are not so bright. It is a showy variety, very pure, very distinct from all others, and an excellent marker for the country shows. When it comes with feather only, it seems as if the same quantity of colour that would be used for all the flame and feather were concentrated in the feather only, it is so dense and rich. In this state it was called Princess Sophia of Gloucester; but a few seasons' growth settled the question, and Madame Vestris is unquestionably the identical flower, although the colour is so much deeper while feathered only. It is a second-row flower, but has been occasionally put into the third. —Triumph Royal is one of the best roses, though abused as much as any by new names when in different characters. It varies from the slightest possible feather to the deepest flame and feather. It is always beautiful, and deserves, however plentiful it may be, and however cheap, to take its stand among the very best class of roses. It is very pure, and its shape is far above the average.—Camuse is beautiful in a bed, but, on account of its form, cannot be safely admitted into a stand for show. The petals are always three one way and three the other; and the three inner ones turn in, while the outer ones keep expanded more. It is a very pure and richly-coloured rose, stands well as a second-row flower, and is always handsomely marked. There is a difference of opinion as to whether Camuse and Brilliant are the same flower; the only perceptible difference being, that Brilliant is full of splashes of red colour, as if it had been sprinkled with a brush; while in form, colour, purity, grass, and all other particulars, they are alike. It is said, however, that Camuse never comes speckled, and Brilliant never comes pure.— Rose Esther, according to a specimen of it exhibited in 1833 at Hampton, is one of the most perfect things that can be imagined. The ground, or white, is of a singular texture; it is not clear white, but a sort of shade, like enamel, and as clear and apparently transparent. A flame up each petal, alike in all six petals, a close cup, rather taller than it ought to be, the bottom as pure as possible, and the whole as perfect a beauty as can well be imagined. Yet this exquisite specimen was but one of those freaks which flowers will take in spite of florists, and which are rarely equalled. The flower is naturally coarse and foul at the bottom; and in some seasons there has not been one clear bottom in twenty.—Lady Crewe is a small rose, often very beautifully marked, and frequently smudged at the bottom, but occasionally as clean and pure as snow. It is a brilliant colour, and, in its feathered state, when there is no flame, quite a little star in the outside row. The petals are too narrow to allow its full expansion; and, indeed, like many country flowers, it seems very unwilling to open fully. Its brilliance, as compared with some roses, is greatly enhanced by the colour on the outside being nearly as good as the inside; but even this is secured by a disadvantage, the comparative thinness of the petals.—Claudiana is a most beautifully coloured rose, good large flower, blooming egg-shaped, and not fully expanding, the petals never losing their individual boat form. This flower, though quite desirable in every bed, is an awkward one to show; for it is seldom to be found without a blue stain on the shoulder among the other colours. It is a third and fourth-row variety; and a dozen would not look too many in any moderate-sized bed. —Catalani is a second and third-row flamed and feathered rose, of extraordinary rich colour, firm petal, pure white; and, besides these qualities, has the advantage of being a free opener. It is a great favourite, and always assists a bed materially; but has been often unjustly confounded with Ceres Blanche and Ponceau Très-blanc.—Lac is a very high-priced rose, and deservedly a favourite, for its extremely brilliant colour. It is a first-row flower, of the full size for its height, but with much too thin a petal. When put on a stand, the place it rests on is seen through enough to cast a dark shade; and this is a sad drawback. Its colour approaches a scarlet; and when it first opens, it is a most beautiful object in a bed.—Rose Catharine, or Athalia, is a rose remarkable for its beautiful and very striking colour, rarely coming perfectly free from a stain in the bottom, and yet so desirable as a bad flower, that nobody of any taste would be without it. The lighter it is marked, the clearer it usually is in the bottom, and the brighter is its marking developed. It is a second row rose; and a few of it in a bed impart great brilliancy.—Camuse de Craix is a very delicate and handsome rose, with a straw-coloured ground, and rich crimson scarlet markings. It is justly esteemed as a star in the first row, and the markings are generally very uniform, and have splendid pencilling. When perfectly bloomed, the appearance is very grand indeed; though it is some days in coming to its proper colour.—Ceres Belleforme is a very compact and beautifully marked rose for the first or second row, but most proper for the first. It opens rather yellow, but bleaches white. The cup does not very much expand, but there are many good points to make up for it. The petals are so well together, that, like Polyphemus and Salvator Rosa, they are like one petal instead of six; and the colouring is always beautiful in all its characters.

Louis XVI. is a very noble byblomen, but a most uncertain one. The white is good, and the marking a deep purple, almost black when in fine condition. The colour is very apt to run down too low, and the bottom to come smudged; and out of a score of Louis XVI. in a bed, there will be times when not one flower would be fine and clear as it ought to be; yet, for the sake of a bloom now and then, everybody grows it. There are what the growers call different strains of it, which means that some flowers and their offsets are generally better than others,

although the same variety. The flower, in all its stages, is striking in a bed, and, when perfectly free from breeder colour, is rich and handsome. It will do for the third or the middle row, according to the size of the root.—Siam is a third or fourth row byblomen, of excellent properties, fine white ground, and purple margins, petals thick, form above the average; but the bottom is yellow for the first period of the bloom, and that condemns it all the early part of the season; and though it bleaches very fine, it must have years before the bloom is off. It has been grown in high character by come cultivators; and, under a notion that the strain was improved, it was called Acapulca.—Reine de Sheba is a very neat thick petalled byblomen, with good white pure bottom, generally well flowered and feathered outside, a second-row flower, rather of the smaller kind. The purple is rather light, the markings generally perfect, or nearly so. The form, though not first rate, is above the average of the old flowers.—Violet Alexander or Violet Quarto is a middle or third row byblomen, exceedingly pure at the bottom, when in condition, apt to sport in the colouring and to have breeder colour, but when fine, a most delicate and beautiful variety.—Ambassador d' Holland is a noble black and white middle-row flower, which has pretty universally a stained bottom, with a dark creamy stain. It has a good bold size, and deserves a place even in best beds, notwithstanding the drawback of its creamy bottom; and its form is good among the large varieties.—Washington is a bold deeply-coloured byblomen, with thick petal, good white and clean bottom; though three of the petals rise above the others. It has been long a favourite; and will go in the second and third rows.—Lawrence's Friend is a very pretty byblomen, with a good deal of colour. At first coming into flower, it is like a tricolor; but it always bleaches white, or nearly so, and the flower, though smaller, and taller in the stem, is very much like a handsome Washington. There is the same characteristic in the separation of the top and bottom petals.—Desdemona is a middle-row, light-coloured byblomen, not always clean, or perfectly marked, but very showy and desirable. The cup is rather long; but in the middle and third row, forms a pleasing feature.—Salvator Rosa is a magnificent byblomen, with nearly all the characteristics of a Polyphemus bizarre; a close, well-formed, compact cup, and pure white, deep purple colours. The petal is thick, the ground pure, and the colour rich. It is a second-row flower, of good average size, and a star in any bed that has it.—Rubens is a rich byblomen of the second or third row, average size, deep fine purple, pure white, clean bottom, nearly as showy as a Louis, and always good in a bed. The form of the cup is not so good as that of some of the more modern flowers, the petals being rather inclined to narrow at the ends; yet it is a noble and desirable flower, and maintains its station in all good beds.—Thalia is a very grand byblomen, with compact, well-formed, but not much expanded cup. The white is exceedingly pure and clear to the bottom; and the bloom is above the average size, and a good deal above average quality. The petals are remarkably thick; and the height is equal to the middle row. It is in all respects a desirable flower; though apt to mark irregularly, until reconciled to the treatment it is undergoing.—Alcon is a large middle row byblomen, clean but loose, and showy but not neatly made. The cup is rather long than otherwise.—Grand Monarque is a third or fourth row byblomen, very showy, but not always pure in the bottom. It is generally feathered strongly, and forms a good feature in a bed. The cup is rather loose, and the white good; yet the flower is not much valued.—Lord Hawkesbury is a very fine looking byblomen, fit for the third row, pure white, long cup, fine purple, and the flower altogether showy, and in a bed desirable.

TULIP-TREE. See Liriodendron.

TUMBREL. A manure cart. The body of it is $4\frac{1}{4}$ feet long, $3\frac{3}{4}$ feet broad, and $2\frac{1}{4}$ feet deep; the wheels are $5\frac{1}{2}$ feet in diameter and six inches broad; and the shafts are fixed, and, in unloading, are lifted into the air. Two horses in line draw the machine,—the trace-horse by the ends of the shafts, and the thill-horse by short traces fixed at the other ends. The tumbrel has a heavy construction and a lumbering motion, and serves no better purpose with two horses than a well-constructed common cart does with one. It is used principally in Norfolk and some of the midland counties of England.

TUMBREL, or Tumbril. A machine used, principally in Lincolnshire, for supplying sheep with artificial food in winter. Its body is a circular cage or crib, about 10 feet in circumference; and is closely wattled to the height of about one foot, and is left unwattled or merely staved immediately above the wattling to the height of about 18 inches, and is then wattled again to the height of about 8 or 10 inches, and is finally left quite open at the top to the breadth of about 18 inches for putting in roots or hay or other sheep-food. The staves are 10 inches asunder, and allow twelve sheep to feed simultaneously at each tumbrel; and the wattling is done with willow, osier, or any kind of pliant brushwood.

TUMOUR. A topical and irregular enlargement in the root, stem, branch, bud, or leaf of a plant. It arises in some instances from obstruction in the ascent of the sap, but in most from puncturing by insects in the deposition of their eggs. Some of the most common instances of it are clubs on the roots of brassicas, knots and bunches on the stem and branches of oaks and elms, and excrescences and galls on the buds and leaves of various common trees and shrubs.

TUMOUR. Any chronic swelling or hard abscess on any part of an animal's body. Some tumours are caused by bruises and other accidents; and some by interior disturbance of the system, by a corrupted state of the fluids, by general debility of constitution, or by various kinds of atmospheric influence and agency; and many which originate in widely different ways, have a widely different character, and require a widely different treatment. Tumours which are much inflamed, but do not tend to suppuration, should be treated with cooling applications, such as a solution of sugar of lead or a lotion of Goulard's extract in water; inflamed tumours which tend to suppuration should be accelerated toward a crisis by means of fomentations and poultices; hard indolent tumours, which are neither inflamed nor painful, but either simply inconvenient, or precursory of some worse development, should be roused to activity by rubbings of stimulating liniment, stimulating

ointment, or even blistering ointment; and very hard or quite inert tumours of the nature of wens can be properly removed only by excision. See the article Abscess.

A topical and somewhat specific disease in the throat of cattle has no more distinct name in veterinary nomenclature than tumour. This disease varies in appearance, virulence, and general character in different districts and different seasons; and, in the form in which it commonly occurs in the southern parts of Scotland, is popularly called Clyers in the throat. It arises sometimes from atmospheric influences, and sometimes from coldness and bleakness of situation, but much more frequently from breeding in-and-in, or from other causes and practices which debilitate the constitution. It is occasionally so prevalent on particular farms or within limited districts as to look like an endemic; but it more frequently occurs so scatteredly among flocks as to appear to have an independent development in each of its subjects. It possesses considerable analogy to strangles in horses, but is somewhat more difficult of treatment, and more fatal in tendency. It seems to be generally connected with a weak or depressed state of the entire system; and, on this account, instead of proceeding to suppuration and forming a freely-discharging abscess, as strangles do in horses, it often assumes an indolent state, and makes but a trifling discharge from different points, and afterwards either forms sinuses, or undergoes a partial absorption of matter and passes into the condition of a hard tumour. It at all times affects the breathing of its subjects, but does not prevent their feeding till the act of deglutition is rendered painful by the great enlargement on the throat. Young heifers are more liable to it than any other kind of cattle, and are unfitted by it for breeding. Any animal affected with it should be confined in a comfortable shed or house; the strength of the system should be increased by means of a nutritious diet combined with tonic medicines, such as the sulphate of iron, in doses of 2 drachms to a middle-sized two or three year old, once a-day, in a little gruel, or 5 grains of iodine in gruel night and morning. The tumour should be laid open if matter is to be felt; but if not, a blister should be well rubbed into the surface of the swelling, and repeated until there is either absorption of the tumour, or the formation of an abscess. Should this plan not answer in raising an energetic action in the tumour, iodine in the form of ointment, in the proportion of 2 drachms of it to 4 ounces of lard, should be well rubbed into the tumour every day until absorption takes place. If the tumour resist these remedies, it should be freely cut into with a lancet, and a little tow put into the wound twice a-day, smeared with blistering ointment, or dipped in a strong solution of sulphate of copper. In the early stages of the disease in those animals which seem to have a comparatively robust constitution, it may be worth while to try what can be done to stop the progress of inflammatory action by bleeding and purging; and in places where the disease assumes an endemic character, and works much havoc, it may become worth the consideration of the proprietor or farmer, where no other plan of prevention can be attempted, to try the slow but sure remedy of belts of planting, so disposed as to protect both the cattle and the crops, and thereby improve the land for every kind of agriculture.

TUNA. See Opuntia.

TUNA-TREE. See Bastard-Cedar.

TUNGSTEN. An elementary metallic substance. It does not naturally occur in an uncombined state; but may be artificially obtained by the action of charcoal or of dry hydrogen at a red heat on tungstic acid. It has a greyish-white colour, a considerable lustre, a considerable brittleness, nearly as great a hardness as steel, a less fusibility than manganese, and a specific gravity of about 17·4. Tungstic acid consists of one atom of tungsten and three atoms of oxygen; and may be readily obtained by prolonged digestion of very finely levigated native tungstate of lime in nitric acid, or by raising the dark brown oxide of tungsten to a red heat in open vessels, or by the action of hydrochloric acid on walfram, the native tungstate of iron and manganese. It is a yellow powder, insoluble in water, and has no action on litmus paper, but combines with alkaline bases to form salts; and when strongly heated in open vessels, it becomes green,—and when acted on by hydrogen at a temperature of between 500° and 600° Fahrenheit, it becomes blue, and is supposed to be changed into a tungstate of the oxide of tungsten.—The dark brown oxide of tungsten consists of one atom of tungsten and two atoms of oxygen; and may be obtained either by an operose process with walfram or by the action of hydrogen at a low red heat on tungstic acid; and when obtained in the former way, is almost black,—in the latter way, brown and capable of taking on a copper colour by polishing. It does not combine with acids; and when heated to redness, burns and passes into tungstic acid.—Tungsten combines in three proportions with chlorine.

TUP. A ram.

TUPA. A genus of ornamental exotic plants of the lobelia family. The charming species, *T. blanda*, is a perennial-rooted, annual-stemmed, pink-flowered herb of about 3 feet in height, from Chili; and the other species are very diversified,—and, in several of the most remarkable instances, formerly ranked as true lobelias. See the article Lobelia.

TUPELO. See Nyssa.

TURBARY. A piece of bog out of which peat-fuel is cut. See the articles Bog and Peat.

TURF. The sward of grass-lands; also the peaty portion of bogs. In the former sense, it is discussed in the articles Grass Lands, Pas-

TURE, and PARING AND BURNING; and in the latter sense, in the articles BOG, PEAT, FUEL, and HEATHS.

TURF-ASHES. See ASHES.

TURF-BOG. See BOG.

TURF-SPADE. See BREAST-PLOUGH and PEAT.

TURGESIA. A genus of ornamental, South-African, herbaceous plants, of the crassulaceous order. Three perennial and four biennial species, varying in height from 6 to 15 inches,—one of the biennials red-flowered, and all the others white-flowered,—have been introduced to Britain; and all love a soil of sandy loam, and require the protection of the greenhouse.

TURKEY,—scientifically *Meleagris*. A genus of birds of the gallinaceous order. A plumeless and papillated skin invests the head and the upper part of the neck; an appendage dangles under the throat, and hangs along the neck; another appendage of a conical form surmounts the forehead, and, in the male, when he is excited to anger, becomes so inflated and elongated as to hang over the point of the beak; a tuft or tassel of stiff hairs hangs from the lower part of the adult male's neck; the coverts of the tail can be erected and displayed in the same manner as in the peacock, but are shorter and stiffer; and the tarsi of the male are armed with weak spurs.

The common turkey, *Meleagris gallo-pavo*, was for a long time the only species known. It is a native of the West Indies and of Continental America, and was introduced to Europe in the 16th century; and in consequence of its ready domestication, its great size, and the excellence of its flesh, it soon became very common, and has long occupied the rank of a higher order of domestic poultry. The wild variety of it in most parts of America has a greenish-brown colour, with a copper gloss; and the black subvariety of our domesticated kinds, is the best for both size and delicacy.

The ocellated turkey, *Meleagris ocellata*, was first found at the bay of Honduras, and seems to have very distinct specific characters. Its general plumage is remarkably brilliant, and almost equals that of the peacock; and its tail-coverts, which are similar in shape to those of the common turkey, are adorned with sapphire-coloured spots, surrounded with circles of gold and ruby.

Turkeys are very clean birds; they love sweet food and abundance of free air; and they prefer to roost in trees, and hop gradually up from the low branches, and find shelter among the boughs from frost and winds. An evergreen tree, such as a yew or a spruce-fir, is a very suitable piece of furnishing in the yard or compartment of the farmery allotted to them; and where this is a-wanting, special artificial provision should exist for large grasp in perching, for profuse ventilation, for perfect constant cleanliness, and for dryness and warmth in winter and coolness in summer. The hen seeks secluded nesting ground, and often strays far from home, and commonly requires to be watched and manœuvred. The number of her eggs in a season is only from twelve to twenty; and each, when newly laid, should be taken away from the nest, and substituted by a piece of chalk closely resembling it in size and form and appearance. When she shows a desire to sit, she should be cooped upon her eggs in the turkey-house; and while she is sitting, she ought never to be disturbed. No turkey should be allowed to sit twice in one season. The newly-hatched birds should be kept for some time in the nest, and maintained in a warm and dry condition, and never handled or in any way artificially treated; and, when they develop the red colour of the head, they may be regarded as safe from the diseases of their infantile state. Young turkeys should be fed three or four times a-day with a pultaceous mixture of fine barley meal and dock leaves, or of barley meal and chopped onions, nettles, and potherbs, but especially, if they can be had, with ants' eggs. Nothing, however, contributes more to advance their growth, and insure their health, than the seeds and insects they pick up in long grass. Yet as the hen is very inconsiderate, and, with the intention of procuring them abundance of these, will roam far away beyond the strength of her progeny, and, so that she is accompanied by some of the hatch, is regardless of the weaker ones, it is good policy to pen her upon a lawn, under a crate, such as earthenware is packed in, so that the chicks can roam about, and return to her call when any danger approaches; and here the food of the young birds, which she would gobble up, can be placed out of her reach. More advanced turkeys thrive best when allowed to roam through meadows, and cater for themselves by the sides of hedges; but they must be fed in the mornings and evenings, or when they return toward home, which they will soon learn to do periodically when they require food. They must, however, be watched on their excursions, by a boy or girl, who should on no account drive them, but merely follow their motions, bringing them home in good time in the afternoon. As turkey-cocks are very pugnacious animals, and, moreover, often destroy the young ducks, we would not recommend one being kept. They often terrify children, and will sometimes attack visiters approaching a house; and at the same time, they are neither ornamental nor useful, but are destructive to gardens or pleasure-grounds, and consume the food that would keep half a dozen fowls. To compensate for the want of cocks at home, the hens may be sent, at certain seasons, to some one of approved breed in the neighbourhood.

TURKEY-OAK. See OAK.

TURK'S CAP. See MARTAGON.

TURMERIC,—botanically *Curcuma*. A genus of ornamental, tropical, perennial-rooted, annual-stemmed, herbaceous plants of the ginger tribe.

Upwards of twenty species have been introduced to the hothouses of Britain, principally from the Indian Continent and the Indian Archipelago. All are handsome in floriculture, and several are cultivated in the East for their uses in medicine and the arts. One, the broad-leaved, is commonly about 12 feet high; and another, the reclinate, is seldom more than about 6 inches high; and nearly all the rest have a height of between 1 foot and 5 feet. Most have either yellow, red, or red and yellow flowers; and the rest have either pink, crimson, brown, or white and violet flowers. A few, such as the zedoary, the zerumbet, the rubescent, and the rusty, love a soil of rich mould; but the others thrive best in sandy loam; and all, except the reclinate, are most readily propagated by division of the root.

The long-rooted turmeric, or zedoary-root turmeric, *Curcuma longa*, grows wild in the open sandy grounds of Malabar and Ceylon, and was introduced to Britain in 1759. Its root is tuberous, oblong, whitish, about as thick as a man's finger, and studded with the vestiges of defunct fleshy fibres; its leaves are subsessile on their sheath, palmated, broad, lanceolate, green above, and leathery below; its flower-stem rises from among the leaves, and is naked, and has commonly a height of about two feet; and its flowers grow in a loose, lateral, cylindrical, truncated spike, and bloom in April and May. The roots are imported into Britain, in casks and cases, from Bengal, China, and Ceylon. The best are firm, short, wrinkled, heavy, free from worm-eating, externally of an ash-colour, and internally of a deep orange-yellow. They break with a short close fracture, and are easily pulverized. Their odour is fragrant, and somewhat similar to that of camphor; and their taste is bitterish, aromatic, biting, and rather acrimonious. They contain, not only aromatic and bitter principles, but a very large proportion of starch and lignin; they yield by distillation with water a heavy, greenish, camphorated, essential oil; they surrender their active principles partly to water, and more completely to oil, ether, or alcohol; and, according to an analysis by John, they consist of 57 per cent. of lignin in combination with a substance which is soluble in potash but insoluble in alcohol, 11 of yellow resin, 12 of yellow extractive, 14 of gum, 1 of volatile oil, and 6 of water. Turmeric root possesses tonic and carminative properties; and is much used in the East for flatulent colic, nausea, difficult menstruation, and other diseases; and has a place in the Dublin pharmacopœia, and in the Materia Medica of various systems of medical botany, but is scarcely ever prescribed by British physicians. It was formerly in high esteem among farriers as a remedy for jaundice or yellows in horses; but it now possesses the reputation of only a common-rate or even inferior aromatic stimulant. It serves as an excellent chemical test of the presence of alkalies,—indicating their action by changing its colour to red brown; and, with the help of an alum mordaunt, it imparts a beautiful but perishable yellow dye to cotton, linen, and woollen fabrics. The Hindoos use it for dyeing both yellow and green; and combine it with lime juice to form the preparation with which they make the perpendicular mark on their foreheads.

The narrow-leaved turmeric, *Curcuma angustifolia*, was introduced to Britain from India in 1822. It has a height of about 3 feet; and carries yellow flowers in July. An alimentary substance, of a starchy nature, is prepared from its roots in Travancore, exactly similar to arrow-root, and so pure and good as to be scarcely distinguishable from the true arrow-root made from *Maranta arundinacea*. The population of the Malabar coast hold it in high estimation.

The zerumbet turmeric, *Curcuma zerumbet*, grows wild in many parts of Hindostan, and is extensively cultivated there for various purposes, and was introduced to Britain in 1807. It has a height of about 3 feet; and carries yellow flowers from April till August. Its roots are largely exposed to sale in the lower provinces of India; and are supposed to constitute a large proportion of the turmeric imported into Britain; and they commonly occur in small round pieces, about one-third of an inch thick, and from $1\frac{1}{2}$ to 2 inches in circumference.

The amada-ginger turmeric, *Curcuma amada*, was introduced to Britain from Bengal in 1819. It has commonly a height of about 2 feet; and carries red and yellow flowers from April till June. It is one of the kinds most frequently cultivated in the East; and has long had there a fully higher reputation than the long-rooted turmeric for medicinal purposes.

TURN. See Hydatid.

TURNERA. A diversified genus of exotic calyciflorous plants, constituting, with the genus piriqueta, the small natural order Turneriaceæ. This order is distinguished from Loaseæ, principally by the stamens being as numerous as the petals, and in their being inserted, not in the throat of the tube, but at the bottom of the calyx. The plants comprise both herbs and small shrubs; and have alternate exstipulate leaves and axillary yellow flowers; and are chiefly natives of tropical America.—About a dozen species of true turneras have been introduced to Britain; and about as many more are known. Two of the introduced species are hardy or half-hardy annuals, three are tender annuals, one is a hothouse evergreen perennial herb, and the rest are hothouse small evergreen shrubs.—One of the last, *Turnera ulmifolia*, was the earliest introduced; and may serve as a sufficient specimen of the whole. Its stem sends out branches on all sides throughout its whole length, and attains a height of from 3 to 10 feet; its branches are slender, and comparatively stiff, and well covered with foliage; its leaves are petiolate,

ovate-lanceolate, serrated, about 2½ inches long and 1½ inch broad, rough and lucid green above, and strongly veined and of a paler green below; its flowers sit close on the axils of the leaves, and have each five large, oval, bright-yellow petals, with twisted and joined claws, and bloom from June till September; and its fruit are short, tubular, one-celled, three-valved capsules, which open at the top and there discharge their seeds. A permanent and distinct variety, *T. u. angustifolia*, was introduced about the same time as the normal plant, and differs from it both in the form of the leaves, and in the size and tint of the flowers.

TURNHOOF. See ALEHOOF.

TURNIP. Any esculent-rooted variety of the genus brassica. See the articles BRASSICA, CABBAGE, COLE, RAPE, and KOHL-RABI. Swedish turnips and turnip-cabbages are varieties and subvarieties of *Brassica campestris napo-brassica;* common turnips are varieties and subvarieties of *Brassica rapa;* and hybrid turnips are the offspring of crosses between common turnips and other brassicas. The subvarieties of *Brassica campestris napo-brassica* are botanically classified into the normal, the common, and the ruta-baga, and were all brought into Britain from Sweden; and the varieties of *Brassica rapa* are botanically classified into the normal, the depressed, the oblong, and the oil-bearing, and all occur in a wild state in the corn-fields of England; but all the kinds of turnip in actual cultivation, whether Swedish, common, or hybrid, admit of several widely different classifications according to their shape and colour and other intrinsic properties, and according to their suitableness for the uses of the garden and the farm, and are more or less the result of powerfully modifying influences exerted by skill and culture upon the natural varieties.

All turnips are biennials, or have two seasons of growth,—one in which they develop leaves directly from the root-crown, and form their large bulbous stem, popularly called their root, and another in which they send up a long flower-stem, with leaves entirely different from those of the first season, and go through the process of flowering and seeding,—and all have blossoms and silicles exactly like those of cabbages and other brassicas; but many, at the same time, exhibit a tendency, in exciting or accelerating circumstances, to complete their cycle of development, or to rush to bloom in the first season, in the manner of annuals.—The root, or rather cauline bulb, of Swedish turnips is harder than that of common turnips,—and resists better the severities of winter,—possesses a higher proportion of nutritional principle and economical value,—and retains its juices and its nutritive properties till a more advanced period in spring; the stem is about one fourth or so shorter; and the leaves have a much darker colour, and less acridity, and more adaptation for food, and are so smooth as to present considerable resemblance to those of several of the expanded kinds of cabbage.—The root or cauline bulb of hybrid turnips, is internally yellow, and is yellow also on the portion of the surface beneath the ground,—and occasions all the class to be popularly called yellow turnips,—but is variously green, purple, dark purple, and other tints on the portion of the exterior above the ground, so as to occasion some varieties to be popularly designated by such names as green-top and purple-top,—and it possesses a hardness, a resistiveness, and a nutritiousness intermediate between that of swedes and that of common turnips, yet very different in different varieties; the leaves are quite or nearly the same as those of common turnips; and the habit and character are those of *Brassica campestris* and *Brassica napus*.—The root or cauline bulb of common turnips is internally white, and is white also in the portion of the surface beneath the ground,—and occasions all the class to be popularly called white turnips,—but is variously white, green, or red in the portion of the surface above the ground,—and is esteemed more palatable to the domesticated animals in the white-topped varieties than in the green or the red-topped ones,—and has, in some varieties, a spherical shape, popularly called globe-turnip,—in others, a depressed or flattened shape, often called Norfolk-turnip,—and in others, an elongated or subfusiform shape, popularly called tankard-turnip; the root-leaves, or leaves of the first season, are large, rough, jagged, and lightish green; the cauline-leaves, or those of the second season, are smooth and pointed; and the stem of ultimate growth, bearing the inflorescence and the seed, is from 2 to 6 feet high. Swedish turnips naturally bloom in June; and common turnips, in April. In the ordinary economy of the farm, Swedish turnips are sown earliest, yellow turnips next, and white turnips last.

Varieties of Swedish Turnip.—With the exception of the root or cauline bulb, which is large, fleshy, and subrotund, instead of small, hard, and fusiform, the specific characters of Swedish turnip and of turnip-rooted cabbage are the same as those of summer rape, *Brassica campestris oleifera;* and these exist chiefly in the leaves,—all of which are somewhat fleshy and have a dark green colour and a glaucous bloom,—the young ones on the root-crown lyrate and roughish,—and the cauline ones of the second season clasping or subcordate, oblong, and subpinnatifid. The root of ruta-baga or true Swedish turnip has a specific gravity of from 20 to 25 per cent. more than that of common turnip, and contains a much larger quantity, weight for weight, of saccharine matter; it bears the vicissitudes of the weather with such powerful hardiness, that a rotten individual of it is scarcely ever seen; and even when bitten by sheep or cattle, or broken by their feet, it so skins over and heals as to continue quite sound.

Though a crop of Swedish turnips looks much lighter on the ground than a crop of common turnips, it owes that appearance, in a considerable degree, to the circumstance of its root being less above the surface; and it largely compensates any real inferiority in bulk by decided superiority in at once weight, nutritiousness, hardiness, durability, and adaptation. Nor does it merely last much longer in spring without running up to flower; but also, when it arrives at that stage of growth, it preserves its nutritious properties far more largely from transmutation or injury; and even after ripening its seed, it retains in its pulp a very considerable portion of sweet and nutritive principles. The roots, too, are far better fitted for storing than those of common turnips; and, when drawn, and freed from tops and tails, and either put in water or secured under a light covering of straw, they continue for a comparatively long time unaltered. Swedish turnips also possess the advantage of being easily transplanted; so that beds of young ones can be advantageously used for filling blanks in the rows of either turnips, potatoes, or any similar crops. They require, however, a greater depth and power of soil than are requisite for common turnips; and succeed best upon loamy land of a nature suitable for wheat, and must be supplied even then with a generous dose of manure, in order to their yielding a full crop; for when grown either upon dry, hungry, gravelly soil with large supplies of manure, or upon good, deep, loamy soil with sparce supplies of manure, they are generally poor and feeble, and seldom produce roots of any considerable size.

The turnip cabbage or turnip-rooted cabbage is the normal *Brassica campestris napo-brassica*, and was erroneously supposed by some distinguished botanists of the last generation to be the source or original type of the cultivated Swedish turnips. It comprises several subvarieties; and, though similar in root to common or white or very bad Swedish turnips, it is very similar in leaf to some common kinds of borecole, and bears very distinct differential characters of both constitution and habit. Its roots grow almost wholly under the surface of the ground, and are naturally so very hardy as to resist all injury from even the severest winters; but they are by no means so valuable as those of even the worst kind of swedes. It is cultivated in the northern parts of Continental Europe, and is much lauded by some Continental writers; but it will probably be superseded in all places by some one or other of the hardiest or otherwise best kinds of ruta-baga, when the latter shall come to be duly known.

The white Swedish turnip is the common variety of *Brassica campestris napo-brassica*, and occupies an intermediate station between the turnip cabbage and the coloured or true Swedish turnip. Its roots are irregularly shaped, and have many branches or fangs; and they are interiorly white-fleshed, and exteriorly white below the surface of the ground, and greenish above. It is decidedly inferior to even the worst kinds of true Swedish turnip; and has undergone little or no improvement from hybridizing or special culture; and is at present an object of no interest to British cultivators; and, when it occasionally appears among true Swedish turnips, is considered as either a degenerated plant or the offspring of bad seed. It found its way into a considerable number of farms in the years immediately following the period when the true Swedish turnip first became known; and it, in consequence, greatly damaged the reputation of that plant, and retarded its rising into general confidence.

The coloured or true Swedish turnip is the ruta-baga variety of *Brassica campestris napo-brassica;* and may readily be distinguished from the other varieties by the comparative largeness and rotundity of its root, by the yellowish colour of the root's flesh, and by the yellowishness of the root's exterior in the part below the ground, and the higher colouredness, either dull red or purple or dull green or some similar tint, of the upper part. The subvarieties of it in cultivation are not nearly so numerous as those of the common turnip,—partly because it has been much less subjected to experiment, and partly on account of its inferior plasticity and sportiveness of constitution; yet a few improved ones have been obtained and established,—some by processes of hybridizing, and others by careful, repeated, judicious selection of plants for the raising of seed-stock.

Skirving's new improved purple-topped swede, was introduced by Mr. William Skirving, of Walton Nursery, near Liverpool; and was pronounced by him to possess all the good qualities of a turnip, as compared with all the known varieties which he was able to collect both in Britain and on the Continent, and to yield a greater weight per acre of sound nutritive bulb than any other variety, and to be also hardier and longer-keeping. Its leaves appear to partake considerably of the character of those of the common turnips, being less smooth and more serrated at the edges than those of the genuine Swedish turnip, and deficient in that glaucous bloom which distinguishes them; so that he may be supposed to have attained the size by hybridizing with some of the larger varieties of yellow turnips.

Ballantyne's new improved purple-topped swede, takes its name from its original introducer, Mr. Ballantyne, nursery and seedsman, Dalkeith. It is, for symmetry and shape, equality of size, and the uniform deep purple colour of its top, unsurpassed by any other variety; yet is more remarkable for the combination of these qualities and for the smallness of its neck, than for the largeness of its bulb.

Scott's prize purple-topped swede, was introduced by Mr. Scott of Southend, near Tranent, in East Lothian. It is ox-heart shaped, purple above ground, and yellow-fleshed, with a small top.

Laing's new purple-topped swede is a decidedly distinct variety. Its leaves are somewhat like those of a lettuce; and are so inserted in the top of the root as to give it much the appearance of a pine-apple. It grows to a good size, keeps well, and bears a very high character among the agriculturists of Berwickshire and Northumberland, where it is extensively cultivated. The crop when in full leaf has a most beautiful appearance.

The green-topped yellow swede has been longer known than the purple-topped, and, since the introduction of the latter, has had less attention bestowed upon it by cultivators, and has fallen somewhat in their estimation; but where the same care is taken in selecting the roots grown for seed, it may be considered as equal in merit to the purple-topped.—Scott's prize green-topped yellow swede, is an improved variety of it, and is in no way inferior to the purple-topped.

Hillyard's Thorpeland swede, has the appearance of a true Swedish turnip, and closely resembles some which were recently raised from seed procured from the Botanic Garden at Upsal. It is said to be more nutritive, bulk for bulk, than some of the largest varieties; but its dwarfish size, and the impossibility of raising any great weight of food per acre from it, must, notwithstanding its other merits, be a great obstacle to its making its way among the larger sorts which now invite the attention of cultivators.

Cox's new improved swede, may be considered as intermediate in colour between the purple and the green-topped sorts. Its roots often attain a large size, but are rather irregular, and of a somewhat coarse-like quality. "Such subvarieties," remarks Mr. Lawson, in reference to Cox's, "are frequently of short duration, being liable to degenerate when the careful selection of the roots to be grown for seed is not attended to; and they often only retain the name for such time as their seed-stalks are grown by the parties with whom they originated; and it occasionally happens, that stocks procured in different parts by the same means, and known under different names, may yet be the same in other respects."

Varieties of Hybrid Turnip.—Hybrid varieties of turnip are obtained either by selecting and cultivating seed-stocks of plants which appear to have undergone natural cross-impregnation, through the agency of insects or the wind, or by carefully conducting a process of artificial cross-impregnation in the manner practised in gardens for obtaining choice new varieties of the rare kinds of flowering plants, or by so combining the two methods as to intermix turnips of different breeds through a series of bloomings in order to expose them to natural cross-impregnation, and then to select from each of the series of crops only such plants for seed-stocks as exhibit improvement and are similar in character. One of the most celebrated and useful and at the same time variable of all the hybrids—the well-known and generally-esteemed Dale's hybrid, raised by Mr. Robert Dale, of Libberton, West Mains, near Edinburgh—was procured by a complexity of method which may suggest valuable hints for guiding the efforts of intelligent agriculturists in search of further improvements. The basis of it was a new hybrid, grown by a gentleman in Berwickshire, and supposed to have been obtained by an indefatigable veteran improver of turnips in Aberdeenshire. Mr. Dale sowed a few ounces of the seed of this hybrid, and found the produce to resemble Swedish turnips in shape, but to be destitute of most of their superior intrinsic properties. He therefore picked out such roots as had most of the yellow appearance, and planted them along with some of the best true swedes he could find; this he continued to do for four successive years; and he afterwards selected the best roots of the complicatedly impregnated produce for raising seeds till all the fine properties of the variety which now bears his name were obtained and became established. "The manner in which this variety was obtained," remarks the narrator of his proceedings, "was not according to the nice rules which horticulturists would have recommended to be adopted; because, as the hybrids were always planted along with the Swedish for producing seed, and the seed collected promiscuously, that part of the seed which was produced from the Swedish would be much more nearly allied to that variety than the seed of the hybrids. But in this as in many other instances of improving plants, the point is often attained more from accidental causes than from the adoption of the rules laid down by scientific cultivators. And, although all the hybrids may not stand in the same relation to the primitive root, the circumstance of the raising the seed being now performed solely by the hybrids themselves, without the assistance as formerly of the Swedish, will always have the tendency to assist in modifying and correcting any irregularity that may exist." Every hybrid obtained in any such way, in fact, is rather a collection of many closely related and intimately similar subvarieties than one really homogeneous or strictly individual variety; and yet, throughout every crop and in all ordinary circumstances, it possesses abundantly sufficient uniformity for all practical purposes both of culture and of application. The several hybrids in most estimation also differ more or less widely from one another in some or most of their best properties; while all, at the same time, when regarded in the aggregate, so combine the characters of Swedish turnips and of common turnips as to occupy a somewhat equable intermediate station be-

tween these two great groups. All the kinds we shall enumerate, except such as we shall designate exclusively garden turnips, are suitable for cultivation in the field.

The Altringham yellow turnip is smaller than most of the approved hybrids, and on that account is more particularly suited for garden culture; yet it is also in good repute in some quarters as a field turnip. It is recommended for its fine globular shape, and the superior solidity of its flesh. It has a light greenish top, very small neck, and tap root.

The Aberdeenshire sugar yellow turnip is very hardy; and buries itself considerably in the ground; and is highly nutritious, and one of the most approved of the lately introduced varieties.

The Border imperial purple-topped yellow turnip was introduced by Mr. R. Hogg, nursery and seedsman, of Dunse, in Berwickshire; and is described as follows by Mr. Hogg himself:—"This turnip possesses all the qualities of the Swedish, with the advantage of being a much freer grower. It succeeds well on every variety of turnip soil, produces a larger crop than the white globe, is a good feeder, and stands the winter better than any of the common yellows. It is in full perfection for using in February, and continues for as long a period as the swedes; and should the latter fail, the Border imperial being sown as late as the month of June, will yield a crop equal if not superior to what might have been expected from the swedes had they succeeded."

The green-topped bullock yellow turnip attains a medium size. Its shape is globular, or somewhat flattened with a very small tap-root. It is an old variety; and is held in deserved estimation.

The purple-topped bullock yellow turnip differs from the preceding chiefly in the colour of the top,—the size, shape, and quality of the roots being pretty nearly the same. It is also highly esteemed; and is considered by some to come nearest to the swedes in hardiness and solidity of texture.

Skirving's improved purple-topped bullock yellow turnip is an improved variety of the preceding; and obtained for its introducer, Mr. William Skirving, of Liverpool, the medal of the Highland Society of Scotland. It has been generally grown for a number of years by the first agriculturists in Lancashire and the north-western counties.

The green-topped and the purple-topped yellow Scotch turnips differ but little in any of their essential properties from the common green-topped and purple-topped bullock yellows. The roots are flatter and grow more in the ground.

The ox-heart yellow is an excellent turnip. Although it comes early to maturity, and attains a considerable size, it is by no means deficient in hardiness.

The yellow globe is a superior turnip, both for field and for garden culture. Its roots are of a medium size, globular, and always nearly under the surface of the ground; its top is greenish; and its leaves rather small and spreading.

The yellow stone turnip differs from the preceding in growing more out of the ground, and having a greener top. In other respects it is nearly similar; and as a garden turnip, it is held in high esteem.

The brown-topped tankard yellow turnip, has a bright yellow root, of a somewhat irregular, long, or tankard shape, with a purple or brownish top; and it is of great repute in Aberdeenshire. A sub-variety of it, with not so very long a shape, is preferred by some growers. Both are excellent turnips.

The green-topped tankard yellow turnip differs from the preceding chiefly in the colour of the top; and of this there is also a sub-variety of a flatter shape.

The large Lawrencekirk yellow tankard turnip, introduced by Mr. Robert Scott of Lawrencekirk, resembles Dale's hybrid in many particulars; and, like it, grows a good deal out of the ground; but is distinguished by its more oblong and more uniformly shaped roots. Like Dale's hybrid, it arrives early at maturity; but it is generally considered rather less hardy, although it yields an equally bulky crop.

Dale's hybrid turnip is distinguished chiefly by its foliage being strong and luxuriant, and its roots of a large size, oblong shape, and of a lightish yellow colour, with light green top, small neck, and tap-root. The form of the root, however, although generally oblong, is rather apt to vary, being sometimes almost globular; but its more material characteristics of large size and luxuriance of growth are always the same. Compared with any other of the yellow field-sorts, it is found to arrive sooner at maturity, and consequently may be sown at a later period of the season; while at the same time, it is equally hardy, or, at least, has been found sufficiently so to withstand the severest winters which have occurred since its introduction. It might seem, from the manner in which Mr. Dale obtained it, or at least from that in which he brought it to perfection, to be rather a variety of swede than a true hybrid; but it distinctly exhibits its intimate connexion with the common turnip, partly by its root having considerable affinity in both form and texture, and chiefly by its leaves being rough and of a vivid green colour and destitute of the swedish glaucousness.

The new purple-top hybrid turnip, raised by Grant Duff, Esq., of Eden, Banffshire, seems more nearly related to the swede than even Dale's hybrid, but has also the rough vivid green root-foliage which characterises the common turnip. Its root has a slightly oblong shape; and is light yellow or almost white on the lower part of the surface, and greenish purple on the top; and is

remarkably firm in texture, and keeps comparatively well and long in spring.

Gordon's yellow turnip is a very superior variety, and derives its name from Mr. Gordon, of Orrock, the father of turnip husbandry, in Aberdeenshire. It is of rather oblong shape, and of deep green colour on the top, generally very slightly tinged with red. It is very nearly allied to Dale's hybrid, being a cross between the Aberdeenshire bullock-yellow and the swede. Sir F. A. Mackenzie, Bart., a very accurate experimentalist, grew a considerable number of the most approved kinds of turnips on his farm, at Conan Mains, near Dingwall, with the view of selecting such as might be found best suited to the soil and climate of Ross-shire; and the result of his experiments was, that of swedes, Skirving's is decidedly the best,—of the hybrids, Gordon's yellow is the best,—and of the white kinds, Scott's purple-topped hybrid, and the old white globe are the best.

Hood's new large yellow turnip is a very superior, large, globular-shaped, hardy turnip, remarkably perfect in symmetry, with rather a lightish green top; and was introduced by Charles Hood, Esq., an eminent farmer, at Inverbrora, in Sutherlandshire.

The Pollexfen yellow turnip derives its name from its introducer, Thomas Pollexfen, Esq., of Cairston,—who had long practice and a peculiar method both in selecting and transplanting the bulbs, and in stocking and preserving the seed. The insular situation of Orkney, too, although in latitude 59° north, renders its climate less exposed to the extremes of heat and cold than in more continental situations farther south, the winters being mild, and the frost so gentle, that the ice is seldom sufficiently strong to sustain the weight of a man; and it is on that account particularly favourable to the growth of turnips, —so that turnip-seed grown in Orkney is highly prized by the Scotch farmers. The Pollexfen yellow is a green-topped turnip of a large size, rather flattish in shape, and very smooth and thin in the skin. Its flesh is firm and nutritious, being slightly impregnated with the green-topped swedish. It is adapted for winter and spring feeding, and is not liable to injury from frost. This turnip obtained the prize at the meeting of the Highland and Agricultural Society of Scotland, held at Inverness, in 1836; and was highly commended in the report.

The Cambridgeshire long tankard yellow turnip, or pudding swede, is cultivated somewhat extensively in Cambridgeshire and Suffolk, but is scarcely known in some large districts of the kingdom. Its root generally grows more than half under ground; and has a lightish yellow colour in the lower parts and a green colour on the top; and is much more elongated in form than that of most other kinds of even tankard turnip; and takes its name of pudding swede, rather from the hardness of its texture, than from any other near resemblance to any true swede.

The purple-topped tankard yellow turnip was formerly cultivated in some districts of England, but has for some time been passing toward total neglect. It is a coarse inferior variety, and does not yield near so large a crop as some of the best kinds, whether tankard or sub-rotund. Its root has a long and somewhat irregular form, and is bright yellow in the lower parts and purple on the top.

Jones' yellow turnip originated many years ago, in the neighbourhood of Stirling, and soon obtained extensive favour throughout the surrounding country. Its root has a considerable resemblance to that of the Altringham yellow, but attains a larger size, and has a yellower hue in both skin and flesh.

The yellow Malta turnip, or Maltese golden turnip, is suited exclusively to garden culture; and is one of the most esteemed of all the hybrids for summer and autumn crops; but is too susceptible of injury from frost to be proper for a late crop. Its leaves are very small; and its root or cauline bulb is also very small, and is slightly flattened above, and much hollowed on the under side, and has a very smooth skin and a bright orange-yellow colour; and its tap-root, as also its neck, is remarkably small.

The Preston or Liverpool yellow turnip is also suited exclusively to garden culture, and for summer and early autumn crops. It considerably resembles the yellow Malta turnip, but attains a larger size, and has stronger foliage, and is less hollowed on the under side of its root.

The Dutch yellow turnip is also suited exclusively to garden culture, and for summer and early autumn crops. It has a superior flavour, and is much esteemed. Its root is small and globular; and has all over a pale yellow colour; but often—especially when grown in full exposure to sun and weather—is very slightly tinged with green on the top.

The large long garden yellow turnip is a hardy and somewhat superior variety, exclusively suited to garden culture, and pretty extensively grown in some parts of Continental Europe, but not much known in Britain. Its root grows about three-fourths under ground, and has a deep yellow colour in all the lower parts and a greenish colour on the top.

The small long yellow turnip is an excellently flavoured variety, suited exclusively to garden culture; and is somewhat largely grown in Holland, France, and other parts of the Continent; and was formerly imported in a grown state for the supply of the London vegetable market; but is little known among the gardeners of Britain. It thrives best on sandy soils, and buries itself so entirely in them, as to enjoy comparatively good natural protection from frost. Its leaves are very small and spreading; and its root is small and fusiform, and terminates abruptly at the

point, and has a light yellow colour, and in general grows entirely under ground.

Varieties of Common Turnip.—White turnips, in a general view, are suitable for use only in the early and middle parts of the year, and are most profitable only when so raised as to be all consumed before any of the swedes or of the firmest and largest hybrids become fit for use; for when they grow beyond a certain size, they lose a considerable proportion of their nutritious principles,—or when allowed to remain on the ground after they attain full bulk, previous to the commencement of the autumn or winter frosts, they become soft, spongy, unpalatable, and comparatively worthless. The depressed and the tankard varieties, in particular, are totally unsuitable for winter feeding,—the former, on account of their retaining moisture in a concavity on their upper surface, so as to be easily rotted and destroyed after the season of heat and of high evaporation has passed away,—and the latter, not so much on account of the softness of their texture, as because they stand mostly above the ground, and are therefore very much exposed to the action of frost. The good or approved varieties of common turnip are exceedingly numerous, and present a great diversity of both external and internal character; and, in some instances, are so near akin to some of the yellow hybrids, as to be distinguishable mainly by the whiteness of the skin and flesh. All those we shall enumerate, except such as we shall state to be suitable only for the garden, are proper for field cultivation.

The white globe turnip comprises a common or normal variety and a considerable number of distinct and rather widely different subvarieties. The root of all its kinds has a globular form, a small neck, a small tap, a smooth skin, and perfectly white skin and flesh; but that of some kinds has been considerably altered from the normal state in consequence of the special care and attention of cultivators in selecting their seed-stocks; and that of any one kind is often not a little affected by the nature and condition of the soil in which it is grown. Thus globes of any kind, and particularly the common white globes, when grown on a very superior rich soil, may be said to be forced beyond their natural size, so as to acquire somewhat of a monstrous or overgrown appearance, and to lose in a great measure their natural symmetry of shape.

The Pomeranian globe turnip was introduced not many years ago from Pomerania, and may be considered the most perfect globe turnip in shape, as well as the most regular or uniform grower. Its skin is smooth and white, and has a somewhat shining or transparent-like appearance; and its leaves are smoothish, and of a dark green colour, with whitish nerves.

The green globe has a fine globular shape, with a small neck and small tap-root; and is very white beneath, and green above the surface of the ground; and is of medium size, hardy, and firm of texture; yet is scarcely so firm as the green round turnip, although it arrives rather earlier at maturity.

The stone globe is considered to be the hardiest of all the entire white globe turnips; and it grows naturally deeper in the soil than the others, and has stronger and darker green foliage.

The red globe turnip is medium-sized, globularly shaped, and firm in texture. This is an old and in some districts a pretty extensively cultivated variety. It is medium early, and generally allowed to be particularly well suited for light soils and exposed elevated situations.

The white round turnip is known in Lincoln by the name of spring white. It is the largest of the round turnips, and, at the same time, the softest and most irregular in shape. It is generally hollowed towards the neck, and, in consequence, is apt to be injured by retaining moisture, which renders it unfit for using, except in the beginning of the winter season. All the round or depressed turnips have a peculiar flattish shape, rather hollow towards their neck, as also on their under side; and when grown to a large size, they become more or less of an irregular round or somewhat cornered shape.

The green-topped round turnip possesses these characters in a less degree than the white round, and is generally of a pretty regular circular shape, flattened but not much hollowed on the upper and the under surfaces, the former of which is of a green colour, and the latter white. It is the hardiest of the round turnips.

The red round turnip is inferior in size to the two former, but rather firmer in texture, and more regular in shape. It should also be used in the early part of the season.

The white tankard turnip has its roots more than half out of the ground, and oblong or tankard-shaped, but often bent or crooked. It is the largest of the tankards, but is also softer in texture than either the red or the green. Its leaves are large and luxuriant. It is the earliest in maturing of any; but will not stand the frost.

The green tankard turnip also has its roots more than half above the ground; and they are of a greenish colour, except on the under surface, which is white.

The red tankard turnip, in size, form, and texture, may be considered as occupying an intermediate place between the white and the green tankards. It is of a bright red colour on the upper surface, and white on the under.

The Lawton hybrid turnip was raised by James Wright, Esq., of Lawton, near Perth; and may be considered as bearing the same relation to the Swede as Dale's hybrid. Its leaves are darkish green, rather small and smoothish; and its roots are roundish or somewhat heart-shaped, being often tapered on the under side, white below, and green above the surface of the ground; and they are hardy, and possessed of more solidity and firmness of texture than most white sorts.

Scott's improved purple-topped hybrid turnip obtained the prize of the Highland Society of Scotland, at the meeting at Glasgow in 1839, and owes its origin to the exertions of Mr. Scott, of Southend, near Tranent. For a white-fleshed turnip, it is remarkably solid, and attains a great size; and it is decidedly the best in point of size, symmetry of shape, uniformity of growth, and quality of flesh, of very many varieties of white turnips which have been simultaneously tested in model-plots by some distinguished experimentalists.

The Lewisham green-topped, ox-heart turnip is an excellent variety, grown in some of the southern districts of England and in Scotland; and it acquired its name from having been introduced by Messrs. Willmot and Co., of Lewisham.

The autumn stubble or six weeks turnip has its roots much above ground, rather large, of an irregular, globular shape, or in form between the white globe and white round, and rather soft. This sort arrives sooner at maturity than any of the others, the tankard turnips perhaps excepted; and from its natural softness of texture, should always be sown late, and used before the severe frosts set in. Its names are descriptive of its forwardness; and it is suited for sowing, in early situations, in autumn, after the corn crop has been removed; and is also valuable for making up blanks in turnip fields, where the first sowing may have partly failed.

The white Dutch turnip is suitable chiefly for the garden, and answers there as an excellent early variety; and it has been recommended also for a field crop when late sowing is necessary, but is not by any means so well adapted for that purpose as the tankard varieties, or the autumn-stubble variety. Its root is of excellent quality when young; but becomes soft, spongy, ill-flavoured, irregularly circular, and much flattened when full-grown.

The red Dutch or early garden turnip is also suitable chiefly for the garden. It is an excellent variety, but is little known in Britain. Its foliage is smaller and of a darker colour than that of the white Dutch turnip; and its root has a very similar shape to the root of that variety, but has a bright red colour in the part of the surface which is above ground.

The white garden turnip, or early stone turnip, is suited exclusively to garden culture; and is one of the best known and most generally cultivated of the garden turnips. It has stronger foliage and a rounder and firmer root than the white Dutch turnip, but is not so well adapted for early spring sowing, and more apt to run to seed; and it acquired its epithet of early, not from any special adaptation which it has for early sowing, but from the circumstance of its arriving soon at maturity when sown at a later period of the season. An improved and carefully selected subvariety of it is cultivated in some parts of England, under the name of the mouse-tail turnip.

The small long white turnip is cultivated on the Continent under the same circumstances as the small long yellow turnip; and it resembles that variety both in the character of the foliage, and in the form and habit of the root, and differs from it principally in the colour of the root.

The Maltese long white turnip, or the small very long turnip, has a general resemblance to the preceding; but the upper part of its root generally grows above the ground, and has a greenish colour,—and the lower part is longer, and tapers more gradually toward the point.

The round black turnip claims connexion with the common or white turnips principally for the whiteness of its flesh, and for its total want of affinity to either the swedes or the hybrids; and, in common with the three other kinds which we shall name in this paragraph, it has a hottish and somewhat radish-like taste, and is suited exclusively to garden culture, and possesses much repute in some parts of the Continent for its sapid and antiscorbutic properties; but is not much known in Britain. Its leaves are few, small, and rather smooth; and its roots grow almost wholly under ground, and have a black-coloured and very rough skin, and are of an irregular roundish form, and often divide or fork or ramify into thick fangs at their lower extremity. —The round brown turnip differs little from the preceding except in the dull brown colour of its roots.—The long black turnip differs from the round black principally in the long carrot-like shape of its roots.—The long brown turnip bears the same relation to the round brown turnip which the long black does to the round black.

The Teltau turnip, or small Berlin turnip, is the smallest of all the known varieties of turnip and of course is suited exclusively to garden culture. Its root is oblong or carrot-shaped, about three inches long, seldom more than an inch in diameter at the thickest part, of a dull transparent whitish colour, or very light lead-colour, and has a peculiar and slightly hot taste.

The History of Turnip Cultivation.—The uses of both the roots and the tops of turnips were as well known to the ancient Romans as to any modern European farmers; and the winter-feeding of cattle with the roots, though a not very old improvement in British husbandry, and justly regarded as one of the most important in modern times, was practised among the ancient Gauls. "The Roman authors," says Pliny, "have treated of *rapa* in only a cursory way; the Greeks more particularly, but as a plant to be cultivated in gardens. If a just order were observed, it should be mentioned immediately after corn, at least after the bean; for no other plant is more excellent or useful, or so well adapted for food to all sorts of animals. The seed, particularly if boiled in water, is proper food for all kinds of village fowls; the leaves serve to fatten quadru-

peds; and in their season, the tender shoots are as agreeable to man as those of any other plant. The turnip also, when dried and preserved, is better than when green; for it becomes hard, and, when kept in earth, it remains good almost to the season of the next crop, and therefore is a constant food. The people on the other side of the Po reckon this plant the third in goodness, or inferior only to grapes and corn. It is dressed in a variety of ways for use at our tables, and when mixed with mustard, is preserved for culinary purposes throughout the year. Besides its natural colour, it may be stained purple and five other colours; and it admits of being more conveniently and variously dressed in this way than any other culinary plant." "Both *rapa* and *napus*," says Columella, "may properly be classed with pulse; for both are used as food by country people. The *rapa*, however, is the more useful of the two; for it yields a greater amount of produce and serves for food, not only to men, but also to oxen, especially in Gaul, where it is used for feeding cattle in winter."

At what time the field cultivation of turnips was begun in Britain is not known; but it seems to have been, if not introduced, at least either reintroduced or powerfully stimulated, from Flanders, and to have taken special root in Norfolk, about two centuries ago; and it possibly was retained in Flanders, throughout all the middle ages, as an heirloom from the ancient Gauls. Worlidge, in his Mystery of Husbandry, printed in 1669-81, says, "In Holland, they slice their turnips with the tops, and rape-seed cakes and grains, &c., and therewith make mashes for the cows, and give it them warm, which the cows eat like hogs." And he complains of the very great neglect of all similar uses of turnips in the farm-economy of England, and remarks, "Although turnips be usually nourished in gardens, and be properly a garden-plant, yet are they, to the very great advantage of the husbandman, sown in his fields in several places in England, not only for culinary uses, as about London and other great cities, but also for the food of cattle." The field cultivation of turnips in Norfolk is commonly said to have been introduced by Lord Townshend, but seems really to have existed before his period; and though long confined to only a very few individuals, it afterwards spread into considerably extensive favour, and was at length greatly improved by incorporation with the row method of sowing according to the system of Tull. The earliest kinds of turnips grown were the oldest and worst varieties of the round or depressed; and these, in common with all the newer sorts of the same group, continue to the present day to be often popularly called Norfolk turnips,—though the kinds now cultivated in Norfolk are equal in diversity and value to at least the average of the kinds grown in the best of the other agricultural districts of the kingdom. "The usual mode of sowing turnips both in Flanders and in Norfolk," said the Rev. Mr. Rham, about ten years ago, "was broadcast; and as the labourers in both countries became very expert in hoeing them out at regular distances, this mode was long preferred. In fact, the cultivation of turnips in rows is scarcely practised at all in Flanders; and, notwithstanding its evident superiority in respect to quantity of produce and economy of labour, it cannot be said to be yet universally adopted in Norfolk,—so slowly does every agricultural improvement spread among the great mass of farmers."

The cultivation of turnips in drills, though introduced by Tull, was early and long known, and in some districts is even yet known, under the name of the Northumberland system. Tull gave his favourite horse-hoeing operations to turnips, not as in modern practice chiefly before sowing, but mostly or wholly after sowing; and he appears to have used principally intervals of three feet. About the year 1745, Mr. Craik of Arbigland, in Dumfries-shire, became the earliest cultivator of drilled turnips on the Scottish borders; about ten years later, Philip Howard, Esq., of Corby, became the earliest cultivator of them in Cumberland, and grew them for some time at intervals of four feet, and afterwards at intervals of two feet; and nearly at the same time, Mr. Pringle, near Coldstream, in Berwickshire, cultivated turnips in drills, at $3\frac{1}{2}$ feet distance, and likewise drilled his grain crops,—following in both cases the general principles of Tull. "At this time," says the General Report of Scotland, "William Dawson, Esq., of Graden, an intelligent and successful farmer in Roxburghshire, after some residence in the county of Norfolk, where he had attentively studied the system of alternate husbandry, adopted the practice of Mr. Pringle, in regard to the cultivation of turnips, in preference to the mode which he had seen practised in that celebrated county. Mr. Dawson began the drilled turnip husbandry in 1764, on an extensive scale, growing nearly 100 acres yearly. He ultimately fixed upon 30 inches as the best interval for the purpose, after repeated trials both of broader and narrower; and his practice has been universally followed in all the border counties."

The turnip husbandry greatly aided the transition from the barbarous agricultural usages of the middle ages to the enlightened ones of the present day; and is now well known to every good farmer to be the sheet anchor or *sine qua non* of the modern alternate and convertible husbandry. See the article ROTATION OF CROPS. "The introduction of turnips into the husbandry of Britain," remarks Brown in his Treatise on Rural Affairs, "occasioned one of those revolutions in the rural art which are constantly occurring among husbandmen. Before the introduction of this root, it was impossible to cultivate light soils successfully, or to devise suitable rotations for cropping them with advantage. It was likewise a difficult task to support live-stock

through the winter and spring months; and the practice of feeding cattle and sheep for market, during these inclement seasons, was hardly ever thought of or attempted, unless in a few instances, where a full stock of hay was provided. The benefits, therefore, which are derived from turnip husbandry are manifold and of great magnitude. Light soils are now cultivated with facility and profit, by which abundance of food is provided for man and beast; the earth is turned to the uses for which it is physically calculated; and, by being suitably cleaned and fertilized by this preparatory crop, a bed is provided for grass-seeds, in which they prosper with greater vigour than after any other mode of preparation."

The Swedish turnip, too, came into use at a fine juncture for completing the great advantages which the field cultivation of the common turnip had begun to confer. It was introduced from Germany to England about the middle of last century, and from England to Scotland in 1766; so that it did not come in till a period of the new husbandry when its value could be appreciated, and did not lag so long behind as to let the defective power of the common turnip for spring-feeding and late winter-feeding become hopelessly discouraging. It soon proved itself of extraordinary service to intelligent and enterprising farmers who had adopted the alternate husbandry, by enabling them with tolerable certainty to fill the wide and critical gap in the supply of food for stock in late winter and early spring, or to keep their stock in full numbers and in pretty good condition during the trying season between the exhaustion of the common turnip and the commencement of summer feeding,—so that they were no longer under the severe alternative of being obliged either to force off their feeding stock to market at the exhaustion of the turnip, bring what price they might, or to carry them on at a vast expense by means of oil-cake, hay, bean-meal, and other costly articles of food; and the Swedish turnip, at the same time, offered a ready source, which eventually came to be well understood and appreciated, of forming those valuable hybrids between it and the common turnip which now occupy so large and advantageous a place in the economy of a great proportion of extensive farms.

But while the turnip-husbandry rapidly effected a revolution, and has long been achieving wonders, in some parts of Britain, it has been dismally neglected, or even continues to be regarded with indifference or dislike in others. Persons who live in districts where the crop is considered so essential that the operations of a farm could not be conducted to profit without it, will scarcely believe that in many parts of the kingdom, even at this date, turnips are grown only by amateurs, or those who are supposed to be making experiments; whilst the expense is considered to be too great for tenants to encounter who pay high rents for their land. The fact is, that many farmers, looking only to present consequences, begrudge the manure required for this crop, and rather apply it to stimulate a crop of corn which they can turn into money at the nearest market,—forgetting that the green crop is not only the procurer of future ones, but that the root is available for fattening sheep and cattle, or, if applied to the store stock, of keeping them not only in good condition, but in increased numbers. In Ireland, too, throughout the greater part of which the turnip husbandry continues still to be unappreciated, absurd and inveterate prejudices are entertained against it in favour of the wretched system of a continual growing of mere corn and potatoes. "Even in the vicinity of bogs and mountains, where the means of raising ashes, in which turnips delight as a pabulum, are on the spot," remarks Martin Doyle, "they are never grown by a mere practical husbandman, though their culture does not necessarily interfere with the raising of the more essentially necessary potato crop. Whence is this? Potatoes, wherever manure can be raised, are in the first case considered more profitable, from the demand for human food in countries where the consumption of grain is so inconsiderable; secondly, from the mistaken notion that potatoes are more remunerative as food for cattle; thirdly, from the conviction that, however extensively sown, they would be stolen as a dainty for the human palate. The first and second objections require no discussion, and the third is of no weight. The petty depredations of women and of urchins cease when the novelty of the crop wears off. The same objection once operated against the culture of turnips, and of beans too, in Great Britain. In parts of Ireland, at this moment, where beans are systematically and abundantly cultivated, the same complaint was made by the farmer on their first introduction, and similar difficulty would be at first experienced in those places where beans, as a field crop, are now utterly unknown, and the purely mental association of boiled garden beans and bacon might lead to the mistake that raw tick beans must also supply excellent and delicate fare. Let turnips once become common in culture, and they will not be improperly meddled with, even in the most dishonest localities. What has not turnip culture effected for England? What has not the same system wrought in Scotland?"

The Preparation of the Land for Turnips.—All comparatively dry soils, from the poorest sand and gravel up to the richest free loams, are more or less suitable for common turnips; while either light soils on a retentive bottom or clayey soils upon any sort of bottom whatever are apt to make them fail, especially in dry seasons; and soils of a comparatively heavy character, or those near akin to the best wheat and bean soils, are the most suitable for Swedish turnips. Yet almost all kinds of soils which are capable of

thorough tillage have, with more or less success, been cropped with even the inferior varieties of white turnip; and all may, with due management, particularly under systems of efficient subsoil-draining, and skilful tillage and manuring and after-culture, be more or less profitably cropped with some of the varieties of hybrids.

Turnips were long cultivated on land which had already borne a crop which was reaped early in summer, and on bare fallow which had been worked and cleared at a sufficiently early period in the season to allow the turnip crop to be sown and grown and removed before the time for sowing winter corn; but all turnips raised in this way, and technically called addish or stubble turnips, yield a comparatively small bulk of produce, and serve very inferior purposes in the course of a rotation, and offer none of the important advantages which are enjoyed in the method of feeding off with sheep, and perform a somewhat inefficient part in connexion with both the general working of the soil and the comprehensive economizing of manure. Turnips, as now cultivated, generally succeed a crop of wheat. In some cases, indeed, on very poor soils, the clover leys are broken up for turnips; and in others, a crop of winter tares, either mown or depastured, is taken off between the wheat crop and the ploughing for turnips;—but as a regular system, the former cannot be pursued, for the frequent recurrence of the turnip and the clover crops would operate injuriously, and defeat the object of the cultivator,—and the latter is applicable only to soils which are quite free from root-weeds, and of a superior staple, or in a very high state of cultivation.

As soon as the corn crop is secured, and the stock has passed over the stubble, the land should be ploughed, in order to subject the soil to the ameliorating influence of the frosts of winter. In all cases the plough should pass below the couch-grass, which is usually most abundant in inferior soils,—but seldom below the mould. In ordinary cases, nothing is more necessary than to prevent the water from standing in any part during the winter; and where the land is intended for swedes, an effort should be made to have it partly or entirely cleared of weeds before the winter. When the land is free from weeds, the cross-ploughing may be begun as soon as the dryness will admit of it; and, in general, it may take place in February with advantage, inasmuch as it exposes a new and more extensive surface to the action of the frosts which generally succeed. If the land be allowed to remain a month or two longer, it may be advantageously crossed with Finlayson's harrow. Where the couch-grass, however, is abundant, it is positively injurious to cross-plough early, as the operation breaks the roots and renders the cleaning of the land afterwards tedious and difficult; and, in every such case, the operation should be delayed until the soil is dry; or even if it should be delayed till the latter end of April, or the beginning of May, more will be effected by one ploughing in this case than by two under different circumstances. When the dryness admits of it, usually in two or three days, the land should be harrowed across, first with the patent or hinge harrows, and subsequently with the loose harrows, which separate the rubbish more effectually from the soil; and then the weeds should be raked off,—an operation which is generally performed by women. As soon as the couch-roots, &c., are cleared off, either by carting into large heaps or burning into small ones, the land may be dragged with Finlayson's grubber or any approved drag, and the same course followed so long as any roots remain. When the roots and hard weeds cannot be raked off, they should be hand-gathered; and no dependence whatever should be placed on the destruction of any by the sun's rays until the 25th of June,—a time when on most soils the sowing should be concluded. It is desirable that the land should lie a week or ten days before the last ploughing is given to it, in order to admit of the germination of such seeds of weeds as may be lying dormant in the soil, and also to afford favourable scope for the accumulation of moisture in a dry season. In the Scotch practice, especially, all land intended for turnips is ploughed as soon as convenient after harvest; and, if even the slightest tendencies exist to retain wetness, it is carefully water-furrowed, in order to lay it completely dry; and, as early in spring as the other duties of the farm will permit, it is subjected to the utmost force and diligence of the whole strength of the teams and the work-people, to reduce it to the finest tilth by repeated ploughings, harrowings, and rollings, and to clean it thoroughly of weeds by the most careful and persevering grubbings, gatherings, and cartings. See the articles Fallow and Ploughing.

The Manuring of Land for Turnips.—A just or skilful enquiry into the most efficient system of manuring land for turnips ought to take account of the comparative market values of the several manures proposed to be employed,—of their influence upon the prompt and rapid early growth of the rising crop, such as shall enable or assist it to escape havoc or destruction from insect depredation,—of their effect upon the development and maturation of the roots, in reference to the bulk and weight of the ultimate produce,—of their control over the chemical constitution of the roots, both with regard to their general feeding and fattening power upon live stock, and with regard to the particular principles which they may most abundantly return to the land through the medium of the farm-yard,—of their capacity of co-operating with the process of feeding-off, for producing the greatest and most harmonious enrichment of the soil,—and of their prospective adaptation to the uses of the succeeding crops of the rotation, their

power to yield due nourishment to each of these crops, and their capacity of resisting too rapid decomposition, or of remaining with sufficient permanency in the soil to give out their principles only as they are wanted, on to the end of the rotation. It is therefore an enquiry of vast comprehensiveness and almost bewildering complexity; and might, both pertinently and profitably, be made to comprise the whole themes of both manure and rotation, or almost the entire science of agricultural chemistry, together with all its most important practical applications. We clearly could not discuss it here without very largely repeating what we have said in other articles; and we must refer intelligent readers, for both the general principles and some of the chief details by which they may work out the enquiry for themselves, to our articles MANURE, FARM-YARD MANURE, BONE-MANURE, GUANO, NITRATES, and AGRICULTURAL CHEMISTRY; and we shall here do no more than first borrow from an able writer in the Yorkshire Agricultural Society's Transactions, a statement of the most approved prevailing empirical practice of experienced farmers in some of the best agricultural districts of the country, and next mention one or two facts, by way of hint and specimen, respecting the action of special manures, both as used alone, and as used in combination with farm-yard manure and special composts.

"In treating of manures with which the turnips should be dressed," says Mr. Milburn, the Yorkshire writer, "farm-yard manure stands the foremost, because it is what every farmer possesses, and, with the exception of the calcareous soils in the East Riding of Yorkshire, is almost invariably employed in the cultivation of turnips. In general, it never will and never can be superseded; and though every deference is due to the practical knowledge of the East Riding farmers, there can be no doubt that if their straw were more carefully made into manure and applied to the turnip crop in conjunction with bones, it would be decidedly advantageous. It is necessary to say that house-made manure, and by fattening cattle, especially such as are consuming artificial food, is the best, and that of horses, cows, pigs, &c., should be mixed as intimately as possible, the hot character of horse's dung neutralizing the coldness of that of the cow, and *vice versâ*. It is desirable to cart this mixture to the fields intended for turnips in January and February, during the frost, or at such other times as convenience may dictate, but the earlier the better. About three weeks before used, it should be turned over the sides of the mixen, being carefully turned into the middle. Without entering, in particular, into the much disputed question of the fermentation of dung being useful or otherwise, thus much every farmer will know well the truth of, that on light soils, and for turnips, well-rotted dung is indispensable where it is used at all. When fermentation is progressing so fast as to induce destructive heat or mouldiness, it may be checked by treading the mixen, and covering it with soil; and when it is sluggish, it may be excited by turning and watering. For sandy or gravelly soils, farm-yard manure is an almost necessary ingredient in producing a crop of turnips. The rapid decomposition of vegetable matter which takes place on such soils requires that there should be a supply for that succulent crop; and, as before stated, there can be no doubt of its utility to calcareous soils; but for peaty descriptions, where there is abundance of vegetable matter, it is less useful. The time for laying on the manure depends on the method of sowing adopted, and clearness of the land from weeds. If the plough-drill be used, it is desirable to immediately precede the plough; if the Norfolk, or large drill, it is better to lay it on a week or two before sowing, to allow it to mix intimately with the soil, especially if other manure is intended to be used, and the soil pretty free from weeds. The quantity to be applied will vary with circumstances; twelve to fourteen tons per acre may be stated as an average, and more, if the soil be poor, and no other manure intended; while less may be used, in proportion as other manures are applied.—Lime stands next in importance as a dressing. The object of all manure is to supply some deficiency, remedy some mechanical inconvenience, or correct some detrimental agent in the soil. When dung, for instance, has been applied for several successive crops, a quantity of undecomposed vegetable matter accumulates, which the natural soluble properties of the soil cannot dissolve, and it remains inert. A dose of lime will correct this, and will bring every particle of such inert matter with which it comes in contact available as food to the plants. It also assists in the intimate pulverization of the soil, as well as corrects any acidity which may exist in it from causes which the agriculturist can seldom foresee or correct, except by its use. It is also destructive to weeds in the soil, and hence exceedingly valuable, for every farmer knows that weeds, being indigenous, are much more ready to grow in the soil than his crops, which are artificial, and often exotic. For peaty soils, an occasional dressing of quicklime is invaluable, especially if there is an addition of clay, road-scrapings, &c., to give the requisite firmness to the soil. It should be laid on as soon as convenient after bringing from the kiln, and in as hot a state as possible. The time for laying on lime is a few weeks before the sowing, in order that the subsequent ploughings may mix it thoroughly with the soil, and thus its effects be more immediate after the sowing. The quantity per acre entirely depends upon the character of the lime in the locality. Two or four chaldrons per acre are used; but as it is applied for turnips generally, in conjunction with other fertilizers, the former may be stated as the better quantity. If dung is also applied,

they should be used at as great a distance of time between each other as circumstances will admit of, and the latter not long before the sowing.—Bones form one of the most valuable manures for turnips on all light soils, on account of their portable and stimulating character; they are least useful on a gravelly or loamy soil. They have converted barren moor lands into rich, fertile, and productive farms, luxuriating in every valuable product of the earth. Their value is beyond all praise. The East Riding of Yorkshire affords a specimen of what they have effected, and they require only to be known to be extensively applied. In many cases, they are used alone; in others, in conjunction with farm-yard manure, with ashes, and with lime. Ashes are sometimes drilled with them as a substitute, by diminishing the quantity of the bones. Lime is a valuable auxiliary on old-going land, or soil which has been long under cultivation. On peaty soils, having a substratum of sand, they have produced wonderful crops, by supplying them with the necessary animal matter. The quantity varies from twelve to thirty bushels per acre. Sixteen bushels per acre will produce a fair crop on average soils, and some farmers say that more than that quantity is waste. It is desirable to mix them with a quantity of ashes when they are drilled in the above quantity. This facilitates the early progress of the plants, and supports them until the bones become available. English bones are generally preferred to foreign; but, from experiments made by the writer, he prefers foreign to English, and also to recent bones; for, although the latter have more of their juices than the former, the former sooner decompose, and the fat and animal juices require considerable chemical changes before they are available as food for the plants. A mixture might be judicious; but he has not tried it, nor is he aware of trial having been made.—Other manures of a miscellaneous character are used for turnips. Pigeons' dung is most valuable; rape-dust has been used successfully; and animalised carbon has also been advantageously employed."

Some of the most important special manures which have been experimented with are guano, the nitrate of potash, the nitrate of soda, poudrette, and Poittevin's manure; but the comparative values of these, and of bones, rape dust, animalised carbon, and other peculiar substances, both in their immediate action on turnips, and in their power over whole rotations, are glanced at in the section on special manures in the article MANURE; and the results of many experiments are stated both there and in some of the articles on the several substances themselves. The joint use of several special manures in combination with one another or with farm-yard manure, especially if conducted with intelligent regard to the precise chemical condition of the soil, and to the precise aggregate wants of the several crops of a rotation, is far more fitted to achieve a high order of results than the wisest possible single use of any one special manure; and even when employed with reference to the mere turnip crop itself, and without any very intelligent application of the doctrines of agricultural chemistry, it has been found to act with very high efficiency. The following tabular view of the particulars of a comparative trial of various compounds, by Mr. Thomas Page, at Merriden in Surrey, is both curious and instructive, and may suggest more useful hints than could be conveyed by an elaborate disquisition. The soil on which the trial took place was a light blowing sand, very shallow, containing many rubbly surface stones, and immediately incumbent on sandstone rock, and lying at a considerable elevation and much exposed; and was broken up from grass as deeply as the plough could go, and cross-ploughed in April, and grubbed and cleaned with Biddel's scarifier and Grant's lever horse-rake; and drill-sown, at distances of 18 inches, with the manures and the red round variety of turnip seed, in the latter part of July; and all parts of it were equal in quality, and were equally treated. "On all the portions where dissolved bones were used, the plants came forwarder to the hoe than where they were not used; but beyond this there was not much perceptible difference in the appearance of the different parts, until from a month to 6 weeks had elapsed, when No. 7 began to grow less rapidly than the rest. At the end of between 7 and 8 weeks No. 1 began to fall off; and in a few days No. 2 followed. Further than this difference, the eye could hardly detect where the separation of each kind of dressing took place."

* By measure 820 bushels per acre, weighing 40 lbs. per bushel.

The widely different effects of different kinds of fertilizers upon the chemical constitution and the feeding powers of the turnip may be sufficiently illustrated from the case of guanoed and non-guanoed Swedish turnips. Two roots of Swedish turnip raised with respectively farm-yard manure and guano, and both furnished by the same grower, analysed by the same chemist, and almost exactly alike in the quantity of their contained water in a recent or undried state, have been found very materially different in the proportions of both their organic and their inorganic constituents. The farm-yard manured turnip, after being deprived of all its contained water, yielded 2·09 per cent. of oil, 2·27 of gum, 44·82 of sugar, 10·35 of pectic acid and albumen, 25·04 of meta-pectic acid, 10·18 of cellular or woody fibre, and 5·68 of saline matter and ash; and the guanoed turnip, after being deprived of all its contained water, yielded 1·26 per cent. of oil, 1·57 of gum, 13·59 of sugar, 5·88 of pectic acid and albumen, 56·09 of meta-pectic acid, 15 of cellular or woody fibre, and 5·8 of saline matter and ash. Both turnips contained nearly the same quantity, or about 69 per cent. of soluble matter in their ash,—but they differed widely in the proportions of the ash's most valuable constituents; for the ash of the farm-yard manured turnip comprised 9·72 per cent. of chloride of potassium, 45·49 of potash and soda, 1·23 of magnesia, 10·17 of lime, 17·86 of sulphuric acid, and 7·73 of phosphoric acid,—while that of the

guanoed turnip comprised 6·45 per cent. of chloride of potassium, 36·29 of potash and soda, 0·39 of magnesia, 11·56 of lime, 16·86 of sulphuric acid, and 19·39 of phosphoric acid. Two inferences may be selected from these facts as specimens of the instructive character of the whole,—and both are exceedingly obvious, and lie on the very surface of the analyses,—that the proportion of oil renders the farm-yard manured turnip about 50 per cent. more favourable for fattening, inasmuch as 100 lbs. of that turnip would supply fat enough for laying on 1½ lb. of live weight, while the same quantity of guanoed turnip would supply enough for laying on only 1 lb.,—and that the proportion of phosphoric acid renders the guanoed turnip incomparably more favourable for forming and building up both bone and muscle, the quantity of that substance being not far from three times greater than in the farm-yard manured turnip, and the quantity of it in the flesh of animals being about ⅓ lb. in every 100 lbs., and in the fresh bones of animals about one-fourth of their whole weight. So far then as these inferences go—as also on the ground of some experiments in feeding which our limits do not allow us to detail—the grand principle seems to be evolved, in regard to the most profitable chemical constitution of turnips, or in regard to their highest aggregate feeding powers, just as formerly in regard to their amount of produce, that the best results are to be attained by the joint use of widely different manures.

The Sowing of Turnips.—In the north of England and the south of Scotland, the usual time of sowing Swedish turnips is from about the middle till the end of May,—hybrid turnips, from about the beginning till the middle of June,—and of common turnips, from about the middle of June till a few days into July. But the best time of sowing, in any circumstances, is dependent considerably on the state of the weather and on the comparative forwardness of the season,—still more on the climate of the place and on the character of the soil,—and yet more on the variety of the turnip and on the intended time and method of using the crop. Any turnips sown too soon are apt to shoot forth their flowering-stem before winter, so as greatly to diminish the nutritiveness of the roots; any turnips sown too late incur a risk of not attaining full size and due maturity; and most common turnips sown at any period which does not allow of their being matured and used in the course of autumn are liable to become soft, spongy, and comparatively worthless.

The quantity of seed for any kind of turnip, in any method of sowing, may be somewhere between 2 and 3 lbs. per imperial acre; but ought to be greatest in kinds which do not admit of mending by transplantation,—in cases of broadcast sowing,—and in situations and seasons which threaten the worst attacks of the turnip-fly.

The Scotch or raised-drill or ridge method of sowing, especially on poor or thin soils, and whenever farm-yard manure constitutes the main or lower pabulum, is decidedly the best. The ridges are made either with a single cast of the double-mould-board plough, or a double one of the common or ribbing plough, and from twenty to twenty-eight inches apart. A cart with manure follows; and women are generally employed to drop the manure into the seams made by the plough. The plough again follows, and closes the ridges, covering the manure; and the drill succeeds, drawn by one horse, and sows one ridge at a time. A light roller goes over the sown ridges to cover the seeds, and sometimes the ridges are rolled before the sowing. This plan takes more time and labour to effect it; but the turnips generally succeed; and if they should be destroyed by the turnip-fly, they can be re-sown with more probability of success than by any other method.

The plough-drill method of sowing is proper only on deep good soils, and in cases where only very bulky manure is employed, or where the intentions of the farmer require the manure to be applied with reference less to the immediate crop than to the whole succeeding rotation. In this method, the manure is spread on the ground; and the plough follows, with the drill so fixed to its right hand side as to deposit the seed immediately in the seam made by the plough.

The large-drill method of sowing on the level surface is the method most expeditious in execution, most suited to the deposition of special manures, and most generally in use throughout the best agricultural districts of England. The peculiarities and advantages of it vary with the different kinds of machines employed for depositing the seeds and the manure, and may be pretty well understood from the account we have given of these implements in the article Sowing-Machines. A single light harrowing is commonly given after sowing with any kind of large drill; and when much heavy rain succeeds, another turn of the harrows may advantageously be given before the land becomes dry, in order to prevent it from scraping.

The old broadcast method of sowing was to spread on the manure, plough it in, and then very carefully sow the seed with the hand. This practice is almost everywhere abandoned; nor can it in any case be recommended or justified. "All the effect of broadcast sowing," remarks Martin Doyle, "can be attained by a drill machine, constructed for sowing at twelve-inch intervals, which is more economical, and operates more regularly, than the most experienced hand. As we by no means maintain the necessity of having ridgelets on sandy land, requiring consolidation of surface, uniform retention of moisture, and adaptation for sheep-folding—the narrow unraised drills, which are a close approximation to broad-cast culture, may, in such

circumstances of soil, and with a view to feeding off the crop on the field, be the best, on the supposition, however, that the manure is of such a nature as can be scattered by hand over the entire surface, or deposited with the drill implement."

The After-Culture of Turnips.—The proper management of a turnip crop, from the time of sowing till the time of maturity, consists in thinning or "singling" the plants to the proper distances, and in a series of operations for destroying weeds and stirring the soil; and, though somewhat modified by differences in the variety of the turnip, in the character of the soil, and in the method of sowing, it is always the same in principle, and may be sufficiently exemplified in all cases by the usual details of it in the case of ridge-sown hybrids.

When the plants acquire the rough leaf, or are about two inches high, or begin to be incommoded by weeds, or about three weeks after sowing, the process of hoeing commences. The first hoeing is done either by a small one-horse plough going and returning along the hollow of each ridge, and cutting off a slice of earth from the sides as near as possible to the turnips, or, more conveniently, by a horse-hoe with lateral coulters passing once along each interval. A few days after this operation, the hand-hoers go to work, each having a little iron hoe, fixed upon a wooden handle about 3 feet in length; and, standing in the hollow with their faces to the ridges, they so hoe the turnip-plants as to leave them standing singly at the distance from each other of from 8 to 12 inches. By this operation, the rows of the turnips are cleaned of all weeds,—the superfluous plants cut up, and pushed into the intervals, where they die,—and the plants to be preserved left standing singly at the distance required. Soon after, weeds will again sprout up in the intervals of the ridges and amongst the plants; so that in the course of 12 days or more, the horse-hoe again passes through the intervals of the ridges, cutting up all the weeds that may have sprung up; and soon after the hand-hoers again go to work with the same instrument as before, cutting up all weeds which may have grown amongst the turnips, and carefully singling any plants that may by chance have been omitted in the first hoeing. Sometimes the horse-hoe, after a short period, passes once more down the intervals; but more generally, the second hand-hoeing concludes the process upon all the drier lands, the weeds being thenceforth kept down by the rapid growth of the plant, and by the overshadowing of the intervals with its leaves. In many instances, however, at an interval of 8 or 10 days after the last hand or horse hoeing, the earth which had been taken from the roots of the plants by these several hoeings, is again laid back, either by the small one-horse plough or by the double mould-board plough passing down the intervals of the rows, and ridging up the earth. The design in this operation is, that any weeds which remain in the intervals, after the former hoeings, may be destroyed, and that the land and turnips may be kept more dry during wet weather and the months of winter. The plants now grow rapidly without farther care; and, by the beginning of September, the leaves of a good crop will have covered the entire surface.

The most important variations in the modifications of after-culture adapted to other cases of turnip-crop than ridge-sown hybrids, concern the distance left between the plants in the operation of singling. And in the case of swedes on good land, this distance ought not to be less than from 12 to 15 inches,—while, in the case of most common turnips, upon almost any kind of land, it ought not to be more than from 6 to 10 inches; for swedes of large size contain greater nourishment, weight for weight, than swedes of small size,—while most kinds of common turnips of large size contain, weight for weight, less nourishment than the same kinds of small size. "As regards the quality of the land, too, it appears that Nature, in destining these two varieties of turnip to be better adapted for two distinct varieties of soils, has also ordained that each soil will be respectively benefitted by that crop which it is calculated to grow to the greatest perfection than by that of an opposite character. Thus it is that Swedish turnips, grown on a heavy soil, at considerable distances asunder, will admit of applying a superior tilth, together with a free action of atmospheric and solar influence on all the vacant spaces, thereby effecting all the good that could be expected from a naked fallow without being alloyed by any of its evils; whereas an open or porous soil, being that best adapted for rough-leaved turnips, will, by such a crop being suffered to grow thick, possess those advantages which it stands so much in need of, namely, a shade from a scorching sun, tending thereby to assist the secretions of the crop, and add to the vegetable staple of the soil."

The Consumption of Turnips.—A common method of consuming turnips is to have them eaten off by sheep. In this case, the turnips are either pulled up by hand, and carried away, as wanted, into the fields in which the sheep are kept, and there spread regularly on the ground; or, more frequently and economically, they are consumed on the field where they have grown, by folding the sheep upon it, and allowing them to eat the plants on the spot. See the articles Fold, Hurdle, and Sheep. One method of feeding off on the spot, is to allow as much of the turnips as the sheep can reach to be eaten just as they stand, and afterwards to pick up the "shells" or bottoms of the roots with a pronged hoe; and another is to allow them to eat only the tops as they stand, and then to take up the roots and slice them into pieces, by means of some one or other of the implements noticed in our article

Turnip-Slicer, and either to leave the pieces scattered on the ground in the immediate vicinity of the place of growth, or to deal them out in feeding-troughs. The design of slicing is to protect the teeth of hoggets and old sheep; and the design of using troughs is to protect the mouths of all sheep, but especially fattening ones, from the dirtiness of the land. The grand use of eating off turnips on the spot, whether whole or sliced, with troughs or without them, is to enrich the land with the refuse of the crop and the droppings of the sheep, and to work and consolidate it into prime condition for the succeeding grain crop by the treading of the sheep's feet and the recumbency of their bodies. A common practice, in all the varieties of this usage, is to place within the fold a small portable rack containing some hay, which acts as a condiment and corrective of the great succulency of the turnips.

Other methods of consuming turnips are to have them carried to the farm-yard, and there given to cows, to store-cattle, and in some instances to horses; and in all such cases, they must be twisted out of the ground by the hand, and deprived of their leaves and tap-roots on the spot by the stroke of a knife or a sickle; and such as are not immediately or very soon to be used, must be stored in some one of the ways to be noticed in next section. The suitable time for taking up most of the varieties is about the beginning of November, or previous to the commencement of the winter frosts; and the condition of soil and weather most advantageous for the operation is after some little time of drought. The act of pulling each plant should be a sharp twisting motion, such as shall freely bring up the whole plant and disengage the soil from its roots; and the acts of lopping off the leaves and the tap-roots, technically called topping and tailing, should be done with as much exactness as possible, so as neither to leave much green or loose matter nor to wound the skin of the root; for when a portion of the leaves is left, it tends to make the turnip vegetate on receiving a slight degree of heat,—and when a wound is inflicted on the skin, it tends to make the turnip rot. All turnips used raw in the farm-yard, require to be sliced before being given to the cattle.

A method of consuming the hardiest varieties of turnips, intermediate between feeding them off with sheep and storing them before winter for farm-yard use, is to leave them alone where they stand, and either to pull up occasional supplies of them in fresh weather, for the use of sheep in pastures or of cattle in the farm-yard in periods of snow or severe frost, or to take them up piecemeal in all sorts of weather as they are wanted. But when taken up during frost, they are often so hard and so firmly fixed to the ground, that they can be raised only with some such implement as the hoe, and not without great labour; nor can they be easily or suitably eaten, unless they be thawed by being placed for a few hours in a pool or running stream, or for ten or twelve hours in some warm house in which cattle are kept.—A modification of this method, of such a nature as partially to combine with it some of the advantages of storing, is described as follows in the Useful Knowledge Society's Treatise on British Husbandry:—"The turnips are drawn by means of a two-pronged hoe or bent fork called 'a grubber,' in the months of November and December, and the bulbs are placed, with the top entire and only a small portion of the root cut off, in the centre furrow, upright, making one furrow contain the plants which grow upon two or three ridges, and taking care that the bottom of each plant shall touch the ground. The soil is then ploughed up to them, covering the outer edges; and if the weather be very severe, a little straw or any species of litter is thrown over them. Those that remain unconsumed in February are then removed to the quarter where they will be required for consumption, and placed as close as possible to each other upon grass land, having then the remainder of the root cut off. This plan has the advantage of preserving the turnips in the best order, alike free from exhaustion by growth and from decay by too much exposure, as well as preventing the attacks of wood-pigeons and crows, which commence their depredations at the season when their usual food begins to fail. The soil is also less deteriorated by this mode, than it would be by allowing the plant to remain in the land."

The Storing of Turnips.—The chief reasons for storing turnips are the necessity, on most systems of winter-feeding, and in all districts where wintry weather is severe and of long continuance, and where snow falls in large quantities and lies long on the ground, of having available supplies in constant readiness for the use of stock,—the expediency of clearing land, for the sowing of any particular crop, previous to the time at which it may be convenient to consume the turnips,—the advantage to both the land and the crop, in all cases where the soil or subsoil is of a stiffish nature, or has any tendency to become retentive, of removing the turnips before the season when moisture becomes prevalent and evaporation becomes low,—and the preservation of the bulbs of the less hardy varieties from the destructive actions and accidents to which they would be liable if allowed to remain in the field.

The common method of storing turnips is to build them in a piled heap, of the form of a potato pit, in a dry and airy situation, conveniently near the place where they are to be consumed; and to cover the heap with straw, and make it secure with ropes,—and to have all the turnips as clear as possible of earth, and not to use any in covering the heap, as it tends to induce heat and either vegetation or fermentation. But

this method is adapted for only the Swedish and the hard hybrid varieties,—as all the white kinds and some of the softish yellow ones possess too much water to be preserved for any length of time; and another method is often practised with the latter, by what is called placing. The tap-roots being taken off, the bulbs with the leaves are placed close together in the position in which they grew, upon some dry place, near to where they are to be consumed; and in this way they will keep longer than if they had been left in the field, as they are not so apt to run to seed. But even the placing system has its objections; for if a tract of dry weather set in, the turnips, from being merely on the surface, become soft and shrivelled, and not so palatable to the cattle, and will even continue so for a considerable time, although the weather should be rainy, until the fibres begin to take hold of the soil; and another objection is, that if the turnips are not placed near the steading, the destruction from game, hares, wood-pigeons, &c., is very great, particularly if the turnip be Swedish. In order to remedy these objections, a third method has been adopted, which has been found to answer every purpose intended. The turnips are brought from the field, without either topping or tailing, to a piece of dry ground near the straw-yard; then a man, with one horse in a plough, makes a straight furrow; the turnips are placed in the furrow, quite close together, till the whole is filled from end to end; then the man with the plough moves round to where he commenced, drawing another furrow quite as close to the turnips as to enable him to cover them; and so on alternately —the men making the furrow and covering the turnips, while the women and girls lay in the turnips. By this method the turnips keep as fresh, preserving all their natural juices, and are as well relished by the cattle, as though they were taken direct from the field. The Report of the Harleston Farmers' Club for 1839, affirms that the best method of preserving roots during the winter is by clamping them, both as regards protection from frost and maintaining their quality, and that the following is a very effectual method of making the clamps:—Select a convenient and dry situation, and pack the roots carefully, with their crowns outside, in a row about six feet wide at the bottom and terminating in a narrow ridge at the top; then dig a trench commencing immediately at the edge of the roots, two feet wide and one deep, turning the mould from the heap; thatch the latter carefully with straw, commencing in the trench, so that all the rain may drain off the heap into it. The clamp may be left two or three weeks in this state, that the evaporation from the roots may escape. The mould already taken out of the trench is then to be laid on the straw, commencing at the bottom of the thatch and covering the heap twelve inches thick throughout, finishing with a sharp edge. Half the trench originally made will, of course, by this plan, be filled up with straw and mould; the other half will remain as a channel for the water falling off the heap; and as sufficient mould will not have been raised from the original excavation, it will be advisable, in procuring more, to make the channel made round the heap a few inches deeper, as well as wider. If the roots are stored late in the season, and the probability of frost setting in renders it necessary to cover the heap with mould as soon as it is made, it would be better to leave the top uncovered for a week or ten days longer, that the heat may escape. There is no objection to the roots being wet and dirty when they are clamped; the tops should be cut off, but not too close to the crown; the roots and fibres should be left on.

The Diseases and Accidents of Turnip Crops.—The extensive and constant cultivation of the turnip has fostered the rapid increase of its natural enemies; and after all the expense, labour, and precautions of even the most skilful cultivator, he sometimes sees his crop seriously injured or entirely destroyed. He can apply at best only palliative remedies; yet he has much in his power; and, when science and discovery shall become more thoroughly blended with agricultural practice, he may hope to acquire means of preventing or obviating every form of disaster. The chief of the many diseases and accidents of the turnip are fully discussed in the articles Turnip-Fly, Anbury, Wire-Worm, Aphis, and Slug; and, for the sake of connected view, they may here be briefly noticed in the group.

The turnip flea-beetle, *Haltica nemorum*, is one of the worst enemies, and attacks the turnip plant in its seed-leaf state, and often destroys a crop, and even the second and third sowings. Various steps have been taken in order to prevent its attacks, and several steeps for the seed used, but without success. Top-dressings of a saline and astringent character have been applied, but have failed. Machines even have been invented; but none have succeeded. The only directions which can be given are, to sow plenty of seed, to use stimulating manure in order to excite the plants to vigorous growth in their first stages, to secure a sufficiency of moisture in the soil at the time of sowing, and especially to keep seedlings in turnip-fields clear of charlock, which nurses the flea.—The black caterpillar larva of the *Athalia spinarum* also preys upon the leaves in a more advanced stage, appearing on the plants when they are about three weeks old.—Another disease to which the turnip is liable is vulgarly called fingers and toes. About a month after the plants have made their appearance, they begin to flag their leaves, and in a few sunny days literally die by acres together. On examination, the fibres of the roots are found enlarged, and the roots covered with tumours

and excrescences of every conceivable shape. A naked fallow is a remedy for it; but all applications to the soil and plant have been ineffectual. —The wire-worm is a sad enemy.—The swarms of aphides, or plant lice, severely injure the turnips, and from the smallness of their size are often unobserved. In 1836 they committed terrible ravages. They suck the juices of the plant, and appear in countless numbers. They are both oviparous and viviparous, and increase with amazing rapidity. Happily they are always followed by swarms of lady-cows, which feed on them, as well as insectivorous birds which destroy vast numbers. No remedy can be applied with any probability of success. Every farmer should carefully protect swallows, red-breasts, &c., which are great destroyers of the aphides.—Slugs, especially on newly-ploughed soils, are great devourers of the turnip plant in all its stages. Ducks will devour them, but always injure the plants. Three bushels of quick-lime per acre, scattered over the plants early in the morning, when the slugs are active, is a certain method of destroying them.—Perhaps the very best preservative from all the diseases is liberal manuring, adapted to the soil, thorough cleaning of the land from weeds, and in short pursuing whatever measures are best for securing a full crop. The vigour of the plants in such cases, and their rapid vegetation, often enable them to overcome many serious attacks.

The Produce of Turnip Crops.—An ordinary or average field turnip, of the kinds most commonly cultivated in Britain, weighs about 6 or 7 pounds; and one of a large variety, grown under the most favourable circumstances, weighs from 20 to nearly 30 pounds. A calculation has been made that one ounce of turnip seed contains from 15,000 to 16,000 seeds,—that therefore each seed weighs only about a 15,000th or 16,000th part of an ounce,—and that, when developing itself into a plant whose cauline bulb has an average weight of about 6 or 7 lbs., it must, on the supposition of an uniform increase of substance during the period of growth, acquire 15 times its own weight in a minute; and by an actual experiment, made on peat soil, it was found that turnips, during the period of their growth, made an average daily increase of 15,990 times the weight of the seeds from which they sprang. "It is not, however, only the size and weight of the root," remarks a popular writer, "which renders the turnip crop so productive. The number contained in a given space, with reference to their size, is very great. Some writers speak rather marvellously on this subject; but it is generally thought to be a good crop when a turnip is obtained from each square foot of ground. Mill considers an average crop to be 11,664 roots per acre, which, at 6 lbs. each, will be 69,984 lbs."

The amount of any one turnip crop, however, is powerfully affected by the condition of the soil, the stage of the rotation, the kind and quantity of the manure, the method of culture, the character of the climate, the prevailing weather of the season, and the particular variety of the plant. A light soil will never produce a maximum crop of Swedish turnips; nor a heavy soil, a maximum crop of common turnips; nor an ill-tilled soil of any kind, a maximum crop of either. A suitable soil in a freshly manured state, or at the commencement of a rotation, will produce, on the average, from 28 to 33 tons per acre; while the same soil, after an intervening crop from the manuring, or in the second year of a rotation, will not produce, on the average, more than from 6 to 8 tons per acre. Different plots of one field of strictly homogeneous characters, treated in exactly the same way, and cropped from one specimen of seed of one variety of turnip, but fertilized with different kinds and composts of good manure, will, as we showed in the section on the manuring of the turnip, yield very widely different produce, both in quantity and in quality. The drill culture, in any given circumstances, will always produce a better crop than the broadcast culture; and the raised-drill culture, in adverse seasons, will generally produce a better, and sometimes very much better, than the large-drill and flat-surface culture. The comparatively cool and moist climate of Scotland and the north of England constantly produces a much larger average turnip crop than the comparatively warm and dry climate of the south of England; and for the same reason, a hot and droughty season will diminish the average in the former districts, and a cold and wet one will increase it in the latter. As to the comparative weight and size of the roots of different varieties, "it has been found, after repeated trials, that sound green-top yellows, of 7 or 8 lbs. weight, gave, as their highest average, 32 cubic inches per pound; which may be assumed as a medium standard of solidity or density, and being compared with the actual weight, will afford a just criterion of their value, and a correct idea of their sizes. Thus, by dividing the number of cubic inches contained in any bulb by 32, (the remainder being halved for 16ths or ounces,) the quotient gives the number of pounds and ounces that should be of the standard solidity; the actual weight of the bulb will indicate the solidity, which will either be at, or above, or below the standard—as the numbers of the weight are equal, or greater, or less than the numbers of the size." Specimens of some of the chief varieties, grown upon different soils and carefully selected, were put to the test on this principle, at Messrs. Drummond's establishment in Stirling, and gave the following results:—

	Weight per standard.	Actual weight.
Swedish turnip,	11 lb. 2 oz.	13 lb. 12 oz.
Ditto,	10 lb. 5 oz.	13 lb. 8 oz.
Green-top yellow,	16 lb.	15 lb.
Ditto,	15 lb.	14 lb.

	Weight per standard.	Actual weight.
Red-top yellow,	12 lb.	12 lb. 10 oz.
Ditto,	11 lb. 8 oz.	11 lb. 12 oz.
Dale's hybrid,	13 lb. 12 oz.	12 lb.
Ditto,	12 lb. 8 oz	11 lb. 8 oz.
White globe,	20 lb. 8 oz.	15 lb. 8 oz.
Ditto,	19 lb.	15 lb.
Red-top white,	16 lb. 8 oz.	13 lb.
Ditto,	14 lb. 8 oz.	12 lb.
Green-top white,	12 lb.	11 lb.
Ditto,	11 lb.	10 lb. 8 oz.
White tankard,	16 lb.	14 lb.
Purple tankard,	12 lb. 10 oz.	11 lb. 8 oz.

It will readily be seen, then, that the produce of turnip crops is exceedingly variable, and not a little difficult to be estimated. In rare cases, it has risen so high as 60 tons per acre, and fallen so low as next to nothing; and in ordinary cases, it ranges throughout greater part of the enormous interval between these extremes; and in average cases of good culture, at the commencement of rotations, or immediately after manurings, it may be set down at something between 28 and 32 tons per acre.

The value or price per acre is even more variable than the weight; for, besides being dependent on the quantity, and therefore controlled by all the same circumstances which control the weight, it is affected also by the special feeding qualities of different specimens of each variety,—by the capacity of each crop, under the varying characters of weather and season, to keep well, and become readily available for winter and spring food,—and by the market fluctuations which result from the aggregate relations of supply and demand. On the whole, however, the turnip crop, regarded simply by itself, or without reference to its place in rotations and to its aid to store-feeding, is never remunerating; and, as compared to the average value of the other crops of a rotation, is commonly and roughly yet somewhat correctly estimated as worth about half a crop.

Forage Crops of Turnip.—The early stone turnip is sometimes cultivated in England, in a manner supplementary to the ordinary feeding crops of the farm, either by being sown on the first-cleared piece of wheat-stubble, and used for spring food, or by being sown in the beginning of July, and used for September food. In the former way, it sometimes answers well, but at other times yields only a scanty bite of green leaves for couples in spring; and in the latter, it commonly succeeds well, and is consumed by being led out to the fields where the cattle are depastured, or upon the stubble immediately after harvest. It is popularly called by the farmers who cultivate it the stubble turnip; and may have got that name either from being sown on stubble land in the one way, or consumed on stubbles in the other. It is a rapidly growing variety, and can be profitably used only two months after it is sown, though it will continue to increase in bulk for a longer period; but it is comparatively very soft and succulent, and seldom acquires a maximum weight in the root of more than about 7 pounds, and it has a tendency to flatness of the top, and is in consequence unsuitable for a winter turnip. It may easily be raised with bone-dust or guano, or with a mixture of either and rape cake.

Any ordinary field turnip of the common or the hybrid kinds may be thinly sown, in the quantity of about 2 lbs. of seed per acre, among the plants and interstices of a bean-crop just before it is hoed for the last time; and if the land has been well tilled for the beans, and has been once horse-hoed or hand-hoed, it will be in pretty good order for receiving the turnip seed, and the young turnip plants will be not at all checked, but rather fostered, by the shade of the beans. If the land be intended for winter wheat, the turnips, as soon as the beans have been carried, are drawn and stored; but if not, they remain to be folded off in the same manner as ordinary turnip crops. One grand objection to this method, however, is that the soil most suitable for beans is far from being suitable for either common or hybrid turnips; and another is that the double crop of beans and turnips abstracts an extraordinary amount of nutrimental matter from the soil, and correspondingly impoverishes it for the succeeding corn crop. But the former objection is mitigated by adopting the practice only on soil of a medium character; and the latter, by prospectively enriching the land, in a superior degree, at the time of manuring.

The repeated cutting of the tops of transplanted Swedish turnips has been recently proposed as a probably good expedient for obtaining large supplies of green food to stall-fed cattle, and was first suggested by an accidental discovery on Mr. Johnstone's farm of Larg-Liddesdale in Galloway, in the summer of 1847. Seedlings of Skirving's swede, sown early in April, were transplanted on the 22d of June; and some began, in the course of from 10 to 20 days, to run to flower,—and were cut over, pretty near the base of the stem, as soon as they went into flower,—and afterwards increased their roots, and sent out a luxuriant growth of new and very delicate stems and leaves, —and were again, at two successive periods, cut over as before, and sent out, after each cutting, a new growth of tender foliage; and at the end of the season, after having yielded a great weight of excellent green food, they had larger bulbs than the swedes of the same field and from the same bed which had not run to flower, and had been allowed to grow in the ordinary way; and one of the bulbs, on being subjected to analysis in the laboratory of the Agricultural Chemistry Association of Scotland, was found to contain so high a proportion of water as nearly 91 per cent., but to be in other respects about as nutritive as the average of Swedish turnips. "The value of this experiment," remarks the intelligent reporter of it, "might depend upon a variety of minute particulars, which should be carefully investi-

gated and stated. When plants were old and predisposed to run to seed before transplanting, they were thrown aside; and transplanted roots, when flowering, were usually looked upon as lost, and pulled up or allowed to run to waste. What in Mr. Johnstone's case had secured success? Was it his having saved his seed early so as to predispose to flowering, and then, taking them up, transplanting them shortly before flowering, and cutting them immediately after they had come into flower? As to the bulbing of the plant, too, was its regularity and success influenced by the cutting of the stem close down, say about half an inch from the turnip? It was very clear that if this practice could be adopted as easily and cheaply as practised by Mr. Johnstone, the system of turnip cropping would be revolutionised completely; the growing of rape and other green foods would be dispensed with; as the turnip, so transplanted, could be put in so as to afford most abundant and nutritious green food for cattle and pigs during summer as well as large roots as food for winter."

The Raising of Turnip Seed.— Good turnip seed is obtained, in small quantity, only from transplanted, large-bulbed, vigorous plants,—and in large quantity, from an untransplanted crop raised immediately from the seeds of such plants; and, in order to its being true to the variety, or unaffected by indefinite natural hybridizing, it must be raised, from first to last, in a situation which cannot be reached by the pollen of any other kind of turnip, or by that of cabbage, borecole, rape, or any other kind of brassica. See the article BRASSICA. The seed of a turnip plant, which runs up to flower without previous transplantation, is generally more or less degenerate; and that of even a carefully transplanted and perfectly suitable turnip-plant, which flowers in the vicinity of some other sort of brassica, is very liable to be injuriously hybridized. The proper time for transplanting is the month of February.

Persons who professionally raise turnip-seed in large quantities for the market annually select from a growing crop a number of the best-formed and most healthy roots, and transplant them into a plot of finely tilled and well-manured soil. The roots are placed in regular rows, by hand, in hollow drills, previously made by the plough; and the intermediate ridgelets are split open to cover them, leaving the crowns bare. No particular after-culture is given, except to keep the ground free from weeds, by means of the hoe. When the pods fill and the seed begins to harden, the crop must be carefully watched, to prevent the depredations of small birds; and the stalks ought to be cut before the seed is completely ripe, as in that state the pods are extremely apt to split open in handling, and to spill the seed. When the stems are sufficiently dried, either the crop may be thrashed out immediately, and the seed put into a dry granary, or the crop may be secured in ordinary ricks, carefully thatched like corn-stacks, and thrashed out in spring. The produce of this transplanted crop is sown in the succeeding year, and is not transplanted; and the seed of this second crop is saved for sale, and is then sold under the name of transplanted turnip-seed. Thus, having two breaks of seed turnips, the cultivator may always keep up a stock of excellent seed; and so also may every farmer who chooses to take the trouble to go through the process for himself. But the seed per acre is so cheap, as hardly to be worth the necessary pains and attention, except to those who do it to some considerable extent for sale. One acre of ground may produce to the value of £50; but any considerable extension of the culture would soon greatly overstock the markets. Farmers, however, who raise their own seed, besides saving the price, have this additional advantage, that they are always sure to obtain good sorts; and those also who possess a rare or very excellent variety may do well to raise their own seeds of it, rather than incur the risk of not obtaining it genuine from a seedsman, or perhaps of not obtaining it at all.

The Chemical Composition of Turnips.—Both the entire chemical constitution of the bulb of Swedish turnips, and the manner in which it is affected by the circumstances of growth and culture, were formerly noticed in the section on the manuring of turnips. The comparative nutritiousness of the bulb of some of the principal varieties may be understood from the following statement:—64 drachms of Swedish turnip afford 110 grains of nutritive matter, 64 drachms of stone turnip afford 85 grains, 64 drachms of white round turnip afford 83 grains, 64 drachms of white globe or white loaf turnip contain 80 grains, and 64 drachms of white tankard turnip contain 76 grains. "Turnip," says Boussingault, speaking apparently of the common white varieties, "is the most watery root I have examined. A slice weighing 2 oz. 17 dwts. dried in the stove, was reduced to 4 dwts. After thorough desiccation, one of turnip weighed 0·075; consequently the root contains 92·5 per cent. of water. One of dried turnip incinerated left 0·0758 of ash; and the composition of the whole was 42·8 per cent. of carbon, 5·54 of hydrogen, 42·4 of oxygen, 1·68 of azote, and 7·58 of ash." But both the proportion of water, and the quality as well as the amount of the nutritive matter, in any variety, from the hardest swede down to the softest globe or tankard, are very considerably affected by soil, climate, weather, manure, culture, and stage of maturity.

The chemical composition of turnip leaves, both absolutely and at successive stages of growth, is an interesting subject of enquiry in connection with the hope which now exists of the capability of the plant being so managed as to yield a succession of cuttings of green forage; and though this has not yet, so far as we know,

been made a subject of investigation in the case of the Swedish turnip, it has, in some degree, been very elaborately ascertained in the case of the white globe turnip, and may be supposed to be not very dissimilar in the case of any of the other rough-leaved varieties, or even in the case of the swede. Some of the chief facts and deductions brought out by experiment were that, on the 28th of June, the fresh leaves contained 88·61 per cent. of water and 2·48 of ash, and the dried leaves contained 21·8 per cent. of ash,—on the 26th of July, the fresh leaves contained 88·46 per cent. of water and 1·84 of ash, and the dried leaves contained 15·95 per cent. of ash,—on the 30th of August, the fresh leaves contained 86·61 per cent. of water and 2·39 of ash, and the dried leaves contained 17·84 per cent. of ash,—and on the 29th of September, the fresh leaves contained 88·66 per cent. of water and 1·95 of ash, and the dried leaves contained 16·31 per cent. of ash; that the per-centage of water in the lower part of the top is greater than in the upper, decreasing from 2 to 5 per cent. as we ascend; that the average quantity of water in the lowest part (90·22 per cent.) of the tops, is nearly 5 per cent. greater than in the highest part, (85·42 per cent.,) and 10 per cent. greater than the mean of the whole green part, including leaves and stalks; that the proportion of mineral matter in the tops increases with the age of the plant; that the average quantity of mineral matter in the green part of the turnip is greater by one fourth part in the highest than in the lowest part; that these averages for the green tops as they were gathered, are—for the highest part 2·19 per cent., for the lowest part 1·75 per cent., and for the whole top 1·98 per cent.; that in the tops dried at 212° Fahr. the proportion of mineral matter is greater in the lowest than in the highest part, by about one twelfth part,—the average for the lowest being 18·21 per cent., for the highest 16·84 per cent., and for the whole top 17·83 per cent. This difference between the relative proportions of mineral or inorganic matter in the upper and lower parts of the top in their green and dry states respectively, arises from the circumstance that the lower part contains also the largest per-centage of water.

The Uses of Turnips for Human Food.—The common culinary uses of garden turnip are so universally known that they do not require to be mentioned. The bulb of the Maltese golden turnip, which has an uniform orange colour, a perfectly spherical shape, and a fine flavour, is sometimes introduced with the dessert instead of fruit. The roots of the round black, round brown, long black, long brown, small Berlin, small long white, and Maltese long white turnips, are much esteemed on the Continent for their peculiar pungency. The bulbs of almost all garden turnips, particularly such as possess a comparatively high degree of the pleasant and characteristic acrimony of the brassica family, whenever cooked in any such simple way as to be easily digestible by a feeble stomach, are eminently serviceable to persons who have a tendency to scrofula, purpura, or any similar disease of the circulating system of the skin.

During a dearth in England in 1629 and 1630, 'very good, white, lasting, and wholesome bread, was made of boiled turnips, deprived of their moisture by pressure, and then kneaded with an equal quantity of wheaten flour.' The scarcity of corn in 1693, led the poor of Essex again to have recourse to this species of bread. It could not, we are told, be distinguished by the eye from a wheaten loaf; neither did the smell much betray it, especially when cold. During the recent famine in Ireland consequent on the failure of the potato crops, Swedish turnip was much recommended for cultivation by the peasantry and the small farmers, both as a general substitute for the potato, and as a special material for making cheap bread. One of the most common recipes of the day for converting it into bread was the following:—Take 8 lb. of Swedish turnips, peeled and weighed raw; put them down to boil in a metal pot, and when boiled strain and squeeze them well in a cloth, and pound them well in the pot; when pounded, squeeze them well again in the cloth, for the more you drive the contained water out of them, the less will the bread taste of the turnip; and then take 3 lb. of home-ground wheaten whole meal, or 4 lb. of such wheaten whole meal as is commonly sold by huxters, and work it up with the prepared turnips, and proceed with the dough in the same manner as with any other griddle bread. But a much more refined method than this, and at the same time scarcely if at all more costly, and applying fully as much to mangel wurzel as to Swedish turnip, was recommended, in the following terms, by the Professor of Chemistry to the Royal Dublin Society. "Neither the mangel wurzel nor Swedish turnip can be boiled without considerable loss of its nutritive matter, and if, after being boiled, the juice is pressed out of it, the loss is of course materially increased. By steaming these roots, there is much less loss of nutritive matter than by boiling them. I have tried a number of different methods of using these roots, but that which appears to me the best, and in which there is no loss of their nutritive matter, is the following:—First, wash and peel the mangel wurzel or turnip, then grate it, and either steam (in tin vessels without holes) or stew the grated pulp in a pot for half an hour, over a slow fire, occasionally stirring it. When it is dressed, use as much wheaten-meal as is necessary to make it into cakes without adding any water (which will be about its own weight, or a little more); bake either on a griddle or in an oven. The cakes thus made will be found very palatable and nutritious. They may be much improved by mixing through the flour a small quantity of carbonate of soda and tartaric acid

in powder, in the proportion of 30 grains of each to every pound of flour. The common muriatic acid of commerce being much cheaper, may be substituted for the tartaric acid, and thus used:—To 30 grains of the muriatic acid, add three times its bulk of water, and mix the diluted acid with the dressed pulp. The dry carbonate of soda is to be added to the flour, and the whole made into a cake. Common salt will be formed in the baking, and need not be put into the cake. The different kinds of meal, as from oats and barley as well as from wheat, will make good cakes with mangel-wurzel or turnip, without the addition of soda and acid. But the best, as might be expected, seem to be produced from the wheaten-meal. The cakes from mangel-wurzel, too, are generally considered as more palatable and better than those from the turnip."—*Dickson's Husbandry of the Ancients.—Reports to the Board of Agriculture.—Reports to the Royal Dublin Society.—Loudon's Works.—Miller's Gardener's Dictionary.—Museum Rusticum.—Society of Gentlemen's Complete Farmer—Arthur Young's Works.—Martin Doyle's Works.—Brown on Rural Affairs.—Transactions of the Yorkshire Agricultural Society.—Transactions of the Highland Society.—Irish Farmer's Magazine.—Irish Farmer's Journal.—Treatise on Vegetable Substances in Library of Entertaining Knowledge.—Philosophical Transactions.—Mills' Husbandry.—Dr. Dickson's Practical Agriculture.—General Report of Scotland.—Quarterly Journal of Agriculture.—Journal of the Royal Agricultural Society of England.—Goodrich Smith's Economy of Farming.—Low's Elements of Agriculture.—Bayldon on Rents and Tillages.—Useful Knowledge Society's Farmer's Series.—Sproule's Treatise on Agriculture.—Lawson's Agriculturist's Manual.—Marshall's County Reports.*

TURNIP-FLY. Any insect which, in either its larva or its imago state, feeds upon any part of the turnip plant. The turnip-fly of most farmers, indeed, is especially or even exclusively the single species, *Haltica nemorum;* but that of some farmers and of most common country people is a whole and very heterogeneous group, and comprises all the beetles which feed on the seed-leaves, all the saw-flies which feed on the expanded root-leaves, and sometimes also the ants which feed on the seeds, the maggots and the wire-worms which feed on the roots, the weevils which cause excrescences on the bulbs, the aphides which desolate the foliage, and the moths and butterflies which infest various parts of the plant. Some of these enemies of the turnip are noticed in the articles SAW-FLIES, WIRE-WORM, BUTTERFLY, and APHIS; and some others, but chiefly the *Haltica nemorum*, will form the topic of the present article.

The genus haltica does not consist in any true sense of flies, but belongs to the cyclica family and chrysomela group of beetles; and it is characterised by having the antennæ slender, much shorter than the body, and eleven-jointed,—the head, as also the thorax, broader than long,—the thorax often with a transverse impression behind and the posterior angles obtuse,—and the tibiæ slender, with a simple spine on the posterior pair. All the species are readily known by the comparatively great thickness of their hinder thighs, and have the power of leaping, like fleas, to a comparatively prodigious distance; and take their generic name of haltica from this leaping power. The grove species, or turnip-fly par excellence, or turnip-flea, or turnip-flea beetle, or earth-flea beetle, or black-jack, *Haltica nemorum*, takes its botanical specific name from the circumstance of having principally frequented woods and groves before the period when turnip cultivation became general, but is now the universally diffused and desolating foe of the young turnip plant. Its eggs are very minute, oval, smooth, and somewhat of the colour of the turnip leaf; and its larva is fleshy, cylindrical, and pale, with six pectoral feet and a pro-leg at the apex,—the head furnished with jaws and large dark eyes, and the first and the last segments marked with dark patches. The perfect insect varies in length from $\frac{3}{4}$ of a line to nearly $1\frac{1}{2}$ line or one-eighth of an inch; and is generally larger and stouter in the case of the female than in that of the male. It is smooth, shining, and of a brassy black colour, with a slight tinge of green, particularly on the wing cases. The antennæ are black, with the second and third joints and the apex of the first of a pale colour. The thorax is convex above, and pretty deeply punctured. The wing cases, which are much wider than the thorax, are likewise thickly and irregularly punctured; and each of them has a pale yellow or slightly sulphur-coloured stripe, running along the middle, curved inwards posteriorly, and not reaching quite to the extremity. The under side of the body and thighs are black; and all the tibiæ and tarsi are of a pale hue. When the beetle is feeding, all the different parts of the mouth are employed; the upper and under lips open to liberate the other organs; the two sets of teeth, or the toothed mandibles, as they are named, meet when closed, and, from their strength and horizontal action, readily break the cuticle of the leaf. The jaws seem to be adapted for keeping in the food during the short process of mastication; and the four feelers hold and steady any portion of the leaf to be eaten, and assist in conducting the detached morsels into the mouth.

Several other and nearly allied kinds of haltica possess very similar habits to *Haltica nemorum*, and share in all its popular names, and present the same characters in a somewhat modified form; and they have received different names from entomologists, such as *H. flexuosa, H. sinuata, H. ochripes, H. intermedia,* and *H. parallela;* and

they differ from one another chiefly in the colour of the legs, and in the form of the longitudinal yellow stripe on the wing-cases. It is very unlikely that they are more than varieties of the same species; and however important it may be, in most other instances, to discriminate closely allied kinds of insects, this is of little consequence in the present instance, as all those mentioned, whether varieties or species, are alike prejudicial to the turnip, and are doubtless precisely similar in both their methods of mischief, and the modes in which they may be kept down or destroyed.

The *Haltica nemorum*, as well as each of the allied kinds, occasionally feeds on a variety of cruciferous plants; but, as already intimated, it is more particularly attached to the turnip, which it attacks both in its perfect and larva state. When the plants have acquired some degree of strength, and the foliage is considerably developed, the injury done is usually insignificant, as the partial consumption of the leaves does not interfere so materially with their functions, as to have the effect of diminishing the size of the bulb. In this respect the larva of the turnip saw-fly, *Athalia spinarum*, is incomparably more to be dreaded, as its greater size and voracity demand a much larger supply of material. But unfortunately the favourite food of the flea-beetle is the young plant, just as it is beginning to unfold the cotyledon leaves. These it consumes with the utmost avidity; and when it is abundant, it often, in a very short time, strips a whole field of its crop. It has, for so small a creature, a truly astonishing voracity; and has been observed, when shut up for the special examination of its habits, to consume no fewer than ten plants every day. The loss which it sometimes occasions, in years and districts favourable to its prolificity, is enormous; and so long ago as 1786, Mr. Young stated that the turnip-crop destroyed by it in Devonshire alone was valued at £100,000.

"The economy of this little pest," says Mr. Curtis, in a long and able paper, of which we shall here give an abstract, "has puzzled the man of science, as well as the practical agriculturist, for many years; and for want of that rigid care which is indispensable in the investigation of natural history, numerous errors have been adopted, which have led to the promulgation of many false theories. Dr. Pearson believed at first that the white spots or dots observable on more than half the turnip-seeds were the eggs of the turnip-fly; but he was compelled to abandon that opinion, having had no flies where the seed was sown in soil contained in pots covered with bell-glasses. Rusticus, however, a contributor to the Entomological Magazine, so strongly insisted upon it, that seeds steeped in brine, or otherwise prepared, have been sold in London at the seed-shops, to insure the grower against the attacks of the fly. It is exceedingly likely that the white dots are occasioned by minute flies alighting upon the seeds while they are drying, and depositing their excrement upon them, which is often white; or they may be particles of pollen from the flowers. It was, however, from the careful investigations of Mr. H. Le Keux that we were first made acquainted with the actual economy of this little beetle. If the spring be warm the sexes pair from April to September, during which period the eggs are deposited by the female on the underside of the rough leaves of the turnips. She lays apparently about one egg daily; and ten pairs laid in a week only forty-three eggs. This indeed was under confinement; but the correctness of this estimate is supported by the fact, that in leaves taken from the field, containing as many as six larvæ, they were all of different sizes, indicating a variety of ages. The eggs are hatched in ten days; and the little maggots immediately begin to eat through the lower skin of the leaf, and to form winding burrows by feeding on the pulp. These burrows are visible enough to the naked eye when the larvæ leave them, and the cuticles are withered and discoloured; but in their early stage, they are discovered with difficulty; indeed it is only by holding the leaf up to the light that they can be well detected. The larvæ are full fed in about sixteen days, when they desert their burrows and bury themselves not quite two inches below the surface of the earth, selecting a spot near to the bulb, where the turnip-leaves protect them from wet and drought. In the earth they become immoveable chrysalides, which are brought to maturity, I believe, in about a fortnight, when the beetle, or fly, as it is called, emerges from its tomb, again to fulfil the laws of nature. The beetles themselves are rather long-lived, for they have been kept in that state from July until the following February. Eighteen inches is about the greatest extent of their leap, which in a straight line, would be, averaging their stature, 216 times their own length; and when it is remembered that this leap is performed in a curved line, it must be admitted that a considerably greater distance is achieved. They seldom walk, and when at rest sit with their hind legs folded under them, ready to skip off in an instant, if disturbed, or when even approached. In warm weather, during sunshine, with the thermometer standing between 70° and 80° in the shade, they fly with facility.

"This little plague is not confined to our island, for it is abundant in Germany, and common everywhere in Sweden, where it is very destructive in its perfect state. Probably in England no portion of the country is perfectly free from these insects; at least every bank and meadow harbours them to a greater or less extent; and they have been found also on grass-lands which had not been ploughed for many years, and where there were no turnips within

half a mile. It will be necessary to consider this part of their history before we enter upon a discussion of the remedies. The turnip-beetles hybernate, or live through the winter, in a torpid state, and may be found under the bark of trees, as well as beneath the fallen leaves, in the chinks of old timber and paling, the stumps of thorns and of other bushes, where the bark does not adhere close to the stem; and the hollow stalks of grass and stubble seem to afford them an asylum during the inclement months of winter; but, inactive as they then are, the warmth of the hand is sufficient to revive them in a few minutes, so that an unusually mild day in January or March will partially seduce them from their retreats, and will render them almost as active as would the ardent sun of summer. On the first indication of spring, if the weather prove fine, warmed by the sun and cheered by his rays, they arouse from their slumbers, and permanently leave their winter quarters for sunny situations, where they may be seen sitting on walls in considerable numbers, or sunning themselves on dry banks and on clods of earth, protected from the wind. They have been observed in gardens on turnips and cabbage-plants as early as March, and in April on the crops in the fields; but May and June appear to be the more usual periods of their first and most fatal attacks. The autumnal crops have been occasionally destroyed by them, and in one instance I have seen recorded, as late as the middle of September. They may be said to be abundant from May to October amongst the grass, and in all fields, whether of wheat, oats, or barley. It seems that the taste of the turnip-beetle is far less fastidious than is generally imagined. This might be fairly inferred from its abounding in situations where the turnip does not grow. There can be little doubt, however, that it prefers those plants which are termed cruciferous, from the shape of their flowers, of which cabbages and turnips are examples; of these the leaves of the horse-radish, the common turnip, and the radish are its favourite food, but cabbages, cauliflowers, colewort, watercresses, ladies'-smocks, and hedge-mustard called jack-by-the-hedge, are often attacked; the charlock or wild mustard is also sometimes covered with them at the end of April, and in May the leaves will be seen pierced with holes, but as soon as the turnips come up they desert other allied plants. Mr. Berry has recorded a remarkable exception, for he says that, after consuming the cabbage-plants, the flies attacked and destroyed the young hops, which belong to a very different tribe of plants. Köllar also states that both summer and winter turnips left for seed suffer in warm and dry weather, from the attacks of the fly injuring the flowers so as to spoil the produce of the seed.

"The next subject to be considered is a remedy against the attacks of the turnip-beetle. Now with regard to the eggs, we see that they are laid on the under side of the rough leaf, where they are pretty well secured from rain, and also protected by the strong and projecting ribs that support the leaf from any injury that might occur from the leaves being ruffled by the wind or other casualties; and the inferior skin, being the most delicate, is best adapted for the entry of the infant and tender maggots into the substance of the leaf. It is not, therefore, at this stage that much could be done in destroying them. The maggots, it is evident, live upon the rough leaf, and do little or no mischief to the growth of the plants; they dwell perfectly secure between the two cuticles, unless it be when they leave the burrows they had first commenced, probably not of common occurrence, to form new ones at a remote part of the same or upon another leaf. At this period they are most probably affected by parasitic enemies. The chrysalis is buried only just beneath the surface of the earth, but it is probably protected in a slight web, forming a cradle for it to lie in free from pressure. I think some efforts might be successfully made for its destruction at this time. It is, however, in its last and perfect state that the mischief is done. It is the beetle which destroys the two first smooth leaves, called the cotyledons, and the heart of the plant between them, by piercing them like a sieve, destroying the cellular tissue and stopping the growth of the plant. They also feed upon the rough leaves, drilling them full of round holes, which are larger on the upper than the under side of the leaf; and if the appetite of the beetle be not satisfied, he enlarges the aperture and thus gives it an irregular form, which dilates with the growth of the leaf: hence the large holes we see at a later period. After all, it is at this stage of their existence, I am inclined to believe, that we can attack them with the best prospect of success, if they cannot be kept off by other means. In collecting the turnip-beetles by sweeping and various methods, large numbers of small carnivorous beetles, belonging to the *Carabidæ* and *Staphylinidæ*, are found with them. These probably feed upon the larvæ; but from the very recent discovery of the early stages of the turnip-beetle, we are yet ignorant of the parasites, of which it may be presumed there are more than one species, that prey upon the maggots and chrysalides; for it is a wise dispensation of Providence to keep every animal in check by some other that is either more powerful or more sagacious than itself; and this counteracting effect is produced in a degree equal, or eventually superior, to the noxious animal, so that in a greater or less space of time the destructive power may be rendered no longer formidable, or be absolutely annihilated by the attacks of its parasites. This natural process, though never failing, is often too slow in its operation to secure immediate relief. The farmer must, therefore, devise means, if possible,

for the more speedy destruction of the enemy. The beetles are seldom found in shady places, except during the winter season, and they cannot bear cold and wet, which are great protections against their increase; it consequently follows that warmth and sunshine are far more favourable to their multiplication, and in such seasons they are most to be dreaded. Showery weather, after a long drought, and cloudy days with gleams of sunshine, also render them abundant, as such seasons do the greater portion of insects; but in a few instances they have been known to do much mischief even in cold weather. That the turnip-beetle is endowed with an acute and powerful sense of smelling is proved by his flying against the wind, and deserting all other plants as soon as a turnip-crop appears in his neighbourhood. Mr. Le Keux says that in May 1836, when the thermometer was at 75° in the shade, during a south wind, great numbers were on the wing, and all proceeding southward; and again, that eight acres, forming the summit of a hill in Devonshire, were sown with turnips, and when the young plants were just rising above the ground, the wind being for more than a week at south-east, wafting the scent to the north-west, they were so destroyed on this side, that nearly an acre was bare, whilst the south-east side was not touched until the plants had attained a size to render the attacks of the beetle of little consequence. From what has been stated, it appears that no season will secure us entirely against the attacks of the turnip-beetle; and that no soil is considered safe from them is evident upon the best testimony; it is very destructive upon strong lands, and not less so on light ones. Neither is the period of their attack limited; for, as one pair of insects may produce five or six broods in a season, there is a constant succession, which renders any plan for extirpating the beetle in any of its three early stages scarcely practicable.

"As the turnip when in rough leaf is not in any danger from the attacks of the beetle, it is evident that our first care must be to preserve the young plant; and this can only be done by the preparation of the soil, or using such speedy means the instant the beetles appear as will destroy or drive them away. The primary object will be to discover the best manure for that purpose, and a dressing that will render, if possible, the soil obnoxious to the insect. It has been correctly said 'that the manure which most effectually promotes the growth of the plant will be the best defence from the insect; and that, when the growth is slowest, the danger from the insect is most serious.' This arises in a great measure from the advantage that insects have over vegetation. A gleam of sunshine is almost sufficient to call them into active life, as we have before observed, and as is evident from the swarms of delicate gnats that may often be seen dancing in the air when frost is on the ground even in January; but it requires the accumulated rays of the sun, and a much longer duration of warmth, to set in action the fluids of plants. Whether any direct protection against the beetle can be expected from manure, since it is ascertained that it is not upon the seeds that the eggs are laid, now becomes a question; for when the maggots escape from their burrows in the leaves, and enter the earth, in order to become chrysalides, before changing to beetles, the manure, I should think, seldom contains sufficient ammonia to destroy them,—and, if I mistake not, any moderate fermentation would rather facilitate than retard their metamorphoses. Moreover, the instinct of insects is so perfect, that the maggot would most assuredly avoid obnoxious spots, so that, if any manure were spread that would injure them, unless it formed a very uniform stratum, it would not insure success, although great advantages might be derived from its use.—Burning has been found the best preventive against the beetle by some, which is readily accounted for, since it would destroy any chrysalides in the land; and as the beetles may be in abundance in the field when it is preparing for turnips, burning would, of course, be destruction to them,—and spreading the ashes afterwards over the ground will prove an additional security. But such a system does not suit sandy soils, neither can it be followed up regularly on any land.—Feeding off the turnips is strongly recommended as an antidote to the beetle, as well as from its peculiar advantages of manuring and preparing the land for the barley-crop and succeeding seeds. I am disposed to attribute the advantages derived from sheep-folding, as regards the beetle, to the perfect stamping down of the soil and herbage, by which all insect life is destroyed, rather than to any peculiar quality in sheep-manure, unless it be contained in their urine.—It is the opinion of a great many agriculturists that raw and long manure harbours the beetle; and if turnips be sown on a stubble-crop they are often completely destroyed. I see Mr. Webb Hall states that he has had to sow stubble-crops three times over; and seed sown on stubble late in August has been taken off by the beetle in more than one instance. Whether this arises from the hollow straws affording a retreat for the beetles, or that the weeds had supported them or the maggots, so that the chrysalides were lying undisturbed in the land, is not easily explained.—Mr. Linton and many others recommend drilling-in, not less than three or even four pounds of seed to the acre, and six or seven pounds broadcast; for he very justly observes that thick sowing causes the plants to grow much more rapidly when young than thin sowing; and by drilling in with the seed a peculiar compost, containing the strongest animal manures, the fly, he says, has never yet disappointed him of obtaining a good crop. I think it probable that the ammonia in this po-

tent manure may be disagreeable, if not destructive, to the insect; and the rapid growth of the plant, from its stimulating effects, defies their attacks. The vegetation of the seed may be accelerated by steeping it in water for twenty-four hours; and the surest way to obtain a strong crop is to sow seed of the same age, otherwise the plants do not come up simultaneously, and the fly will attack and destroy the crop in detail. Mr. Linton also adds that he has found more benefit from the manure he describes in the succeeding crops of clover-seeds than from three or four chaldrons of lime to the acre. With regard to the use of lime, a great deal must depend upon the soil on which it is used, which may account for the conflicting opinions respecting its effects in protecting the turnips against the fly. From six to eight bushels of quicklime per acre may be sown over the young plants successfully in dry weather; but it must be repeated after rain or dew; and this, as well as soot, requires to be regularly and evenly dusted over the plants. Mr. Birk says that he used slaked lime with perfect success; and although profusely, it did not at all injure the plants. It should be slaked at the time of use, and ought to be spread in the very hot state, when it burns the fly. Some danger to the plant seems to attend this process, arising from the heat generated by the lime; at least so I presume; but some little explanation is required in these statements to distinguish clearly between slaked and quick or unslaked lime. Very different were the results from Mr. Le Keux's experiments. Forty bushels of lime per acre were spread, he says, immediately before the seeds were sown, and did no good; and when the plants came up, and the fly was observed attacking them, lime-dust was thrown over them, so that many of the plants were quite white with a coat of it; after which as many flies were found upon those as upon any that were free, and they were eventually devoured. This is again quite at variance with the opinion that repeated dustings of ashes and soot, when the plants are wet with dew, will keep off the fly, and prevent their feeding. In another place he states that the upper part of a field in a sheltered situation, with a south aspect, which had been sown with barley, was well dressed with lime, and sown early in May with white stone turnips, which were destroyed as soon as they appeared above ground; the land was sown again, and harrowed, the surface being thickly strewed over with wood-ashes; the plants were, however, devoured as rapidly as before.—The growth of the turnips being stunted by too frequent repetitions, they become fingery on light sandy soils, and are then more likely to fall a sacrifice to the fly. A good coat of clay or chalk has the effect in Norfolk and Suffolk of invigorating the land, and giving it the power of again producing good crops once in four years. The culture of mangold-wurtzel is well deserving the attention of the farmer, when the land gets tired of turnips; and it has the additional recommendation of not encouraging the increase of the turnip-beetles. As it is quite certain, I should say, that the beetles are attracted by scent, it appears to me likely that, if a field of turnips were planted round with a belt of mangold-wurtzel, the turnips might escape their attacks, if not entirely, to a very considerable extent; especially when the insects are believed to come from a distance; for at the early stage of the plants, a few hours of respite may be of vital importance. The Swedish turnip, or ruta-baga, whether it be a hybrid produced by the turnip and cabbage, or a distinct species, has not the strong scent at an advanced period which is so perceptible in the English turnip when in rough leaf; and if there be as marked a difference of smell in the seed-leaves, it would give the former a decided advantage in exposed situations, where the beetles are attracted from distant localities. Being sown in May or June, however, is, I conceive, not a recommendation, as I believe that to be a period of the year when the first principal brood is generally at its maximum, as the second is in August or September; but the temperature of the seasons may in this respect make a variation of a fortnight or three weeks on either side of the average. However this may be, it is admitted on all sides that the beetle is weakest in July. I fear, on the other hand, that no early sowing can insure the turnip-crop; for as the beetles hybernate, the same warmth and sunshine that make the seed vegetate will bring the swarms of beetles from their retreats; and it is worth considering whether by early sowing we do not entice a hungry horde from their winter quarters, or from the banks and meadows where they are first supported; whereas by not sowing until midsummer the beetles may in the mean while be starved and drawn off to more favourable localities, or have fallen a sacrifice to small birds and the casualties of the wet and cold of our spring. Such seasons we know do not agree with the beetles; and I have observed that, when the dew is upon the turnips in the autumn, they keep under the leaves, and appear to be asleep; and windy weather has a similar effect in rendering them quiescent. The crops being attacked and destroyed in the autumn does not altogether militate against good success at midsummer, especially in forward seasons. Similar objections to the above may be urged against sowing the white turnips with the swedes; for if the quantity of beetles be small, the swedes may be preserved in consequence of the turnip being their favourite food; but, on the other hand, multitudes may sometimes be thus attracted from a distance, which would not otherwise, it may be presumed, have detected the swedes, from their scent being less perceptible.—Some benefit might be derived from destroying those cruciferous plants *Erysi-*

mum alliaria and *Cardamine pratensis*, to which these *Alticæ* are so strongly attached, for they grow in abundance in every hedge and meadow; they appear long before the turnips come up, and attract and give support to the parents of the future swarms that are to sweep away the crops of the farmer. As these plants often flower at the beginning of April, and produce their leaves at a much earlier period, it is almost certain that they nurse the fly, and are its great resources for food and nourishment in the earliest days of spring. But how to eradicate the *Cardamine* is for future consideration. The hedge-mustard, and other cruciferous plants on banks and road-sides, are quite under our control; and it is a duty which we owe to our neighbour as well as to ourselves to keep our fields and hedges clear of charlock and every allied weed of that family, all of which harbour the turnip-beetle.—Before dismissing this portion of the subject two or three remarks will be useful. It is certain that manure gives strength to the turnip-plant, but it is doubtful if it will destroy the beetles. Hoeing and rolling may harass and kill many of them; and as this process promotes the more rapid growth of the plants, it must be attended with no slight advantages. I expect also that, if it were performed in damp days, or after heavy dews, the benefit would be increased; for if the beetles leap in moist weather they often fall upon their backs, where they stick, and after being exhausted become torpid and apparently dead, if the air be cold; but they reanimate as they are dried by the sun. In cold and wet weather it might not prove less efficient; for multitudes of the flies are then sheltered under and about the clods, which being broken down, the insects must perish by the pressure; and if there were any chrysalides in the earth, they would in all probability suffer the same fate.—There are many who consider that turnips should be sown immediately after ploughing, and that much of the success attending a crop depends upon the diligence employed in getting in the manure and seed; whilst some maintain that the land should lie undisturbed for a fortnight before sowing. Such conflicting opinions, as far as the fly is concerned, may often be reconciled by the difference of the seasons when the observations were made. We know that turnips must not be sown in too dry nor too wet a state of the soil, yet this is precisely the state most fitted for the production of the fly; for it is well ascertained that a moderate degree of moisture is necessary to bring forth or to hatch almost all insects,—and if this be accompanied by a mild air it is the better suited to them. It is therefore reasonable to expect that after a fine early spring the turnip-beetles will be found most abundant.—From the dislike the fly has to repeated wet, I have always thought that watering the turnips would be highly useful; and this opinion is supported by Mr. Bayldon, who recommends them to be watered every other day, four, five, and six times, if necessary. Irrigating the land would not have so good an effect, I think, as watering, because the beetles would only be floated off the leaves if they were detached at all; and if they were left thus for two or three days, there would be a great chance of their recovering when the plants were left dry; whereas by the watering they would be forcibly brushed off, and get set fast in the earth and die. The benefit would be most felt, I conceive, on heavy lands, with regard to the annihilation of the beetles; but it would everywhere have the advantage of destroying the chrysalis, by stopping up the pores of the soil, and so preventing the exit of the fly.—Nitrate of soda has been tried in two instances on crops of Swedish turnips with very beneficial effects; and it probably assists, from its peculiar qualities, in checking the increase of the beetles. The nitrate was sown two or three days after the seed; and it may be used on all soils excepting on chalk. It should be sown broadcast, mixed with wood-ashes, which enable the sower to spread it more regularly.

"We now come to what may be termed direct remedies. The Paul-net, as it is called, after its inventor, although it has been considered as a toy, yet I am of opinion might be usefully employed; for I have seen a quart bottle filled with the little turnip-beetles that were all caught with this net. If I remember correctly, Mr. Paul's plan was to sow a small spot with white turnips early, as a decoy, and over that space to draw his net. It always struck me that vast quantities made their escape by skipping out of the net, which was its greatest defect; but this might be remedied by placing some sawdust at the extremity of the bag, mixed with lumps of common ammonia, or sprinkled with spirits of turpentine, which perhaps would be better; but either of these would kill a great many, and stupify the remainder, until the contents of the net were subjected to sufficient heat to deprive them of life. This process is no doubt troublesome, and requires to be repeated; and unless, perhaps, some alterations were made, it would not answer on an extensive scale. This, however, is no fatal objection to the principle.—A board newly painted or tarred, and drawn over the turnips will catch multitudes of the beetles; for on being disturbed they leap against it, and cannot release themselves. I should recommend white paint; and the brighter it is the better, as all insects are attracted by light colours. Neither wet nor windy weather would be suited to these operations; for it is ascertained that the beetles are at such seasons disinclined to move; neither would mid-day in fine weather do, as they are then active, and fly well; for it is a well-known fact, corroborated also by the flight of swallows, that in hot days and sunshine insects fly high, whilst in damp weather they keep upon or near

the ground.—Fumigation by burning stubble, weeds, &c., to windward of the field, so that the smoke drives along the ground, has proved effectual; but I should prefer burning to leeward as a preventive, for as the beetles are attracted by the scent of the turnips, and fly towards the wind, they would be baffled by such a manœuvre. —Watering the plants with brine sufficiently strong to affect the insects, but not strong enough to injure the young plants, would, I expect, prove a most successful remedy; and when in rough leaf it would also kill the larvæ, and even destroy the eggs that were exposed to its influence.—In Hanover, fields of white turnips have been preserved from the fly by thickly sprinkling the dust of chalky roads on the young plants at night, when a heavy dew is falling, until they appeared covered with the powder. The fly, it is said, will at once disappear, especially if the next day be a bright sunshine, and the dust is dried upon the leaves, which prevents their little teeth from gnawing the leaf, or disgusts them in some other way, and they depart to more agreeable quarters. If the sprinkling be immediately succeeded by heavy rains, so that the dust is washed off, the operation must be repeated. Several other means are suggested by M. Wundram, which have proved to be useless in this country; and his reasoning induces a belief that he is not well acquainted with the habits of the turnip-fly. An infusion of wormwood sprinkled over the young plants and seed-beds will, he says, secure them from the attacks of the flies, as they dislike the bitterness thus conveyed.—Drawing boughs of the elder over the field is supposed to annoy the beetles, and drive them away; and the leaves of the alder, when fresh gathered, being covered with a glutinous liquor, and those of the lime, &c., when the honey-dew is upon them, are recommended to be strewed in gardens for the purpose of catching the turnip-beetles.—I confess that I have no faith in the plants being rendered obnoxious to the fly from steeping the seeds in oil, brine, brimstone, or milk, as practised by many. Such immersions may render the plants stronger, or cause more of the seeds to vegetate, which will at once account for the success that is said to be derived from this process. If, indeed, the eggs of the insect were laid upon the seed, the oil and brine would be most efficacious; but that notion is exploded. —Mr. Le Keux says that washing over the plants with sulphate of potash had no effect; and he very justly observes that, if the upper surface of the leaf could be poisoned, the beetles might feed upon the under side with impunity. Powdered sulphur, strewed one-tenth of an inch thick, did not deter the flies from attacking the plants, but it improved their appearance. Snuff, asafœtida, a powder called anti-tinea, for preserving furs, proved equally powerless. They did retire from carbonate of ammonia, and died immediately on being exposed to the effluvia from it; but a small bit placed an inch from the plant would destroy it also. This, or something that would overpower the scent of the turnips, might perhaps be advantageously employed in driving away or deceiving the fly. One ounce of tar, one ounce of olive-oil, and two ounces of strong caustic potash, well mixed together, and shaken up with the requisite quantity of water, were next poured, the fourth day after sowing, over a patch on a hill swarming with the fly, at the end of August. Not many of the seeds came up, but the few plants from them were of a healthy colour, and acquired the rough leaf, a few only on the windward side being punctured; but several days' rain occurred at the most critical time, which might be their best protection.

"Such are the remedies proposed; but I fear it is not by the experiments of a few philosophic men that we can hope to discover any positive antidote to so great an evil. We want correct data from every sort of soil under the various influences of climate and effects of cultivation, before we can fairly grasp the subject. Until we became acquainted with the economy of the beetle, we were groping in the dark. That important discovery has brought us a few steps towards the light; and those who wish to follow in the path of truth should try and examine Mr. Le Keux's experiments, which it is easy to do by filling a garden-pot with earth, carefully sifted to take out all worms, centipedes, or other living animals, which might destroy the chrysalides. When this is done, plant in it a small turnip, in rough leaf, having a fine wire-gauze guard, large enough to enclose the plant, and fitting just inside the top of the pot. One or more pairs of the beetles must be placed, with a fresh turnip leaf, in a large-mouthed transparent bottle, then tie over the end a piece of muslin, to prevent the escape of the insects; for if the cork or stopper be put in, the bottle will become wet inside, which will prevent the females from laying any eggs. I imagine they will not adhere to the damp leaf. The leaf may be examined daily through a magnifying-glass; and as soon as any eggs are discovered, they may be placed in the pot where the turnip is growing, that the little maggots may be able to get at the living leaves as soon as they hatch. The progress of the insect may thus be traced through its different stages; and it will only be necessary to place the garden-pot in a saucer, into which water should be daily poured, if necessary, to nourish and refresh the plant.—Let us not forget that amongst our best friends are the small birds, a great number of which, such as the grey and yellow wagtails, no doubt destroy incredible numbers of these insects in their various stages. Their nests ought to be protected, and the birds themselves defended from persecution."

Two small beetles of the curculio or weevil family often make considerable havoc upon turnips when in flower and seed, and have thence

Bairds Turnip Slicer.

Engd. by G.R. Swanston, Edinr.

A. Fullarton & Co. London & Edinburgh.

obtained the name of turnip-seed weevils; and one of the two also destroys young turnips by puncturing the leaves, and has occasionally been found almost as mischievous as the *Haltica nemorum*. This latter, called *Curculio contractus* or *Ceutorhynchus contractus*, makes its attacks on the leaves in its imago state; and is from $\frac{3}{4}$ of a line to 1 line long, and of a black colour, with a coppery tinge,—the head and thorax coarsely punctured,—and the elytra generally green, sometimes inclining to blue, and rarely blackish. The other, called *Curculio obstrictus* or *Ceutorhynchus assimilis*, is similar in appearance, but about twice as long; and both make their devastations upon the seed-pods and the seeds in their maggot state. Both also, in their imago state, are so sensitive that they fall down, if only approached suddenly, from the flowers or leaves on which they are feeding; and may be easily collected, when they abound in the turnip-flowers left for seed, by shaking the stalks over a large net or cloth. But as they immediately unfold their legs and begin to run away after the shock is over, the contents thus collected must be swept into a pail of lime and water or urine until they can be removed and destroyed by pouring boiling water over them; for as their horny jackets are very hard, they are not easily killed by being merely trampled on or beaten.

TURNIP SAW-FLY. See Saw-Flies.

TURNIP-SEED FLY. See Turnip Fly.

TURNIP-SLICER. An implement for cutting turnips into pieces, for the use of sheep and cattle. It is very widely various in structure; and comprises the three kinds of form,—the turnip-chopper, the turnip-slicer proper, and the turnip cutting cart; and each of the two latter kinds also comprises widely different varieties.

The turnip-chopper consists of a handle and two iron blades resembling common garden hoes,—the blades placed perpendicularly upon the end of the handle, and at a right angle to each other, so as to form a cross; and, by a single stroke upon a turnip bulb, lying either where it grew or elsewhere on the ground or in a trough, it cuts the bulb into four parts; and may, when necessary, be used to subdivide any or each of them into four other parts. It is an efficient tool in the hand of an expert man; but, when the quantity of turnips to be cut is large, it requires great strength of arm for maintaining the prolonged exertion. An old variety of it has on the reverse end of the handle a two-pronged fork for giving additional weight to the stroke, and for picking entangled or deep-seated roots out of the ground. But a separate implement, bearing the name of a turnip-picker, is now commonly used for the latter purpose; and is sometimes so modified, with a curved blade instead of a fork for its head, as to be serviceable for either chopping away the body of the bulb from the tap-root, or picking out the shell or bottom of an eaten bulb. The turnip-chopper, in any of its varieties, is better suited for the field than for the farm-yard; and cuts the turnip-bulb into a form of section which is found very manageable for the mouth of most sheep and cattle.

The revolving turnip-slicer, is one of the best of its old forms; and in a shape which serves as the type or groundwork of some of the best improved varieties of the present day, consists principally of a hopper and a fly-wheel or disc set upon a standard or frame. "The area of the fly-wheel is covered with wood; and there are two cutting-knives, each nearly the length between the rim and the centre, placed in it at equal distances from each other, that is, one on each side of the centre, straight in a line dividing the circle into two semicircles. The hopper is placed up in such a position as that the turnips put into it shall always at its under side press against the side of the wheel. This under mouth of the hopper is made of the same breadth as the length of the cutting-knives, that is, somewhat less than the radius of the wheel. The wheel is made to revolve, so as that the knives shall cut when passing down by the under mouth of the hopper. At the face of each cutting knife there is a space left, by which the slice cut off falls down at the opposite side of the wheel to that at which the hopper is attached; and by every revolution of the fly-wheel, each of the knives passes the hopper and cuts a slice off all the turnips which are at the time passing against the wheel." A variety of this implement, invented by Mr. Baird of Shotts, has a circular cast-iron plate instead of the wooden disc, and is provided with transverse cutters for dissecting each slice of turnip into smaller pieces, and, with the exception of the knives and cutters, is made entirely of cast-iron. The plate is cast a broad rim or thickened edge which gives it, when in motion, the centrifugal power of a true fly-wheel; the thickness of the slices is regulated by the distance of the knives from the face of the plate; and each knife is preceded by three or more lancet-pointed studs which by slitting the turnips in passing, prepare the slices for falling in pieces when they are detached from the knives at each revolution of the plate.—Most of the recent and improved revolving disced turnip-slicers, as well as Mr. Baird's, are provided with a contrivance for dissecting the slices into pieces; and many have this contrivance in the form of small knives, standing crosswise before the edge of the slicing knife, and fixed upon a small plate which may be inserted or removed at pleasure; so that when this plate is absent the turnips are cut merely into slices,—and when it is present, they are dissected also into small pieces. Some of the machines, likewise, are mounted on mere quadrupedal frames, while others are mounted on wheelbarrow-formed frames; and the latter are convenient either for travelling along a field, or for depositing supplies of the sliced turnips in a series of troughs.—Mere slices are sufficiently

manageable in farm-yard feeding for cattle, but are liable in the field to be rubbed on the ground and besmeared with mud before they can be mastered; and sections of slices, about 1¼ inch broad, ¾ of an inch thick, and of the length of the diameter of the turnip, are, in all circumstances, very convenient for sheep.

The cylindrical turnip-slicer, or Gardner's patent turnip-cutter, was invented by Mr. Gardner of Banbury; and is generally acknowledged to be the best implement of its class at present in use. It has become very extensively diffused in England; and is so well known to the majority of large English farmers, as scarcely to require any description. It comprises a hopper, a cylinder, and a receiving box,—the first mounted above the second, the second above the third, all adjusted upon a simple quadrupedal frame; the cylinder revolves upon an axis resting immediately on the frame, and is armed with knives for cutting the turnips into small pieces for sheep; and the knives have cutting edges at right angles, and are placed accordingly above one another from the margin inward till they form a junction at the centre.

The lever turnip-slicer is a reciprocating machine, and has, at the end of a trough or hopper, a case of cutters of a gridiron shape, so commanded by a fixed lever handle as to cut the turnips into oblong pieces. The person who uses this implement works the lever handle with his right hand, and presses forward the turnips with his left; and he may either hold untopped turnips by the tops during the operation, or push forward topped ones with a small fork, or a sharp-pointed stick, or a kind of wooden trowel.

The improved lever turnip-slicer, or Wallace's turnip-slicer, differs materially in construction from the preceding, and was invented by Mr. John Wallace of Kirkconnell in Kirkcudbrightshire. "It consists of a stock, 2 feet 10 inches long, and about 6 inches broad, formed of two pieces of hard wood connected by an iron bar, which is repeated on the opposite edge, and the whole bolted together. The two pieces forming the stock being withdrawn from each other so far as to leave a rectangular opening bounded on the two ends by the pieces of the stock, and on the two sides by the iron bars, which, to the extent of the opening, are thinned off to a sharp edge, and thus form the two exterior cutters. The stock is supported at a height of 2 feet upon four legs. Two cutter blocks are appended to the stock by mortice and tenon at the respective ends of the opening, and are further secured by the bolts of the side bars. Into these blocks the remaining cutters are inserted in corresponding pairs, and also secured by bolts. The cutters thus arranged, form a cradle-shaped receptacle, into which the turnip is laid to be sliced; and a lever is jointed on a bolt at one end of the stock and armed over the receptacle with a block, which is stretched on its lower face with iron knobs, and which fits loosely into the receptacle." In operating with this machine, the workman takes hold of the lever with the right hand, and, having raised it sufficiently high, throws a turnip into the receptacle with the left; and when he brings down the lever, the knobs prevent the turnip from sliding backward or forward, and the force of the pressure pushes the turnip against the edge of the cutters, and separates it into slices by one stroke.

The turnip-cutting-cart is simply an ingenious adaptation of the revolving disc turnip-slicer to any common turnip cart; and affords a very convenient mode of feeding sheep on pastures or lawns. Two good varieties of it are in use,—the one invented by Arthur Biddell of Rayford, the inventor of the well-known scarifier which bears his name, and the other invented by James Kirkwood of Tranent. The large cog-wheel of the slicer, in Biddell's, is attached to the back part of the nave of the cart-wheel; an upright lever, moving in a fulcrum-bolt in the cart sill, brings the small cog-wheel into gear with the large cog-wheel on the nave; a small wedge at the top of the lever, passing through the rail of the cart, keeps the cog-wheels either in gear, when the slicer is worked, or out of gear when not required to be turned by the horse; the axle of the smaller cog-wheel, passing through the end of the upright lever which is its only wear at that end, goes under the cart and half-way across, where, at a right angle, it meets, and, by a small pair of bevil-wheels, is connected with the axle of the slicing-wheel, with its two knives; and when this slicing-wheel is put in motion, by the base moving forward, and the cog-wheels being put into gear, it turns with great velocity, and the turnips roll to the knives from a sloping false bottom; and when the cart is wanted for common agricultural purposes, this false bottom and the slicing-wheel are temporarily removed.—The machine, in Kirkwood's invention, is attached by means of a chain to the hind part of a cart loaded with turnips; and when the cart is drawn forward, the machine rolls upon its own wheels, and derives motion from them to its slicing-wheel and feeding roller; and a boy or a man sits in the cart and pitches the turnips into the hopper;—and when the machine is detached from the cart, and has a winch-handle applied to its cutter-wheel shaft, it is converted into a perfectly efficient hand turnip-slicer.

Several of the chief advantages of turnip-slicing, either in folding sheep on the turnips or in supplying them with them in other fields, may here be profitably stated.—1. The most obvious, though perhaps not eventually the most valuable, has reference to the sheep's teeth. Pulling and tearing at the turnip loosens the two front cutting teeth of the hoggs and old sheep to such an extent, that they are apt to fall out, and, in many cases, actually do so. In this deficient state of the mouth, it is impossible that the younger animals

can eat a hard Swede turnip, and in such a quantity as quickly to fatten and be ready for the market. Indeed, if the turnips be not cut, many of the flock can scarcely exist, and, while in the midst of plenty, may be actually starving. The teeth of the more aged sheep, again, from a variety of accidents and diseases to which they are liable, and from having been also much worn down by the hardness of many plants on which they have subsisted, are often, before they are put on the turnips, in a very imperfect condition, which necessarily prevents them from rapidly taking on fat, when folded on turnips, according to the old way. The malformation, also, in the structure of the upper jaw of some varieties of sheep, known in Scotland by the name of *grun-mouthed*, is another reason to adopt the plan of feeding sheep, when folded on turnips, with these roots cut into thin, narrow slices.—2. The hoggs and the older sheep, when placed on turnips, will feed much quicker and be kept in a more healthy condition, when these roots are cut with machines into small, narrow slices, which they can easily take into their mouths, and which are placed before them in long wooden troughs within the fold; and they will sooner fill themselves, and lie down, and ruminate. It is certain that the less time is taken up in eating, the more speedily will the animal become fat; and that the quicker that flesh can be laid on, the greater economy will there be of food. By treating the young sheep or hoggs in this way, at about a year old most of them may be sent from the turnip field to market fit for the butcher. This is a very great benefit to the farmer, not only enabling him to increase the number of his sheep, but also better to prepare his fields for growing his grain crops.—3. Another signal advantage in this management of turnips, is that if any part of the field be poorer in its soil than other parts, it may be made equally rich and productive in bearing crops of grain and grass with the richer portions of the land. In feeding the sheep with cut turnips, they may be made to stand, as long as it is wished, on any particular part; and by judiciously removing the troughs to different parts within the fold, the manure may be equally well distributed all over it. There can be no more effectual plan than this of improving poor, sandy, gravelly soils. The flock, confined within the fold, tread and render the earth more compact and retentive of moisture; and by their droppings, urine, and perhaps perspirable matters exuded from the fleeces while lying on the ground, make it fitter to yield heavier and richer crops of grass and grain.—4. The carcass of the sheep is not the only part of the animal which is improved by this method of feeding; but the wool also is produced in greater quantity, and of better quality. The more improved higher condition of the sheep, influences the quantity and quality of the fleece. "It ought never to be forgotten, that the growth of the wool is liable to be materially affected by the system of feeding pursued. It is essential to the evenness and strength of the staple, that the feeding of the animal should be uniform, without any sudden interruption or transition. Where this is suffered to take place, the natural progress of the wool is for a while most injuriously interfered with. It continues to grow, but the new fibre is unhealthy, and becomes so weak as to snap under the operations of the manufacturer. Much wool is injured in this way by the change between summer and winter keep; and sudden transition from rich to poor, and from poor to rich feeding, ought most carefully to be avoided."—5. Another advantage resulting from this mode of feeding, is that there is a much smaller waste of turnip,—that we have it in our power to give the animals just what kind and quantity of food we may think proper,—that these useful roots, the farmer's chief dependence for the winter keep of his woolly stock, may be preserved to a late season of the year, when provender is most in demand for them. It is the opinion of good judges, that the slicing of turnips, and putting them into wooden troughs to be eaten by the flock, makes these roots go farther by one-fourth than in the old way of feeding. Every part of the root is rendered eatable. To make the turnip, therefore, go as far as possible in feeding stock of all kinds, whether in the stall, the farm-yard, or the sheepfold in the turnip field, let no farmer be without the useful turnip-cutting machine.—6. Wherever an experiment has been made to fold upon a turnip field two lots of sheep, equal in all respects as to age and condition, putting at Martinmas the one lot into one fold, the other into another, and continuing to feed regularly the two lots,—shifting at stated times the fold to fresh portions of the field, the one lot to be fed in the usual way on the turnips, together with supplies of oil-cake, salt, and cut hay and straw, but the other to have the turnips cut into thin narrow slices, and placed in troughs before the sheep,—it will be found that the lot which has had the turnips supplied to them cut by the machine, with the oil-cake, salt, and cut hay and straw, will be as forward in the middle of February, as the former lot would be in April. But, should the two lots be kept feeding for twenty weeks, the lot which has had the turnips supplied cut into thin narrow slices, will fetch from 4s. to 5s. a-head more than the individuals of the other lot; and this increased value of the sheep will cover all the expense of oil-cake, turnip machines, and the extra wages of attendance in working them; and a feeder will receive a handsome return, remunerating him for what may be held by those unacquainted with this mode of feeding an extraordinary outlay.

TURNSOLE. See LITMUS.

TURNSTONE,—scientifically *Strepsilas*. A genus of birds, belonging to the longirostrous family of waders. They are allied to the sandpipers, but stand rather low. Their bill is short, conical, pointed, and without any depression or inflation; their nasal fossæ do not extend along more than half the bill; their toes are without membranes; and their thumb barely reaches the ground. They take the name of turnstone from the habit of overturning stones with their bills in search of worms and molluscs.—The common turnstone, *Strepsilas interpres*, occurs in many parts of both of the great continents of the world; and frequents the coast of Britain, either singly or in small flocks, from August till May. It resembles the sanderling or some of the small plovers; and has a variedly red and black mouth, white head and belly, and black cheeks and breast; but its young, who arrive with it in August, have none of the bright strong tints of the adult. This bird has a total length of 9½ inches; and it feeds on worms, thin-shelled molluscs, and the smaller crustacea.

TURNWREST PLOUGH. See PLOUGH.

TURPENTINE. The resinous semi-fluid product of pine trees and fir trees, and of the *Pistacia terebinthus*. Turpentines have a peculiar and somewhat aromatic odour, and a pungent, heating, bitterish taste; they are very inflammable, and burn with a white flame, and give off much smoke; and they readily combine with fixed oils, and dissolve in ether or alcohol, but do not mix with water. They have a place in the materia medica of both human and cattle pharmacy; and act externally as irritants and rubefacients, and internally as stimulants, diuretics, cathartics, and anthelmintics; but they require to be used with discrimination, and have very various adaptations to different species of animals, to different parts of the body, and in different states of the system.

Common turpentine exudes in transparent drops, from artificial wounds near the foot of the wild or Scotch pine; and may be obtained to the amount of from 6 to 12 pounds a-year for about a century from one tree. It varies in consistency and comparative purity and other characters, according to the precise method in which it exudes; and it is purified by exposure to the sun's rays in barrels with perforated bottoms, and by liquefying there, and filtering through the bottoms. It generally has a greater opacity than other turpentines, a greater consistency than honey, and a dirty yellow colour; it is of main use for yielding the essential oil of turpentine; and it serves well as an ingredient in some ointments in farriery, but is not nearly so much used in any department of medicine as Venice turpentine.

Venice turpentine is obtained from the larch, and from one or more of the American firs. It exudes from a tapping in trees of above twelve years of age; and is produced by a vigorous tree to the amount of 7 or 8 pounds a-year for 40 or 50 years. It is less unpleasant to the smell and taste than common turpentine, and has a more fluid consistency, and a yellowish colour. It is used in veterinary medicine, internally as an ingredient in cough mixtures and diuretic balls, and externally as a chief ingredient in stimulating and digestive ointments and in mange mixtures. The Canadian turpentine or Canada balsam is noticed in the article CANADA BALSAM; and the Chian or Cyprus turpentine is noticed in the article PISTACHIA-TREE.

The spirit, oil, or essential oil of turpentine is obtained by distillation with water from either common or Venice turpentine; and floats on the top of the water in the receiver of the still; and is easily separated thence, and afterwards rectified. About 120 lbs. of it are obtained from 500 lbs. of good turpentine. It is quite liquid, perfectly limpid and colourless, and extremely light, volatile, and inflammable; it has a peculiar and very powerful and penetrating odour, and a bitterish, very pungent taste; it is very sparingly soluble in cold alcohol, but accords in most of its other chemical qualities with the essential oils; it is believed by the majority of chemists to consist of 14 equivalents of carbon, 1 of oxygen, and 10 of hydrogen; and it is converted, by a stream of chlorine passing through it, into a substance similar to camphor. It is used in various ways and for widely different purposes, internally and externally, both in human medicine and in veterinary medicine; but requires to be prescribed with much more discrimination and a much higher professional knowledge than even the semi-fluid turpentines. A chief internal use of it, for example, is as an anthelmintic in man and an antipasmodic in the horse,—but it is defeated or rendered mischievous by alcoholic accompaniment in man, and possesses very doubtful vermifugal power upon the horse; and a chief external use of it in both is as an irritating or blistering substance,—yet it may be terribly disastrous if applied to man's head, and is sometimes very injuriously exciting when applied to any one of many parts of the horse.

TURPENTINE MOTH. Two insects of the tortrix family of moths. They take their name from the circumstance of causing turpentine tumours in young fir-trees; and they sometimes inflict considerable damage on young fir plantations. The one is scientifically called *Cnephasia resinella* and the other *Argyrolepia turionella*. The former measures about 8 lines from tip to tip of the wings; its upper side is dark brown; its back is marked with longitudinal silvery lines; its wings are traversed with lines of lighter hue than the ground colour, and of a metallic lustre; its under wings are almost black, with a yellow and brownish line just within the fringes; and its under side is wholly of a light

greyish-brown colour. The female appears in May or June, and lays her eggs on the young shoots of fir trees; the larvæ penetrate to the alburnum, and cause the terebinthine sap to form excrescences, which gradually harden; and the shoots either wither entirely away, or remain vital in only the lower part, and do not throw out young branches thence till the following year. The *Argyrolepia turionella* is so similar in appearance to the *Cnephasia resinella* as to be readily mistaken for it by an unpractised observer; and it has similar habits, and works mischief in a similar way, by depositing its eggs on the buds of young fir-trees. The only known remedy is to destroy the turpentine tumours, or to cut off and burn the infected twigs, at the time when they are inhabited by the active larvæ.

TURPENTINE (Oil of). See Turpentine.

TURPENTINE TREE. See Pistachia-Tree.

TURRÆA. A genus of ornamental, tropical, ligneous plants, of the bead-tree family. Several species, small evergreen trees of naturally about 20 feet in height, have been introduced to the hothouse collections of Britain; and they love a soil of peaty loam, and are propagable from cuttings.

TURRITIS. See Tower Mustard.

TUSHES. See Tooth and Age of Animals.

TUSSAC-GRASS,—botanically *Dactylis Cæspitosa*. A hardy, forage grass, of the cock's-foot genus and fescue tribe, introduced to Britain in 1844. It almost excited a sensation throughout the well-informed part of the British agricultural community at its introduction; and has since been subjected to a great variety of cultural experiments, in widely different ways and distant situations, in the hope of its proving an exceedingly valuable addition to our field-plants,—particularly on poor soils and swampy grounds, along the shores and upon sea-islands. It abounds in the Falkland Islands, and has been found also in Staten Land, in the Auckland Islands, in the Straits of Magelhaens, and in the vicinity of Cape Horn. It has long been known to botanists; and is alluded to by most of the great navigators who have touched at the Falkland Islands since the days of Cook; but was not brought prominently into notice till the recent voyage of discovery in the antarctic regions under the superintendence of Captain Ross. It is called tussac-grass from its roots being so densely matted together as to make the lower parts of its stalks form a large tuft or tussac. These basal or columnar portions, formed by the close approximation of the stems or culms, often rise to a considerable height—from 4 to 6 feet; and the long tapering leaves then diverge from them, and hang down all around, often in a very graceful curve, like the falling waters of a *jet d'eau*. The masses are insulated, generally a few feet apart; and the leaves, meeting above, form a kind of arched roof, beneath which the ground is generally quite bare of vegetation. A tussac ground thus forms a complete labyrinth; and a man may walk among its green arcades completely concealed from view. The earlier naturalists who examined it thought it to be a fescue, and called it *Festuca flabellata* and *Festuca cæspitosa;* but Forster notices it under the name of *Dactylis cæspitosa*,—and that appellation is now retained, as a careful examination of its character leaves no doubt that it belongs to the genus *Dactylis*. The tussac is perennial. The root consists of a dense mass of tortuous fibres. The stems, which spring from the little hillock formed by the roots, are numerous, erect, branched or divided only at the base, from 3 to 4 feet long, smooth, and compressed. The leaves are numerous, the lower ones very long, not unfrequently from 5 to 8 feet, about an inch broad at the base, and gradually tapering to a point; from above the middle they are curved downwards, or even pendent; the stem-leaves become gradually shorter upwards, and are of a pale glaucous or sea-green colour; and the other leaves are pale yellow. The panicle is a span long or upwards, very dense, forming a somewhat interrupted spike, nearly two inches broad, compressed and obtuse; the branches short and erect; the rachis angled. The spikelet is composed of three or four florets, of a pale yellow-green colour; the calycine glumes are lanceolate, acuminate, longer than the spike of flowers, slightly keeled, shortly ciliated on the back, $3\frac{1}{2}$ lines long, the margins a little involute, and, as well as the apex, membraneous and transparent, the superior one a little longer than the other, three-nerved, the nerves ciliated; the lower glume or palea of the corolla is ovate, concave, compressed, and sharply keeled, bluntly trifid at the apex, and five-nerved; the stamens amount to three; the anthers have a pale yellow-colour; the ovary is nearly ovate and glabrous; and the fruit is elongate-ovate, or almost cylindrical, slightly trigonous, of a pale yellow colour, and smooth.

It will at once appear, from the length and breadth of the leaves, the dimensions of the culms, and the profusion in which both these are produced, what an immense quantity of herbage this plant is calculated to afford. Both the leaves and the stems abound in saccharine matter, and form a most nutritious food. The inner portion of the stem, for a little way above the root, is soft, crisp, well-flavoured, somewhat akin in gout to the kernel of a nut, and is often eaten by the inhabitants of the Falkland islands. The young shoots also are boiled and eaten like asparagus. But it is as affording pasturage for cattle that the tussac is to be chiefly valued. The Falkland Islands have long been known to be inhabited by many wild cattle and troops of horses; and these are principally supported by this grass, and prefer it to every other kind of food; and in common with every herbivorous animal on the islands, they devour it with avidity, and are affirmed to fatten on it in a short time. Their predilection is shown for it both in a green state

and when dried, insomuch that cows and horses often eat the thatch from the roofs of the houses when this happens, as it often does, to be composed of tussac grass. "During several long rides into the country," says Lieut. R. C. Moody, the Governor of the Falkland Islands, "I have always found the tussac flourishing most vigorously in spots exposed to the sea, and on soil unfit for any other plant, viz., the rankest peat-bog, black or red. It is singular to observe the beaten footpaths of the wild cattle and horses, marked like a foot-track across fields in England; extending for miles over barren moor-land, and always terminating in some point or peninsula covered with this favourite fodder; amid which one is almost certain to meet with solitary old bulls, or, perhaps, a herd of cattle—very likely a troop of wild horses, just trotting off as they scent the coming stranger from afar. I have not tried how it would be relished if made into hay, but cattle will eat the dry thatch off the roof of a house in winter; their preference to tussac-grass being so great that they scent it a considerable distance, and use every effort to get at it. Some bundles, which had been stacked in the yard at the back of Government House, were quickly detected, and the cattle from the village made, every night, repeated attempts to reach them, which occasioned great trouble to the sentry upon duty." "Tussac," continues the same authority, "is green all the year round; frost does not appear to injure it, nor does snow cover it; it is a soft, succulent, and highly nutritious grass, extremely relished by all animals—cattle, horses, sheep, and pigs. There is an island in Berkeley Sound that can be reached at low water from the main; the area of this island is as nearly as possible 800 acres, and there are about 400 acres of tussac-grass upon it; the remainder of the island is thinly covered with coarse wing-grass and rush on peat-bog—a very wretched piece of pasture-land, affording scarcely any nutriment. Last autumn I caused the Government herd, consisting of 800 head of cattle and about 60 or 70 horses, to be placed on this island for the winter months; the animals remained on the island nearly six months, with no other nutriment than what the island afforded; towards the end of that time, they began to get poor, and the tussac was eaten down to the roots; by next autumn it will have entirely recovered. I am compelled to let the cattle graze the tussac from want of hands and means to make different arrangements; nor do I consider any other plan a matter of sufficient moment in the present state of the colony to warrant the outlay requisite to economise properly this invaluable food. But in England, where labour is cheap, I would act differently; the cattle could be folded in an adjoining paddock to the field of tussac, and fed over the wall or fence by men cutting the tussac in bundles, commencing with the upper row and passing regularly through the field; by the time they had cut the last row, the first would be ready to cut again. Had such a plan been adopted by me in the island I mentioned above, I feel confident the 400 acres of tussac would have amply supplied the 800 head of cattle for twelve instead of six months. It is incredible how much is injured by being trodden down and eaten too close; and the horses, from preferring the root, do more mischief than the cattle. I ought to mention that the plant is of slow growth, and would probably be three years in coming to perfection, during which period, however, it might be cut annually with advantage. When once full-grown, it springs up rapidly after being cut down, the blades reaching their full height of 7 feet by the end of summer, though cut down in the spring. I kept up a favourite horse in a loose box one winter, and had him fed entirely on tussac, cut for him and given green. He ate it greedily, and was always in excellent condition; but as a general rule, I should consider it soft food for a horse doing any work. When it is remembered that this invaluable provision of nature thrives luxuriantly where scarcely any other vegetation will exist—that it is most nutritious, and much relished by cattle, it is impossible to resist feeling the most earnest desire to see it extensively tried in those portions of the United Kingdom which in climate and soil bear some resemblance to the Falkland Islands. I might easily expatiate on the extreme beauty of its vegetation, covering rocky storm-beaten promontories and small islands with a dark rich verdure, always reminding me of tropical luxuriance; but its importance in a practical point of view is what I am desirous of making fully known to all interested in agricultural pursuits."

Tussac, in its natural state, is generally found growing near the shore, and flourishes best where the saline spray dashes over it. Indeed, exposure to the sea-breeze, and the peculiar influences which emanate from the ocean, are conditions which seem essential to its prosperity. It is then only that it reaches its most stately proportions, and assumes that exuberant and imposing form, which have led one author to speak of it as the "splendid tussac-grass, the gold and glory of the Falklands." As it recedes from the ocean, it becomes dwarfed and sickly, as if out of its kindred and appropriate element, in this respect resembling our own native *Arundo arenaria*, *Triticum junceum*, and certain other gramineous plants. As with these also, and a considerable number of other species, the glaucous colour of the tussac grass may be regarded as indicating it to be a littoral plant; for it would seem as if many of the plants growing near the sea caught their hues, as they are known to acquire certain other of their properties, from the element in their vicinity. It is probable that the saline matter the plant derives from the spray and sea breezes, contributes not a little to

render it so palatable to cattle. The ground on which the tussac grass flourishes best is a wet peaty soil, often very bleak and poor, and scarcely capable of sustaining any other kind of herbage. "If the shore be bold, and the sea-bank high and rocky," says Lieut. R. C. Moody, in reference to the experimental culture of it in Britain, "I should choose the most exposed points. If the spray, but not the actual wave, dashes over it, so much the better. I do not think that sowing it in the shifting sand would answer in the first instance, though when the grass once takes root in any soil, the drift-sand blowing over it, amongst it, and almost burying it, does not seem to injure it. I would try some in the sand that has been fixed by the bent, but as near the sea as possible. The tussac loves the spray, and the finest plants are almost growing in the water. If the breezes from the sea carry a great quantity of moisture to the peat-bog behind the tract of sand, I conceive the tussac-grass would answer extremely well in it. We have tussac-grass growing on peat-bogs on exposed islands in the Falklands, in places 800 and 1000 feet above the sea; but these sites are exposed to the westerly gales, which are laden with moisture. Some of the finest young plants I have seen grew from seed sown in rich mould in my garden, 300 yards from the shore of a deep inland harbour, and protected from the winds by a high turf wall. This artificial mode seems to contradict what I before stated. Nature prefers the first-mentioned places; but as the latter is a fact, I would recommend both to be tried. In the garden, I was so successful with the plants from seed, that I proceeded to transplant suckers from the wild ones on the rocky shore to the rich mould in the garden, and I found them to thrive vigorously. I took suckers from these again, also from the plants raised by seed, and planted out more rows. Every plant answered admirably. I cut them down, and they grew more bushy and spread, throwing out fresh suckers; and I could soon have filled a paddock with the plants. In laying out a piece of ground for tussac-grass, the following circumstances must be borne in mind:—the plant grows in bunches occupying from 2 to 3 and sometimes even 5 feet in diameter, and the blades of grass when full-grown are 7 or 8 feet long. The roots seem forced up from the ground, and I have been in patches of fine full-grown tussac in which a man on horseback is almost concealed. I should therefore sow the seed in rows 2 feet apart, some in a garden, and some on exposed points of peaty soil close to the sea, and within reach of the spray, carefully weeding between the plants as they grow up. When they are 9 inches or a foot high, the suckers might be separated and planted out 3 feet apart in rows. As the plants grow large, every alternate row should again be planted out, in order to leave room for a man, cow, or horse to pass between the rows without treading down the plants. To raise from seed appears a more uncertain and much slower method than that of planting out suckers from the finest plants." A coloured figure of tussac is given in *Plate XXI.*

TUSSILAGO. See Colt's Foot.

TUTSAN. See Hypericum.

TWAYBLADE,—botanically *Listera.* A small genus of curious, indigenous, perennial-rooted, annual-stemmed herbaceous plants, of the orchis order. The ovate-leaved species, *L. ovata*, called by some botanists *Neottia latifolia*, inhabits woods, groves, and other shady places; and has a height of about a foot; and carries green-coloured flowers in May and June. The heart-leaved species, *L. cordata*, inhabits moist heaths; and has a height of about 3 or 4 inches; and carries brown-coloured flowers in June and July. Both species may be cultivated in the garden in a mixed soil of loam and peat, and are propagated by division of the root.

TWEEDIA. A genus of ornamental, exotic, twining plants, of the figwort family. The blue-flowered species, *T. cærulea*, was introduced to the greenhouses of Britain about 13 years ago from Buenos Ayres. Its root is fibrous; its stem is slender, twining, scarcely branching, somewhat woody, and about 6 feet high; its whole surface, except the upper lamina of the corolla, is clothed with whitish downy hairs; its leaves are opposite, petiolate, cordate-lanceolate, entire, from 1½ to 2 inches long and ½ an inch broad; its inflorescence is umbellate, with from 3 to 5 flowers in each umbel; and its corolla is rotate and five-parted, and has a pinkish colour on the under surface, and a fine sky-blue colour on the upper surface. When the plant is trained to a neat trellis in a sunny exposure, the effect of its beautiful flowers is extremely fine. The plant loves a soil of sandy loam, and may be propagated from cuttings. A dye similar to indigo might probably be obtained from its flowers.

TWITCH. An instrument used for holding a horse in restraint and making him stand quiet during a surgical operation. It is made by fixing a noose of cord to the end of a stick; and is put on the horse's upper lip and twisted rather tight.

TWITCH-GRASS. See Couch-Grass.

TYLOPHORA. A genus of ornamental, exotic, evergreen twining plants, of the swallow-wort family. Three species, all about 10 or 12 feet high, blooming in June and July, loving a soil of peaty loam, and propagable from cuttings, have been introduced to British gardens from India and Australia; and two or three more are known. The name tylophora signifies "wart-bearing," and alludes to the leaves of the corolla.

TYPHA. See Cat's-Tail.

TYPHUS FEVER. See Fever.

U

UDAL TENURE. An old and peculiar local tenure in Orkney and Shetland. A proprietor of land holding by this tenure pays certain duties to the lessee of the crown-rents and granter of the bishop's rents, and pays also his proportion of any general tax which is levied on the kingdom, but requires no other title to his property than mere possession, certified in the rental book of the lessee of the crown-rents. But holders by udal tenure long ago began to find their seeming privilege a serious evil, and were glad to exchange it for a system of regular charters and sasines.

UDDER. The glandular organ of a cow, a mare, an ewe, or other female mammal which secretes milk. The udder of the cow is an unique mass, composed of two symmetrical parts, simply united to each other by a cellular tissue, lax, and very abundant; and each of the parts comprises two divisions or quarters, which consist of many small granules, and are connected together by a compact laminous tissue; and from each quarter proceed systems of ducts, which form successive unions and confluences, somewhat in the manner of the many affluents of a large river, till they terminate in one grand excretory canal, which passes down through the elongated mammilary body called the teat. Its lactiferous tubes, however, do not, as might be supposed, proceed exactly from smaller to larger ducts by a gradual and regular enlargement, because it would not have been proper that the secretion of milk should escape as it was formed, and therefore we find an apparatus adapted for the purpose of retaining it for a proper time. This apparatus is to be found both in the teat and in the internal construction of the udder. The teat resembles a funnel in shape, and somewhat in office; and it is possessed of a considerable degree of elasticity. It seems formed principally of the cutis with some muscular fibres; and it is covered on the outside by cuticle, like every other part of the body; but the cuticle here not only covers the exterior, but also turns upwards and lines the inside of the extremity of the teat, as far as it is contracted, and there terminates by a frilled edge, the rest of the interior of the teats and ducts being lined by mucous membrane. But as the udder in most animals is attached in a pendulous manner to the body, and as the weight of the column of fluid would press with a force which would, in every case, overcome the resistance of the contractions of the extremity, or prove oppressive to the teat, there is, in the internal arrangement of the udder, a provision made to obviate this difficulty. The various ducts, as they are united, do not become gradually enlarged, so as to admit the ready flow of milk in a continued stream to the teat, but are so arranged as to take off, in a great measure, the extreme pressure to which the teat is exposed. Each main duct, as it enters into another, has a contraction produced, by which a kind of valvular apparatus is formed in such a manner as to become pouches or sacs, capable of containing the great body of the milk. In consequence of this arrangement, it is necessary that a kind of movement upwards, or lift, should be given to the udder, before the teat is drawn, to force out the milk, and by this lift the milk is displaced from these pouches, and escapes into the teat, and is then easily squeezed out; while the contractions or pouches, at the same time, resist in a certain degree the return or reflux of the displaced milk. This valvular arrangement is thus a very beautiful combination of exquisite mechanism with organic functions; and readily explains why a series of lifting actions is requisite in the artificial milking of the cow, why the calf, the lamb, and the colt jerk up their nose into the udder, and why the pig and the puppy push up the teat with their feet. The comparative smallness of the mare's udder, and its having only two teats instead of the four of a ruminant, seem to be a benign provision for facilitating her speed of motion and severity of labour, and are amply and beautifully compensated by the special adaptation of the qualities of the milk to the wants of the foal.

Inflammation in the cow's udder is a somewhat common disease, and frequently assumes a very severe character. One cause of it is the simple but roguish practice of allowing the milk to accumulate excessively in the udder, when about to send cows to market, with a view of making them appear greater milkers than they really are. The consequence of this 'hefting,' as it is termed, is a painful distention of the vessels; and this is frequently followed by inflammation, which attacks either the glandular structure or the cellular substance by which it is united. In the first case, the disease generally attacks the whole of one quarter, or it may extend to the half or whole of the udder, and is always sudden in its attacks, rapid in its progress, and dangerous and obstinate in its effects. The quarter or whole of the udder becomes suddenly hot, painful, and hard to the touch; there is a degree of symptomatic fever present; the secretion of milk is par-

tially or completely suspended; and if any is formed, as sometimes occurs in mild cases, the milk is either mixed with curd, is like whey, is bloody, or, instead of either, there is pus; these different states of the secretion varying according to the intensity of the inflammation, or the length of time it has existed.—Another cause is the coarse mode of milking,—the method of tearing and tugging at the teat,—which is practised by some dairy-maids. In this mode of milking, the operator does not imitate the principles which instinct has taught the calf, and which depend on the valvular structure of the lactiferous outlets of the ducts; but she merely dips her hand into a little milk, and, by successively stripping the teat between her fingers and thumb, unloads the udder; and she in consequence more or less irritates the teat, and renders it liable to cracks and chops, which are followed by inflammation, extending to the rest of the quarter. This accounts for the disease occurring more frequently among the cows under the charge of one milker than it does in those under the charge of another; and as this practice is more common in some parts of the country than in others, it also accounts for the disease being more common in these parts.—Another set of causes is the excited state of the constitution about the period of parturition, the arousal of the sympathy which exists between the udder and the uterus, the shock and struggle of the glandular powers of the udder at the commencement of the process of secreting milk, the retention of the placenta beyond a due period after parturition, and the derangement of the organs of digestion, specially about the time of parturition, but generally also at any other period.—Other causes are travelling with a loaded udder soon after parturition, lying on a rough hard surface, the virus of cow-pox, and various external injuries, such as wounds, blows, and bruises.

"In all cases of inflammation of the cow's udder, with perhaps the exception of cases of it from external injuries," says Professor Dick, "the great object we must have in view, is to obtain resolution of the inflammation, which is the most favourable termination of it in almost every part; but we frequently find that the violence is so great, that instead of subsiding, mortification rapidly ensues, while in other cases, abscesses form in various parts of the udder. It will be found advisable, when the udder becomes inflamed, to abstract a quantity of blood from the animal, say from four to six quarts. This may be either taken from the neck or from the mammillary or 'milk veins,' as they are termed, and which run so conspicuously along the surface of the abdomen, as they proceed from the udder. A pound or a pound and a-half of Epsom salts should also be given, and the dose repeated if a full effect is not produced in from 12 to 18 hours, and fomentations of hot water as constantly applied as possible; and a sort of suspensory bandage would be found of service to relieve the pressure and weight, and may be used during the fomentations. An emollient poultice may be applied at night, composed of bran and linseed meal; or if the pain is great, decoctions of chamomile flowers may be used with the fomentations, and a hemlock poultice at night; and, should these means not seem to afford relief, some cooling lotion may be tried, as nitre and common salt, each 10 oz. dissolved in a quart of water, or 1 oz. Goulard's extract of lead, half a pint of vinegar, and a quart of water; or, when the more active inflammation has subsided, some discutient lotion may be used, such as ½ oz. muriate of ammonia, dissolved in water, vinegar, or spirits of wine, each 8 oz. and applied twice a-day. In these severe cases, the bleeding and physic should be freely repeated, and the poultices and fomentations continued until the inflammation is subdued, and the wounds have assumed a healthy appearance, and well healed up. It often happens that the disease is materially increased by the irritation arising from milking while the teat is chopped, or has cow-pox on it, and is in a state of inflammation; but although this is the case, the contents of the ducts must be removed, if there is any secretion, because when the secretion accumulates, it distends the parts, and thereby increases the disease. It is, however, often difficult to extract the fluid from the teat, more especially in those cases where it is sore, and from which probably the whole mischief has arisen, because the swelling interrupts the passage; or if the inflammation has not completely suspended the secretion, it produces a morbid one; and instead of a uniform fluid, there is a mixture of coagulated milk, or coagulum from the blood, which, from its thick curdled consistence, cannot pass through the opening of the teat; and which therefore serves to plug up the passage, and neither can pass itself, nor allow the thinner part of the secretion to pass. To remedy this, I have been informed that it is sometimes the practice to cut off the extremity of the teat; but this, while it may in some measure serve to relieve the inflammation of the quarter of the udder, evidently precludes the chance of a useful recovery of the part. It is therefore better to make a perpendicular incision in the teat, by which the matter may be discharged, and there will then be a chance of the teat healing up and fulfilling its function, should the secretion be restored. But as the inflammation is not in all cases alike active, it will be found that sometimes the curdled matter may be removed through the opening of the teat, with sufficient readiness to answer all the purposes required, and this may be done either by introducing a small silver probe or a canula."

ULCER. An abraded and morbidly secreting surface on any part of the body of an animal. It breaks down or wears away parts which become absorbed through the medium of the lymphatics,

and it always produces a discharge of pus or of some other morbid secretion. It may arise from one or more of many widely different causes; and may assume any one of many widely different aggregate characters; and must be treated, in each instance, according to its cause and character. It may be a simple ulcer, arising from a severe or neglected or mismanaged wound or bruise; or a sinuous ulcer, running under the integuments, and having a narrow but not callous orifice; or a fistulous ulcer running deeply, tubularly, and ramifiedly under the integuments, and having a narrow and callous orifice; or a fungous ulcer, covered with fungous flesh, and continuously reproducing it; or a putrid ulcer, more or less of the nature of gangrene or of an eating fetid sore; or a carious ulcer, depending on caries in a bone or a cartilage; or a glanderous ulcer, more or less identical with the disease of glanders in the horse; or a cancerous ulcer, more or less identical with canker in the horse's feet, or with phagadenic cancer in any part of the body of either the horse or any other animal. See the articles WOUND, ABSCESS, FISTULA, FUNGUS, CARIES, GANGRENE, GLANDERS, FARCY, and CANCER.

The simple recent ulcer of horses or cattle generally heals spontaneously, or with such easy aid as the application of tincture of myrrh, solution of alum, or some other mild astringent; but a foul chronic ulcer, whether it have or have not a fistulous character, is sometimes so stubborn as to require both skilful and very persevering treatment. "When ulcers have continued for a long time," says Delabere Blaine, with special reference to the horse, "it is often necessary to employ constitutional remedies to establish a cure. In full habits we increase the other secretions, as those of the bowels, the kidneys, the skin, &c., by purgatives, diuretics, and such remedies as act on the skin. We also lessen the excess of morbid secretion of pus, by establishing a new and artificial drain in the neighbourhood, which is done by setons or by rowels. In some cases, instead of existing plethora, the ulcer has occasioned or is accompanied by great irritability of system, which must be combated by opium, and other sedatives; or if debility become very apparent, tonics must be given, together with a liberal diet. In general cases, stable soiling, a coarse of carrots, or other total change of food, assists the healing and restorative process greatly. In general cases, the longer an ulcer has lasted, the more obstinately will the vessels have gained a diseased habit, and the more difficulty there will be to bring them back to a healthy state. The external means employed for this purpose are usually three,—stimulating injections, seton, or incision."

ULEX. See FURZE.

ULMIN. See HUMUS.

ULMUS. See ELM.

UMBEL. An inflorescence which has a number of flower-stalks diverging from a common centre like the rays of an umbrella, and bearing their flowers on their extremity, all at nearly one elevation. When each ray is undivided, so as to bear but one flower, the umbel is said to be simple; and when each ray is ramified, so as to divide into a number of pedicels, and to terminate in a number of flowers, the umbel is said to be compound. Familiar instances of umbellate inflorescence are the carrot, the parsnip, and the common hemlock.

UMBELLIFEROUS PLANTS, or UMBELLIFERÆ. A natural order of calyciflorous exogens, "one of the least attractive groups of plants," says Loudon, "and at the same time one of the most important to the world. They are not more useful as food, than they are dangerous as poison. While in their native ditches, they are often suspicious lurid weeds; but under the influence of cultivation, they lay aside their venom, and become wholesome food for man. They are generally recognised by their hollow stems and cut leaves, with what botanists call a sheathing petiole, that is to say, with a petiole the base of which wraps round the stem. Their flowers are mostly white or yellow; rarely, as in *Astrantia*, some species of *Caucalis*, and others, of a pink colour; or blue, as *Eryngium*. The inflorescence is umbellate; and their fruit consists of two ribbed portions, improperly called seeds, which are held together by a common axis, and a thickened discus. All are natives of damp ditches or way-sides, in cool parts of the world; in the tropics they are extremely rare. The simplicity of their structure, and uniformity of their appearance, have rendered their classification a matter of very great difficulty. It has been attempted in modern days by Sprengel, Lagasca, Koch, and Decandolle, all of whom have added much to our knowledge. The culinary and agricultural importance of many species is well known. The parsnip and carrot form a large part of the staple winter store of the inhabitants of Europe, as the *Arracachas* do of those of South America; and the Prangos of Thibet is supposed to be the most important and productive of any in the whole world, as a forage plant. The medicinal properties of Umbelliferæ are not more powerful than they are at variance with each other. While the seeds of some are aromatic and stimulating in the highest degree, the fresh roots and leaves of others are not less narcotic. This has been supposed to arise from the difference in the state of the sap in different parts of the plant; and it has been thought that the narcotic principle is only to be found in the ascending sap, while the aromatic stimulant properties are found in the juices which are fully elaborated and matured." A general rule of some value to persons but indifferently acquainted with botany—the more so as many of the most common wild Umbelliferæ of entirely opposite properties are so nearly alike in general appearance as to be readily mis-

taken for one another by the ignorant—is that those species which inhabit watery sites are usually poisonous, and those which inhabit high dry sites are usually wholesome; and so much does this rule hold that it may possibly suggest some explanation why certain species which are poisonous in their wild state become wholesome by cultivation, and why certain other species, such as *Œnanthe fistulosa* and *Œnanthe crocata*, are violently poisonous in some districts and comparatively or wholly innocuous in others. Two of the most remarkable instances of species which are poisonous in their wild state becoming wholesome and esculent by cultivation occur in the common celery and in *Œnanthe pimpinelloides*. Some of the most remarkable medicinal species are those which yield galbanum, opopanax, and asafœtida. Koch and Decandolle classify the Umbelliferæ into three suborders, according to the form of the seed. The smallest suborder, called Coilospermæ, has channelled seeds, and comprises only one tribe, represented by the genus coriandrum; the middle suborder, called Campylospermæ, has curved seeds, and comprises three tribes, represented by the genera caucalis, scandix, and smyrnium; and the largest suborder, called Orthospermæ, has straight seeds, and comprises eleven tribes, represented by the genera hydrocotyle, sanicula, ammi, seseli, angelica, peucedanum, tordylium, siler, cuminum, thapsia, and daucus. About a dozen hothouse species, upwards of 50 greenhouse species, and between 500 and 600 hardy species—nearly all herbs and belonging to upwards of 100 genera—at present occur in the gardens and wilds of Britain.

UMBILICUS. See Navelwort.

UMBRELLA-TREE. Two ornamental exotic trees of about 30 or 35 feet in height,—the one the *Magnolia tripetala*, a hardy, deciduous, white-flowered native of North America,—and the other the *Hibiscus guineensis*, a tropical, evergreen, purple-flowered native of Western Africa. Both occur in British collections.

UMBRELLA-WORT,—botanically *Oxybaphus*. A genus of curious exotic plants, of the order Nyctagineæ. About a dozen species, varying in height from 1 foot to 6 or 8 feet,—some evergreen erect herbs, others evergreen trailers, and others deciduous trailers,—some hardy and others requiring a little protection,—most purple-flowered and blooming in July and August,—have been introduced to British collections from various parts of North America; and the greater number love a soil of sandy peat, and require to be propagated from seed.

UNDER-DRAINING. See Draining.

UNDERWOOD. Shrubby, stunted, or coppice growths of forest trees,—either the literal 'underwood' of natural forests, or any kind of wood which is too small to be accounted timber. See the articles Coppice, Plantation, and Timber.

UNIOLA,—popularly *Seaside-Oat*. A genus of exotic grasses, of the fescue tribe. Four hardy perennial species, two of them about 4 feet in height, the other two less than 1 foot in height, and all blooming toward the end of summer, have been introduced to British collections from North America; but they do not possess any agricultural interest.

UNONA. A genus of ornamental, tropical, evergreen, ligneous plants, of the custard apple family. Nearly a dozen species, variously shrubs, climbers, and small trees, mostly brown-flowered, and all loving a soil of peaty loam, and propagable from cuttings, have been introduced to British hothouses from India and Guiana; and about 30 more are known. The esculent species, *U. esculenta*, a climber of 10 or 12 feet in height, introduced about 30 years ago from Madras, ranks in its native country as a fruit tree.

UNSOUNDNESS. See Soundness.

URANIA. A magnificent, evergreen, tropical plant, of the banana tribe. It naturally inhabits the sultriest forests of Madagascar; and was, a considerable time ago, introduced to British collections. It takes its name of urania, or "the heavenly plant," from the stately grandeur of its appearance; and it constitutes a genus of itself, and is specifically called *speciosa* or the showy. It attains a height of about 20 feet, and carries red flowers, and loves a soil of peaty loam, and is propagated from suckers.

URANIUM. One of the rare metals. It was discovered in 1789 by Klaproth, in the mineral called pitchblende, which is a compound of protoxide of uranium and oxide of iron. Uranium does not naturally occur uncombined; and though known to be a simple or elementary body, is not well understood in its detached state. The protoxide of it consists of one equivalent of the metal and one equivalent of oxygen, and has a very dark green colour, and most powerfully resists the action of heat, and forms green salts by combination with acids; and is employed in the arts for giving a black colour to porcelain. The peroxide of uranium consists of two equivalents of the metal and three equivalents of oxygen, and has a yellow or orange colour, and forms salts of a similar tint, and combines with alkalies as well as with acids, and suffers permutation into the protoxide by the action of strong heat, and is employed in the arts for giving an orange colour to porcelain. Sulphuret of uranium is formed by passing the vapour of bisulphuret of carbon over strongly heated protoxide of uranium, and has a dark grey colour, almost black, and suffers reconversion into the protoxide when heated in the open air.

URARIA. A genus of ornamental exotic plants, of the hedysarum division of the leguminous order. Six or seven species, varying in height from 1½ to 8 feet, carrying either purple or lilac or pink flowers in the latter part of summer, all but one evergreen shrubs, some of them having pinnate leaves, two or three paired, and a terminating odd leaflet, others having trifoliate leaves,

with the terminal ones petiolate, have been introduced to British gardens from India, China, Brazil, and Western Africa; and all love a soil of sandy loam and require to be propagated from seeds. Several were ranked by Linnæus and his immediate successors among the true hedysarums.

URATES. Salts of uric or lithic acid. This acid is a common constituent of urinary calculi; and always occurs in healthy urine, combined with some alkali; and is precipitated from urine by means of any acid which robs it of the alkali. It forms at first in brick-coloured crystals; but when pure, it is white, tasteless, and inodorous. It consists of 6 equivalents of carbon, 2 of hydrogen, 3 of oxygen, and 2 of nitrogen. It is insoluble in alcohol, and cannot be thoroughly dissolved in less than about 10,000 times its own weight of water at 60° Fahr. It reddens litmus paper, and combines with alkalies and alkaline earths and oxides, but does not effervesce with alkaline carbonates. It is decomposed by chlorine; and when acted on by nitric acid, it leaves a beautiful purple residuum, with distinct acid properties.

The principal urates, or pure salts of uric acid, are those of ammonia, potash, and soda. Urate of ammonia is soluble to a considerable degree in boiling water, but more sparingly in cold water. The urates of soda and potash, when neutral, are of very sparing solubility; but an excess of either of the fixed alkalies takes up a large quantity of the acid. See the articles Urea and Urine.

The urate of the manure market is an artificial fertilizer prepared by a Company in London; and ranks in some respects with special manures, and in others with factorial and patent ones. See the article Manure. It is a dry powdery substance; and is applied by the drill in the quantity of about 6½ cwts. per acre, and has the reputation of being a very powerful fertilizer, and acts with equal or at least similar effect on turnips, tares, rye, wheat, and winter barley. Two competent and credible experimentalists reported as follows respecting it in September, 1841: —"I applied it broadcast," said the one, "on two acres in the centre of a twelve-acre field of sandy land, at the rate of 6½ cwts., and at the cost of 33s. per acre. The rest of the field I dressed with bone-dust at the rate of two quarters, and costing 52s. per acre. Up to the present time, I perceive no difference whatever between the two, the whole field promising to be a very good crop. The turnips are drilled at 18 inches apart, and set out at the same distance." "I drilled a ton of urate upon 3 acres, in rows 17 inches apart," said the other, "upon a very hot gravelly soil. The adjoining portion of the field was manured, in the usual way, with 14 loads per acre of farm-yard manure. The turnips in the urate were fit to hoe 7 days before the other manured part; and from their first appearance, a stranger could point where the urate commenced and ended. The difference is still evidently in its favour; both portions were sown the same day. I certainly consider it a good artificial dressing, and that its fertilizing qualities are great."

URCEOLINA. A recently discovered genus of ornamental exotic plants, of the amaryllis order. The name alludes to the pitcher form of the flower. The pendulous species, *U. pendula*, has yellow and green flowers, and blooms in June, and was introduced to the greenhouses of Britain a few years ago from the Andes.

URE. The udder of a cow or ewe or other mammal. The word is provincial.

UREA. A chief and characteristic constituent of urine. It can be separated by a somewhat easy chemical process; and it forms into crystalline plates, which cross one another in various directions or assume the shape of four-sided prisms, and which are transparent, yellowish-white or almost colourless, and of a slight pearly lustre. It is viscid and difficult to cut; it has a faint fetid odour, similar to that of garlic or arsenic, and a strong and acrid taste, similar to that of ammoniacal salts; it leaves a sensation of coldness on the tongue, like that left by saltpetre; it attracts moisture from the atmosphere, and deliquesces into a thick brown fluid; it is very soluble in water, and evolves much cold during solution; it melts at a temperature of about 248° Fahr., and decomposes at a rather higher temperature, swelling up and evaporating with an insufferably fetid odour, and passing into carbonate of ammonia and cyanuric acid; it dissolves but does not decompose under the action of hydrochloric acid; and it effervesces and decomposes under the action of nitric acid, giving off nitrous, azotic, and carbonic acid gases, and leaving a residuum which is white and concrete, and which eventually shows traces of ammonia and prussic acid. It has a specific gravity of about 1·35; it consists of two equivalents of carbon, four of hydrogen, two of oxygen, and two of nitrogen; and it is the only animal compound, or animal organic secretion, which has yet been artificially formed. A pure aqueous solution of urea may be heated to the boiling point, or exposed to the atmosphere for several months, without undergoing any change; but an aqueous solution of it containing the other constituents of urine—in other words, aqueously diluted urine, or much more urine itself—decomposes by a temperature of 212 Fahr., or rapidly passes into putrefactive decomposition by exposure to the atmosphere, and is converted in either case almost wholly into carbonate of ammonia. A solution of soda, potash, lime, magnesia, or barytes also rapidly dissolves and decomposes urea, changing it principally into carbonate of ammonia. The decomposition of urea, in any ordinary way, therefore, whether as a constituent of urine or of guano or

of any other excrement, becomes a rich source of the nitrogenous element in the nutrition of plants. See the articles URINE, LIQUID MANURE, GUANO, and AMMONIA.

UREDO. A large genus of minute hypodermous fungi, of the eutophytous group, and coniomycetous tribe. Several species are identified with two of the worst corn diseases of our country; about 60 species produce on various plants of the gardens and wilds of Britain the diseases which are popularly called blight and rust and mildew; and many species occur in other countries, additional to those which occur in Britain. See the articles MILDEW, SMUT, and FUNGUS. Most of the species in Britain have either a brown, orange, or yellow colour; and the greater number appear and come to maturity in summer or the early part of autumn. Species of a pulverulent or finely powdery nature infest the leaves of ficaria, potentilla, bramble, and carex; species of a scattered nature infest the leaves of geranium, primrose, alchemilla, beet, armeria, hypericums, epilobiums, anthyllis, burnet, and various umbelliferæ; species of a spreading nature infest the leaves of polygonum, alchemilla, and various rosaceæ; species which grow in a spotted manner infest the leaves of sorrel, and various compositæ and scrophulariaceæ; species which grow in the manner of patches infest the leaves of sphondylium and the bean-plant; species which have the appearance of pustules infest the leaves of mint, luzula, and sallow; species which have a mottled appearance infest the leaves of sallow and rose; species which have a gyrose appearance infest the leaves of coltsfoot, mercury, and raspberry; species which have a bright or brilliant appearance infest the leaves of saxifrage, campanula, and purging flax; species which have a very minute appearance infest the leaves of dock, polygonum, vaccinium, oak, and equisetum; and species which have a different appearance from any of the preceding infest the leaves of common field thistle, willow, ragweed, rye, stinking iris, bellflower, periwinkle, cerastium, and various leguminosæ.

URENA. A genus of exotic plants, of the mallow family. Upwards of a dozen species,—some of them annuals, and others small evergreen shrubs,—some with leaves undivided or slightly three-lobed, and others with leaves deeply and sublobedly three-lobed or deeply and sublobedly five-lobed,—and most about 2 or 3 feet high, and carrying either red or purple or carmine-coloured flowers,—have been introduced to British gardens, principally from India and tropical America. The most interesting is the showy, *U. speciosa*, an evergreen shrub of about 3 feet high, carrying pink flowers in November, introduced in 1828 from Ava, loving a soil of sandy loam, and requiring to be propagated from cuttings.

URETERS. The ducts which convey the urine from the kidneys to the bladder. Those of the ox are considerably larger than those of the horse, and have a stronger internal membrane, and terminate nearer to the neck of the bladder and nearer to each other.

URETHRA. The membranous and muscular canal which conveys the urine from the bladder. In the male horse, it is of considerable length, but, though making a curvature in passing over the bones of the pubis, is seldom if ever obstructed; in the ox, it is at once long and narrow and curved, and is frequently obstructed by calculi; and in mares and cows, it is very wide and short, and easily admits of an artificial withdrawal of retained urine by means of introducing the finger and keeping the neck of the bladder open. See the articles CALCULUS and LITHOTOMY.

URIC ACID. See URATES.

URINARY CALCULI. See CALCULUS.

URINE. The excrementitious liquid which is separated by the kidneys and collected in the bladder and expelled through the urethra of animals. It does not serve any ulterior purpose in the animal economy; but it is entirely an excrement, and simply consists of substances which are not wanted in the system, and whose accumulation or retention would disturb the health or endanger or destroy the life. It therefore is exceedingly compound; and contains various saline principles, animal earths, and highly azotised peculiar principles; and is necessarily a very powerful fertilizer. It widely varies in composition in different species of animals, in different states of health, under different kinds of regimen, and according to the kind and quantity of liquid received into the stomach; and it widely varies, also, in comparative quantity within any given period, and in the comparative degree of its concentration or dilution. A normal or very healthy specimen of it from the human subject is transparent, limpid, and of an amber colour; and has a saline taste, and a specific gravity of about 1·03; and, while warm, emits a slightly aromatic and not disagreeable odour; and gives a red tint to litmus paper, evincing the presence of a free acid or of a super-salt; and, after standing a few hours, makes a perceptible deposit of insoluble matter, and throws up a scum or light floating cloud of mucus and of super-urate of ammonia. Most other urine, except such as is either very morbid or excessively diluted, possesses similar chemical characters, and has a thicker consistency than water, and ranges in specific gravity at from 1·005 to 1·033; and all urine, no matter how healthy, soon begins to putrefy on exposure to the atmosphere, becomes turbid and dark-coloured, emits first an urinous odour and afterwards an alkaline and very offensive fetor, loses its acid reaction, deposits the earthy phosphates, and gradually generates a large quantity of carbonate of ammonia; and it undergoes similar changes by continuous boiling, and owes them in either case principally to the decomposition of its urea. See

the article Urea. The study of the multitudinous, intricate, great, and widely diversified changes which are made on the normal chemical composition of human urine by jaundice, dropsy, diabetes, inflammatory affections, and more or less by almost all other diseases which in any way affect the blood or the intestinal secretions, is an interesting example of the application of chemistry to the pathology and the practice of medicine, and has of late years been prosecuted to limits which have afforded valuable instruction to even intelligent and highly experienced physicians; and the same kind of study might no doubt be pursued, with very eminent advantage, in veterinary medicine.

Urine is employed in making phosphorus, sal-ammoniac, and carbonate of ammonia; and is mixed with the earths and composts of nitre beds; and, in a putrid state, is very useful in scouring woollens. But its grand use is in the capacity of a manure; and here it is vastly more valuable than most small cultivators or even many intelligent farmers are at all aware. Several of the most distinguished agricultural chemists have estimated that 90·9 parts of cows' urine or 55·95 parts of human urine or 15·3 parts of horses' urine ought to produce as great fertilizing effects as 100 parts of ordinary farm-yard manure; and Liebig relates that one hundred parts of wheat grown on a soil manured with cow-dung afforded only 11·95 parts of gluten and 62·3 parts of amylin or starch, while the same quantity grown on a soil manured with human urine yielded the maximum of gluten, namely 35·1 per cent., or nearly three times as much as the other. And although the expense of collecting urine manure and of conveying it to the field is considerably greater than that of collecting and carrying farm-yard manure, yet the difference is more than counterbalanced by the general and uniform distribution of the fertilizing principles upon the soil. But we have elsewhere discussed the whole question of economizing and using urine as a fertilizer, either by itself, or in dilution with water, or in several methods of chemical preparation, or as a basis of compound liquid manures, or as an ingredient in solid or semifluid composts; so that, in the sequel of the present article, we need only to discuss separately the qualities of the chief kinds of urine which are at the farmer's command; and this we shall do principally with the aid of Dr. Sprengel's Essay on Animal Manures. See the articles Liquid Manure, Excrement, Manure, and Farm-Yard Manure.

The urine of cattle, when fresh, has a yellow colour, occasioned by a small quantity of resinous colouring matter; but on standing a longer time exposed to the air, it assumes a brown, and even, at last, a black colour. This is to be ascribed to the formation of humic acid, from the organic bodies which are passing into decomposition. In summer, fresh urine of cattle always contains a portion of ammonia, while in winter it does not possess a trace of it; hence we see that in hot weather the urea, which is the principal source of ammonia, undergoes decomposition while remaining in the animal body. Urine which has been exposed for a year and a half in contact with the air no longer contains any organic remains, but salts only, or mineral bodies dissolved in water; yet it is still endued with strong manuring properties. When urine is applied, in its fresh state, to living plants, it either speedily destroys them, or brings them into a sickly condition,—an effect resulting partly from the excess of caustic ammonia which it contains, and partly from the decomposition of the urea. We therefore allow the urine to become putrid before making use of it, in order that the urea may be decomposed, and the caustic ammonia converted into the state of carbonate, humate, or acetate of ammonia. The urine of oxen has already been many times chemically investigated; and its component parts are found naturally to vary, as in the case of solid excrementitious matter, according to the food given to the animal. Brande was the first who investigated it; and he found that 100 parts, by weight, were composed of 68 of water, 4 of urea, 4 of carbonate of ammonia, 6 of sulphate of potash, 15 of muriates of ammonia and lime, and 3 of phosphate of lime. This analysis, however, is certainly incorrect; for there is never found in urine which still retains urea, and has, accordingly, undergone only a partial putrefaction, an amount of 32 per cent. of solid matter. When urine, on the contrary, stands exposed for a long time in contact with the air, the amount of water it contains is diminished by evaporation, and the proportion of the solid matter becomes then naturally greater. Now, such urine may probably have been that which Mr. Brande examined. He has, however, overlooked many other bodies occurring in this fluid, particularly soda and lime. According to Sprengel's more careful analysis of the fresh urine of cows fed in a pasture abounding with good nourishing grass, several kinds of clover and vetch, a mixture of field fennel and plantain, much dandelion, hawkbit, and a great proportion of common daisy, 100,000 parts, by weight, were found to be composed of 92,624 of water, 4,000 of urea, along with some resinous colouring matter, 10 of albumen, 190 of mucus, 90 of benzoic acid or hippuric acid, 516 of lactic acid, 256 of carbonic acid, 205 of ammonia, 664 of potash, 554 of soda, 405 of sulphuric acid, 70 of phosphoric acid, 272 of chlorine, combined with soda, lime, and magnesia, forming salts, 65 of lime, 36 of magnesia, 2 of alumina, 4 of oxide of iron, 1 of oxide of manganese, and 36 of silica. But all the acids and the chlorine were in combination with the alkalies and the alkaline earths, forming salts. Cattle urine contains in winter very much less, often scarcely half the quantity of urea found in Sprengel's

analysis, and is then, of course, much less valuable as manure. It also contains less manuring matter the more water the cows drink,—a circumstance to which attention must be paid. In summer, it passes very quickly into a state of putrefaction, and much ammonia is consequently developed in the form of gas; likewise carbonic acid, and a portion of sulphuretted and phosphuretted hydrogen, which likewise partly assume the gaseous state. The last two gases are the cause of the intolerable odour of putrefying urine. The caustic ammonia arising in every case from the decomposition of the urea and the other organic bodies of urine which contain nitrogen remains partly dissolved in water, and is the substance through which urine not properly putrefied is so apt to injure plants. If, on the contrary, the urine remains a long time exposed to the air, the caustic ammonia absorbs from it carbonic acid, becomes mild, and the urine may then be employed without danger as a manure for vegetation. That the putrefied urine actually contains much carbonic acid combined with the ammonia, we find by mixing it with mineral acids, when strong effervescence ensues. Another analysis by Sprengel of cattle urine which had been exposed to the air for a month to putrefy, and had lost very little by evaporation, exhibited the following as the composition of 100,000 parts by weight:—95,442 of water, 1,000 of urea, along with a portion of resinous colouring matter, 0 of albumen, 40 of mucus, 250 of benzoic or hippuric acid, 500 of lactic acid, 1 of acetic acid, 165 of carbonic acid, 487 of ammonia, occurring partly in an uncombined state, 664 of potash, 554 of soda, 338 of sulphuric acid, 26 of phosphoric acid, 272 of chlorine, 2 of lime, 22 of magnesia, 1 of sulphuretted hydrogen, 5 of silica, 1 of oxide of iron, and 180 of sediment consisting of phosphate and carbonate of lime and magnesia, alumina, silica, and oxide of iron, and oxide of manganese. Thus, if the urine of cattle, which has been putrefying for a month, contains more than as much again of ammonia as urine in its fresh state, it would obviously have contained a still greater proportion if some of it had not evaporated during the time; and that this escape of the gas actually did take place was made evident, not only from the smell, but also on the application of chemical tests,—for instance, by holding muriatic acid near it, when a dense white vapour of sal-ammoniac, in every case, immediately ensued. The ammonia, which escapes in the form of gas, naturally occasions a direct and not inconsiderable loss of that element to which the putrefying urine owes its principal action as a manure; so that it is of importance to add to the decomposing urine some substance containing an acid principle, which not only combines with the ammonia as it becomes gradually developed, but also neutralizes it. See the article Liquid Manure.

When cattle urine is left for three months or longer in the tank, a considerable portion of the carbonate of ammonia formed in it is lost, for the carbonate evaporates as well as the caustic ammonia, though more slowly. A small quantity of carbonate of ammonia is also continually evaporating from urine even when mixed with water; and therefore when the caustic ammonia has been rendered mild by its conversion into carbonate, no time should be lost in applying it as a manure to growing plants. The escape of the volatile ammonia, however, is prevented the most completely when the urine is mixed with humus, and then either left to putrefy or laid on the field and immediately ploughed in. Urine, five or six months old, contains not a trace of its original urea, mucus, and albumen; on the other hand, there are found in it carbonate, sulphate, and humate of ammonia, humates of lime and magnesia, common salt, and also some benzoate, lactate, and acetate of ammonia. The lactic, acetic and benzoic or hippuric acids, belonging to the class of organic bodies, do not injure vegetation, being united to the ammonia, and therefore in some measure incorporated as inorganic matters.—If urine has not been mixed with water, and contains a certain quantity of solid excrement, it is said to be a sign that it has acquired its proper maturity in the tank when no further scum or froth arises to the surface even when the liquid is stirred up. No doubt, this is a certain proof that the fermentation of the urine is completed, and that it may now be applied without injury to growing vegetables; for the scum, or bubbles, are occasioned by the carbonic acid, which cannot even begin to escape until it has saturated all the ammonia present. Still, although urine which froths no longer contains caustic ammonia, and consequently is no longer injurious to vegetable life—how much ammonia up to the moment when this is the case has escaped in the form of gas, and how much of the choicest manuring element has been up to that point lost by the urine! On this consideration we should at once hasten to convey the urine as fresh as possible to the field, but to a field which has no crop on it. In fact, whoever is obliged, for want of straw, to collect the urine separately,—whoever, if he be compelled to do this, mixes no water with it, or who fails also to employ some neutralizing substance to combine with the ammonia which is produced in so great a degree during the summer, suffers a loss of manure which exceeds all belief! It is indeed only a gaseous substance, and not a solid material visible to the eye, which thus escapes and is lost; but for all that it is of greater importance to the nourishment of plants than perhaps any other portion of the excrements.

Sheep drink very little water, and therefore void comparatively little urine; yet even when they take no drink whatever, the water of their urine and that found in their solid excrements

is greater in amount than what existed originally in their food; so that as they likewise breathe out water in the form of vapour from their lungs, and evaporate it through the skin, they must produce water chemically from oxygen and hydrogen during the process of digestion. Their urine, on account of its small amount, is never collected and used by itself, but is always taken up by the litter, and applied to the land along with the solid excrements; and though not belonging to circumstances to which much attention is devoted in agriculture, it is nevertheless interesting to learn its component parts. Sprengel several times submitted it to a superficial chemical analysis, and found that it is more abundant in salts than the urine of the cow, without, however, containing so many substances possessing nitrogen; and that 100,000 parts by weight of the fresh urine of sheep kept at grass, and which, when tested, was found to indicate neither acid nor alkaline properties, contained 96,000 parts of water, 2,800 of urea, along with some albumen and colouring matter, and 1,200 of salts of potash, soda, lime, and magnesia, with traces of silica, alumina, iron, and manganese. Sheep urine, therefore, contains 4 per cent. more water than cattle urine; but possessing a tolerable quantity of urea, it passes quickly into decomposition, and developes, in consequence, much ammonia,—a fact which explains the occurrence of the strong ammoniacal smell in the places where sheep are kept; this smell being much increased, however, by the ammonia likewise produced in the decomposition of the solid excrements, which contain much nitrogen, and by the exhalation of a certain degree of ammonia through the skin of the sheep. The ammonia thus formed naturally evaporates the sooner when the manure is deficient in moisture, which would retain it. Hence it is obvious how great a quantity of the ammonia of this very valuable manure is lost in the ordinary management of the dung when sheep are kept in houses.

Horses drink less water than cattle; and as they lose at the same time much moisture by evaporation through the skin, they also discharge much less urine. According to Fourcroy and Vauquelin, their urine contains 94 per cent. of water, 0·7 of urea, 2·4 of benzoate of soda, 0·9 of carbonate of soda, 1·1 of carbonate of lime, and 0·9 of muriate of potash. This analysis, however, as can be easily proved, is not quite correct; for it ought to comprise small proportions of mucus, albumen, magnesian salts, phosphate of lime, colouring matter, and some other less important substances. Since horse urine contains much less nitrogenous matter than cattle urine, it has much less value as a manure; and on account of its small amount it is never worth the trouble of being collected and employed by itself, but is brought to the soil in mixture with the solid excrement and litter. The circumstance of the urine of the horse containing so few substances united with nitrogen explains to us how it happens that in the solid excrements there are found so many of these bodies. The nitrogen derived by the body from the food is again, however, partly lost by evaporation through the skin, combined with hydrogen, and forming ammonia; the perspiration of the horse always having, from this cause, an ammoniacal odour.

The urine of hogs is more copious than that of any other domesticated animals, in consequence of their using a comparatively large quantity of liquid food; and it acquires in putrefaction the most intolerable odour, occasioned by a peculiar volatile substance, at present imperfectly known; and it is this substance probably which communicates the unpleasant flavour to esculent roots. According to Sprengel's investigation, 100,000 parts, by weight, of the urine of pigs fed on corn offal, consisted of 92,600 of water, 5,640 of urea, with a very little mucus, albumen, and colouring matter, and 1,760 of salts, as common salt, muriate of potash, gypsum, carbonate of lime, and sulphate of soda. It results from this analysis, that the urine of the pig contains rather a smaller proportion of water than the urine of cattle, and $1\frac{1}{2}$ per cent. more of urea; and this circumstance perfectly explains the reason of its being more caustic in its fresh state than that of cattle, a larger supply of ammonia being created out of the greater amount of urea; so that before the urine of the pig can be applied with propriety to growing plants, it must have undergone putrefaction. To prevent, however, an useless escape of the ammonia, it will be very advisable to dilute it with a good deal of water before exposing it to putrefy, or to proceed with it as already recommended in the case of cattle urine. The ill effects of pig urine, not properly putrefied, are commonly ascribed to the presence of a peculiar acidity; but they arise from no other cause than the caustic ammonia. When this urine is conducted, as is generally the case, into the manure pit, a great loss of manuring matter, in the form of gas, always takes place; and it is, therefore, the best plan to convey it by itself into a tank, and mix it with a large quantity of water. For this plan, however, a judicious arrangement of the sty is necessary; and, if situated near the cattle-stalls, the urine of the pig can be led to that of the cattle, and there allowed to putrefy. It is maintained that, when the urine of the pig gets into a pond containing fish, it kills them: should this actually be the case, the effect would probably be occasioned by sulphuretted hydrogen, resulting from the decomposition of gypsum, and constituting a gaseous poison, to the action of which fishes are very sensible, and of which a very small quantity is required to kill them instantly.

Human urine contains rather more water than that of cattle; and as it also holds less urea and

other manuring elements, it is not quite so valuable. It has often been the subject of most accurate chemical investigations for medical and pathological objects; and these investigations are available for the farmer, showing as they do the value of this fluid for agricultural purposes, and how it must be treated in order to derive from it the greatest possible advantage. In the vicinity of great cities, it is always to be had at a cheap rate and in great quantities. According to the investigations of Berzelius—who does not, however, state the kind of food taken—100·000 parts by weight of human urine contain 93·300 of water, 3·010 of urea, 1·714 of salivary matter, osmazome, lactic acid, and lactate of ammonia, 0·032 of mucus of the bladder, 0·100 of uric acid, 0·165 of phosphate of ammonia, 0·150 of muriate of ammonia, 0·371 of sulphate of ammonia, 0·316 of sulphate of soda, 0·445 of common salt, 0·294 of phosphate of soda, 0·100 of phosphates of lime and magnesia, with a trace of fluate of lime, and 0·003 of silica. Besides these substances, certain portions of the following have also been found in human urine,—albumen, gelatine, a resinous substance, colouring matter, fat, acetic, benzoic, and carbonic acids, sulphuretted hydrogen, muriate of lime, and oxide of iron. It passes like the urine of other animals into rapid decomposition, developing much ammonia. It would therefore be very injudicious not to take care to secure the ammonia in combination, as in the case of cattle urine; and this may be accomplished either by dilution with water, or by the addition of sulphuric acid, sulphuric acid salts, or humic acid. Mixture with earth abounding with humus, when such earth can be obtained, is always the best; and for this purpose the earth may be laid in heaps, and the urine poured over them until the whole of the humic acid is neutralized by the ammonia which forms, —a point which can easily be ascertained by the smell, for when neutralized, the ammoniacal smell is immediately perceived. The heaps should be frequently turned over and loosened, for the purpose of allowing the water to drain away. We may proceed in the same manner with cattle urine, and so obtain a manure, surpassing in its quality the best preparation of dung. In its unputrefied state, or at least so long as it still contains caustic ammonia, human urine cannot be applied with more impunity than cattle urine to green plants, as it immediately kills them, unless the soil should happen to abound with humic acid. If, therefore, we have no opportunity of allowing it to putrefy in mixture with some soil rich in humus, it can be applied only to the manuring of fields which have no crops growing on them.

URINE (Bloody). See Redwater.

URINE (Excessive Discharge of). See Diabetes.

URINE (Incontinence of). A continual dropping of urine, occasioned by the debilitated state of the neck of the bladder and of the bladder itself. The most frequent cause of it is excessive and prolonged distension of the bladder by excessive accumulation of urine, putting the muscular fibres of the bladder so severely on the stretch as permanently to weaken them, or to deprive them of their contractility. In the case of the horse, the best remedy, probably, is to turn him to grass; and when this cannot be done, he should be kept in a loose box on green food or on a moderate quantity of hay and water, and some bran mashes or a mixture of bran and oats. The only medicine likely to be serviceable to him is an iron tonic, accompanied in bad or obstinate cases with some tincture of cantharides.

URINE (Retention of). A want of power to evacuate urine. It arises either from loss of contractility in the muscular fibres of the bladder, or from inflammation or some other disease of the neck of the bladder. In the horse, it is occasioned sometimes by riding him for a considerable time and urging him forward, without allowing him opportunity to stale,—and sometimes by working him unduly hard, or not allowing him sufficient repose, or not affording him additional and frequent opportunities to stale, after having given him a diuretic ball. It may be ascertained to exist in the horse by introducing the hand within the rectum, and feeling the bladder to be distended. Everything must be avoided which tends to increase the secretion of urine; and if any degree of fever be present, blood must be taken and a dose of castor oil and a laxative glyster given; and if relief be not speedily enough obtained by these means, the urine must be artificially drawn off,—in the case of a mare, by introducing the finger or a short tube into the urethra and holding open the mouth of the bladder,—and in the case of a male horse, by passing a long, smooth, cylindrical piece of whalebone up the urethra as far as it will readily go, making an incision where the end of it is felt a few inches under the fundament, and through this incision introducing a catheter. A ball of opium, saltpetre, and camphor, in due quantities and proportions, mixed up with flour and syrup, may now be given; and, for some days, very little water must be allowed, and everything of a diuretic kind carefully avoided.

URINE (Suppression of). The partial or total cessation of the proper functions of the kidneys, so that very little urine or none is secreted. It arises sometimes from torpor in the kidneys, sometimes from inflammation in them, and sometimes from a gradual decay of their structure. See the articles Inflammation and Kidney. Gradual decay of the kidneys of the horse arises sometimes from the carrying of heavy loads, but more commonly from the improper use of strong diuretics; and is not indicated by any particular symptoms till it has made considerable progress; and then shows

itself by occasional retentions of urine, and by eruptions on different parts of the body; and, when it advances so far as to put a complete end to secretion, the animal soon dies.

UROPETALON. A genus of exotic, ornamental, bulbous-rooted plants, of the asphodel order. The name signifies 'tailed petal,' and is descriptive. Six species, varying in height from 8 to 24 inches, and mostly carrying greenish flowers in the latter part of summer, have been introduced to British gardens, principally from Africa; and they require frame or greenhouse protection; and love a soil of loamy peat, and are propagated from offsets.

URRY. A sort of blue or black clay, lying near a vein of coal.

URTICA. See Nettle.

URUS. See Ox.

URVILLÆA. A genus of ornamental, tropical, climbing plants, of the soap-berry family. Two species, the elm-like and the rusty, both white-flowered, and between 20 and 30 feet high, have been introduced to British gardens from South America; and they thrive best in a soil of sandy peat, and are propagated from cuttings.

USNEA. A genus of lichens, of the homothalamous tribe. Three species, varying in height from 2 to 4 inches, and all having a greenish colour, flourishing in winter, and inhabiting old trees, are indigenous in Britain; and one of these, *U. plicata*, of a pendulous habit, comprising a hairy variety, *U. p. hirta*, of a nearly erect habit, is sometimes used as a dye-stuff.

USTILAGO. A genus of minute fungi,—hypodermous, eutophytous, and coniomycetous,—nearly allied to the uredines. They have a burned or scorched appearance, and were originally identified with the cereal disease called burnt-ear, and may be regarded as more truly allied to smut than even any strict uredo. Five species occur in Britain; and infect the grains of wheat, the grains of barley, the fructification of some of the carices, and the herbage of the corn-field scabious and of various caryophylleaceæ; and they have either a black or otherwise very dark colour; and in most instances, make their appearance and come to maturity in the latter part of summer. See the articles Mildew, Smut, Fungus, and Uredo.

UTERUS. See Womb.

UTRICULARIA. See Hooded Milfoil.

UVARIA. A genus of ornamental, tropical, evergreen, ligneous plants, of the custard-apple family. Seven or eight species, chiefly erect shrubs of about 6 feet in height, but one a twiner of about 20 feet in height, have been introduced to British gardens from India; and they love a soil of peaty loam, and are propagated from cuttings. Most have brownish coloured flowers; and they take their name of uvaria from the circumstance of their fruit having some resemblance to bunches of grapes.

UVA URSI. See Arbutus.

UVULARIA. A genus of ornamental, hardy, perennial-rooted, annual-stemmed, North-American, herbaceous plants, of the melanthium family. Six species, varying in height from 6 to 15 inches, and chiefly carrying yellow flowers in May and June, have been introduced into Britain; and all love a soil of peaty loam, and are propagated from suckers. The earliest introduced may serve as a specimen of the whole. Its root comprises many thick fleshy fibres, and sends up several stems; its stems, for the most part, divide into two at a small height from the ground, and spread asunder; its leaves are connate, or surround the stem in a manner as if it went through them, and are broad-based, oblong, pointed, and smooth; and its flowers come out on slender footstalks from the bosom of the leaves, and hang downward, and comprise each six oblong, acutely pointed, yellow petals.

V

VACCINATION. See Cow-Pox.

VACCINIUM. A genus of ornamental, calyciflorous, ligneous plants, constituting, with the genus oxycoccus, the natural order Vaccinieæ. This order is nearly allied to the heaths; and is characterised principally by its inferior berry; and is diffused, in its natural state, throughout a large portion of Europe, Asia, and North America. Only four of its species belong to the genus oxycoccus. But two species of the genus vaccinium grow wild in Britain, nearly fifty have been introduced from other countries, and a few more are known. Two or three of the vacciniums in Britain are tender evergreen shrubs, a few are hardy evergreen undershrubs, and all the rest are hardy deciduous undershrubs, shrubs, or small trees. Several possess considerable reputation and value for sake of their esculent fruit; and almost all are beautiful or more or less elegant. Two or three of the best known are described in the articles Cowberry, Whortleberry, and Myrtle Bilberry. The majority thrive

best in a soil of peat, and the rest in a mixture of peat and loam. One or two are propagated most readily from cuttings, three or four from suckers, and all the rest from layers.

The most interesting, additional to those noticed in other articles, are the diffuse, *V. diffusum*, a hardy deciduous tree of about 20 or 25 feet in height, carrying pink flowers from May till July, and introduced from Carolina in 1765; the bear's grape, *V. arctostaphylos*, a hardy deciduous shrub of 10 or 12 feet in height, carrying white flowers from April till June, and introduced from Caucasus in 1800; the bushy, *V. dumosum*, a hardy deciduous shrub, of 3 or 4 feet in height, carrying white flowers in May and June, and introduced from North America in 1774; the pleasing, *V. amœnum*, a hardy deciduous shrub, of 6 or 8 feet in height, carrying white flowers in May and June, and introduced from North America in 1765; the Maryland, *V. marianum*, a hardy deciduous shrub, of about 2 feet in height, carrying white flowers in May and June, and introduced from Maryland in 1812; the Pennsylvanian, *V. pennsylvanicum*, a hardy deciduous fruiting undershrub, of about 20 inches in height, carrying white and blush flowers in May and June, and introduced from North America in 1772; the narrow-leaved or myrtle-like, *V. angustifolium*, a hardy deciduous small shrub, of about 2 feet in height, carrying pink flowers in April and May, and introduced from North America in 1776; the Madeira, *V. madeirense*, a hardy deciduous fruiting shrub, of 6 or 7 feet in height, carrying red and green flowers from June till August, and introduced from Madeira in 1777; the beautiful, *V. venustum*, a hardy deciduous shrub of about 3 feet in height, carrying pink flowers in May and June, and introduced from North America in 1770; the corymbose, *V. corymbosum*, a hardy deciduous shrub of about 8 feet in height, carrying white flowers in May, and introduced from North America in 1806; the glossy, *V. nitidum*, a hardy evergreen undershrub of about 20 inches in height, carrying pink flowers in May and June, introduced from Carolina in 1794, and comprising a decumbent variety, *V. n. decumbens*, of about only one half its own height; the frondose, *V. frondosum*, a hardy deciduous shrub of about 3 feet in height, carrying white and green flowers in May and June, and introduced from North America in 1761; the pale, the long-stemmed, and the white-flowered, *V. pallidum*, *V. stamineum*, and *V. album*, hardy deciduous small shrubs, about 2 feet high, carrying white flowers in May and June, and introduced from North America in 1772; the twiggy, *V. virgatum*, a hardy deciduous shrub, about 3 feet high, carrying pink flowers in April and May, introduced from North America in 1767, and comprising a variety, *V. v. angustifolium*, with narrow leaves and white flowers; the resinous, *V. resinosum*, a hardy deciduous shrub, 3 or 4 feet high, carrying purple and green flowers in May and June, introduced from North America in 1772, and comprising three varieties, with viridescent, rubescent, and yellowish flowers; the myrsine-leaved, *V. myrsinites*, a hardy evergreen undershrub, about 20 inches high, carrying pink flowers in May and June, introduced from Florida and Carolina, and comprising two varieties with respectively lanceolate leaves and obtuse leaves; the myrtle-leaved, *V. myrtifolium*, a slightly tender evergreen trailer, about 10 or 12 inches high, carrying white flowers from May till July, and introduced from Carolina in 1812; the earth-spread, *V. humifusum*, a hardy, very handsome, very small evergreen trailer, only 2 or 3 inches high, carrying white flowers in May, and introduced from the Rocky Mountains in 1827; and the meridional, *V. meridionale*, a tender evergreen small shrub, about 2 feet high, carrying white and green flowers from March till June, and introduced from Jamaica in 1778.

VAGS. Turfs cut and dried for fuel. The word is provincial.

VALANTIA. A genus of hardy herbaceous plants, of the madder family. The crosswort species, *V. cruciata*—called by some botanists *Galium cruciatum*,—is a perennial-rooted, trailing native of Britain, about 15 or 20 inches high, carrying yellow flowers in May and June. Five annual species, and five perennial-rooted trailing ones, all with flowers of more or less of a herbaceous colour, have been introduced to Britain principally from Continental Europe; but they do not possess much interest, otherwise than as being near akin to the bedstraws and the true madders.

VALERIAN,—botanically *Valeriana*. A genus of ornamental, calyciflorous, herbaceous plants, constituting the type of the natural order Valerianaceæ. This order is intermediate in botanical character between the teazel and the madder families; and consists of small, neat, symmetrical herbs, many of which are more or less suitable for the parterre, and some useful for either culinary or medicinal or economical purposes. One or two greenhouse species and upwards of 50 hardy ones, belonging to the genera valeriana, valerianella, patrinia, fedia, and centranthus, occur at present in British collections. Three indigenous species, nearly 20 introduced exotic species, and about 50 known unintroduced species belong to the valerian genus; and excepting one biennial and one tuberous-rooted perennial, all the introduced species are fibrous-rooted, annual-stemmed perennials. Most thrive well in any common soil; and all are propagated by division of the plant.

The officinal valerian, or great wild valerian, *V. officinalis*, is a perennial-rooted, annual-stemmed indigen of many parts of Britain. One variety of it inhabits woods and marshy grounds, and another inhabits high pastures and heaths; and the latter is superior to the former in medicinal power. The roots comprise long and slender

fibres issuing from heads; the stems are cylindrical, grooved, hollow, and 3 or 4 feet high, and terminate in flowering branches disposed crosswise; the leaves are opposite, connate, pinnate, bearded at the base below, largest at the bottom of the stem, and of decreasing size toward the summit; the leaflets are serrated, deeply veined, dark green above, and paler below, and the terminal one is a little larger than the rest; the flowers grow in corymbs, and are small, odorous, and interspersed with lanceolate, bearded, pale bracts, and have a flesh-coloured tubular corolla, with five reflected, obtuse, marginal segments, and bloom in June and July; and the capsule is crowned with feathery down, and contains one oblong-ovate, compressed seed. The root is the part used in medicine; and is best in plants which grow wild on calcareous soil; and should be dug up at some time during the autumnal and hybernal repose of the plant. It loses three-fourths of its weight by drying. It has a warm, bitter, subacrid taste, and a strong, peculiar odour, which is highly attractive to cats, but decidedly unpleasant to most human beings. It contains gum, starch, extractive, resin, a very thin greenish-white volatile oil, and a large proportion of woody fibre; it surrenders its active matter to alcohol, boiling water, and solution of the pure alkalies; and it is converted by a small dose of nitric acid into resin, and by a larger one into oxalic acid. It possesses antispasmodic, tonic, and emmenagogue properties; and acts well upon the human subject in cases of hysteria, hemicrania, hypochondriasis, symptomatic epilepsy, and other affections connected with morbid nervous susceptibility; but it is of little use to the farrier, except perhaps as an antispasmodic,—and not of much in even that capacity.

The dicœcious or small marsh valerian, *V. dioica*, is a perennial-rooted indigen of marshes and moist boggy meadows in many parts of Britain. Its stem is from 6 to 12 inches high; its leaves are entire; and its flowers are flesh-coloured, and have short blunt spurs, and bloom from May till July.

The Pyrenean or heart-leaved valerian, *V. pyrenaica*, is a perennial-rooted indigen of woods in various parts of Scotland. Its stem is furrowed and about 3 feet high; its cauline leaves are heart-shaped and serrated,—and the upper ones stand on downy foot-stalks; and its flowers are flesh-coloured or light rose-coloured, and have short spurs, and bloom in May and June. Its odour is similar to that of the officinal species.

The jatamansi valerian, *V. iatamansi*, a native of the mountains of Nepaul, is thought by some distinguished oriental botanists to be the precious spikenard of the ancients. Its root is fusiform, and about the thickness of the human finger, and bears on its upper part articulations so covered with dense fibres as to have somewhat the appearance of the tails of animals.

VALERIANELLA. See Lamb's Lettuce.

VALERIAN (Greek.) See Greek Valerian.

VALLESIA. A genus of ornamental, tropical, ligneous plants of the dog's bane family. Two species,—both white-flowered, summer-blooming, evergreen shrubs of about 3 feet in height,—have been introduced to British collections from tropical America.

VALLISNERIA. A genus of curious, floating aquatic plants, of the hydrocharis family. The spiral species, *V. spiralis*, is a native of the Rhone and of other rivers in Southern France and in Italy, and was introduced about 30 years ago to the botanical collections of Britain. It exhibits, in a very manifest and somewhat unique way, one of those exquisite contrivances which exist by the million in every department of creation, and evince the surpassing wisdom and provident care and infinite intelligence of the Almighty. It carries a large heavy flower, which requires always to float on the surface of the water, and would speedily perish either if much submerged or if left dry or pendulous; and it at the same time inhabits streams which are subject to great and sudden changes of volume, often alternately rising several feet above and falling several feet below their ordinary dimensions. The stem of the plant, therefore, though slender, is very long and of a spiral or cork-screw form, and so highly flexible as very easily to extend or contract; and it so readily and uniformly lengthens with the rise of the water and shortens with its fall, that the head or flower constantly and neatly lies on the surface.

VALLOTA. An ornamental, bulbous-rooted, South-African plant, of the amaryllis family. It was introduced to the greenhouses of Britain about 75 years ago; and it formerly ranked as a true amaryllis; but it now constitutes a genus of itself with the specific name of *purpurea* or the purple. It has a height of about 20 inches, and carries scarlet flowers in May and June; but it comprises a smaller variety, *V. p. minor*, of little more than half the height of the normal plant. It thrives best in a mixture of peat and sand.

VALONIA. A kind of acorn, used by tanners and dyers, and forming a very considerable article of export from the Morea and the Levant. It has a bright drab colour, and maintains this as long as it is kept dry; but it turns black when exposed to moisture, and is then so injured as to lose much of its strength and value. The more substance it has in its husk or cup it is the more valuable. Though a bulky article, it is always estimated and bought and sold by weight. In 1838, between 70 and 80 tons of it were imported into Britain.

VALUATION. See Lease and Tenant-Right.

VALUATION OF TIMBER. As all timber is sold by the cube foot, this price of course regulates the price of all scantling; consequently if we calculate how much of any sized scantling will make a cube foot, and add the price of saw-

ing, we shall at once determine the value of such scantling. This calculation is simple and easy, but it occurs so frequently, and for such a variety of sizes, that the following table, in which the quantities are shown on inspection, will be very useful.

A TABLE showing what length of timber of any scantling from 2 inches to 12 inches square, will make a cube foot of timber.

EXAMPLE OF THE USE OF THE ABOVE TABLE.

Having taken the quarter girt of any piece of timber by measurement, find the corresponding quarter girt in the table, and the number in the column headed 'area' that stands opposite being taken out, is to be multiplied by the length of the tree in feet, and the product will be the contents in cubic feet and decimals of a foot. Thus suppose a piece of timber 16 feet 9 inches long, (or 16·75 feet,) and its quarter girt to be 20 inches; its corresponding area is 2·717, therefore $2{\cdot}717 \times 16{\cdot}75 = 45{\cdot}50975$ feet the contents.

VANADIUM. One of the rare metals. It was not discovered till 1830; but was then discovered by two mutually independent parties, in the iron ore of Tuberg in Sweden and in a peculiar mineral at Wanlockhead in Scotland. It has a strong metallic lustre and a somewhat silver-like appearance, but is so extremely brittle that it cannot be removed from the position in which it is obtained in its separate or proper state without falling into powder. It is insoluble in boiling sulphuric, hydrochloric, or hydrofluoric acid; but it dissolves in nitric or nitromuriatic acid, and gives the solution a beautiful dark blue colour. It combines in three proportions with oxygen, forming a protoxide, a binoxide, and an acid; and it combines also with chlorine, bromine, sulphur, and phosphorus. Vanadic acid is the most important of the compounds; and has a light rust-yellow colour in the state of fine powder, and a reddish colour with a shade of orange and a strong lustre in a state of fusion; and is tasteless and insoluble in alcohol and very slightly soluble in water; and combines somewhat in the manner of a base with sulphuric, phosphoric, and phosphoro-silicic

acids; and unites, in its proper capacity of an acid, with salifiable bases, often in two or more proportions, forming soluble salts with the alkalies, and in general sparingly soluble salts with the other metallic oxides.

VANDA. A genus of ornamental, tropical plants, of the orchis family. Eight or nine species, chiefly epiphytes, varying in height from 8 to 25 inches, were introduced to Britain, principally from China, within the first 35 years of the present century. Three of the most handsome are the many-flowered, *V. multiflora*, two feet high, carrying yellow flowers in June; the taper-leaved, *V. teres*, two feet high, carrying pale yellow flowers in June; and Roxburgh's, *V. Roxburghi*, 18 inches high, carrying white and purple flowers in November, and comprising one variety with whole colour, and another with tesselated sepals and petals. See the article Orchis.

VANGUIERA. A genus of curious, exotic, evergreen shrubs, of the madder family. The eatable species, *V. edulis*, is a native of India, and was introduced thence about 40 years ago to the botanical collections of Britain. It ranks, in the estimation of the Hindoos, as a fruit shrub; and it has naturally a height of between 12 and 20 feet. Two species, 3 or 4 feet high, have been introduced from Madagascar.

VANILLA. A genus of ornamental, economical, tropical plants of the orchis family. Two climbing species, the smooth-leaved and the aromatic,—and one epiphytous species, the two-coloured,—have been introduced to British hothouses from tropical America; and all, inclusive of a number of varieties, are remarkable for the fragrance of their fruit or pods, but cannot, without difficulty, be made to thrive and still less to fructify under artificial European culture. The fruit of the most common varieties has long been assiduously gathered in their native regions, and exported thence to Britain and other countries, as an esteemed ingredient for flavouring or perfuming ices, creams, chocolate, snuff, hair-oils, fine unguents, and other preparations. "The plant which produces the fruit called vanilla," says Miller, "hath a trailing stem, somewhat like common ivy, but not so woody, which fastens itself to whatever tree grows near it, by small fibres or roots which are produced at every joint, which fasten to the bark of the tree, and by which the plants are often nourished when they are cut or broken off from the root, a considerable height from the ground, in like manner as the ivy is often seen in England. The leaves are as large as those of the common laurel, but are not quite so thick. These are produced alternately at every joint, which are 6 or 7 inches asunder, and are of a lively green colour on the upper side, but of a paler green underneath. The stems of these plants shoot into many branches, which fasten themselves also to the branches of the trees, by which means they rise 18 or 20 feet high, and spread quite over some of the smaller trees to which they are joined. The flowers are of a greenish yellow colour, mixed with white, which, when fallen, are succeeded by the fruit, which are 6 or 7 inches long. The method used to prepare the fruit, is, when it turns of a yellow colour, and begins to open, to gather it, and lay it in small heaps to ferment two or three days, in the same manner as is practised for the cocoa or chocolate pods; then they spread them in the sun to dry, and when they are about half dried, they flat them with their hands, and afterwards rub them over with the oil of palma christi, or of the cocoa; then they expose them to the sun again to dry, and afterward they rub them over with oil a second time; then they put them in small bundles, covering them with the leaves of the Indian reed, to preserve them. These plants produce but one crop of fruit in a year, which is commonly ripe in May, fit for gathering; for they do not let them remain on the plants to be perfectly mature, because then they are not so fit for use. While the fruit is green, it affords no remarkable scent; but as it ripens, it emits a most grateful aromatic odour. When the fruit begins to open, the birds attack them and devour all the seeds very greedily, but do not eat any other part of the fruit. The fruit which are brought to Europe, are of a dark brown colour, about 6 inches long, and scarce an inch broad; they are wrinkled on the outside, and full of a vast number of black seeds, like grains of sands, of a pleasant smell, like balsam of Peru." The best kind to experiment with in British gardens is *V. planifolia*,—a climber introduced from the West Indies in 1800; and any attempt to bring it to fruit must be aided by artificial fecundation; and this is done by carefully removing the retinaculum which covers the stigmatic part of the column, and then drawing out the inward-turned anther and pushing it down till it comes in contact with the bearded stigmatic part. By this management fruit have recently been obtained in British hothouses as finely fragrant as any which are imported from Mexico.

VAPOUR. A body in such an aeriform state as, while for the time truly gaseous, has a readiness to return to the liquid or the solid state at or above ordinary temperature and pressure. See the article Aeriform Bodies. Vaporization, or the conversion of a liquid or a solid into vapour, is effected by heat; and takes place either slowly and quietly in evaporation, or rapidly and tumultuously in ebullition. See the articles Evaporation and Boiling. A considerable number of substances will not vaporize under the strongest heat of our furnaces; a few, such as arsenic, camphor, and sal-ammoniac, pass direct from the solid state into vapour; and the great majority are first liquefied and then vaporized, and differ very widely from one another as to the degree of heat by which their vaporization is effected, and as to the comparative density

which their vapours assume. The vapour of water is lighter than air, at the same temperature and under the same pressure, in the proportion of 1,000 to 1,604; but the vapour of alcohol is half as heavy again as air, and that of ether is more than twice and a half as heavy. See the article GAS. The determination of the height of the plane of watery vapour in the atmosphere, is a desideratum of great meteorological importance, and connects itself with all the most interesting questions regarding the distribution of aeriform water over the globe, and regarding the irrigation of the continents. But one of the best and most recent attempts toward it, made in a series of experiments during Sir James Ross's voyage of discovery to the Southern Seas, was in a great measure a failure, and attained no more than a vague approximation, "giving an elevation of about 2,000 feet as its mean height in the tropical regions." See the article ATMOSPHERE.

VARIETIES IN PLANTS. The tendency is more or less common in all plants, to vary from the character first stamped upon them. This disposition is increased by removal from their native climate or locality, and greatly by cultivation. By a constant selection of some particular quality in successive crops, a gradual removal from the character of the original is effected. Most of our finest fruits, we have reason to believe, have been gradually produced by the improvement of the original native kinds. The improvements effected in former ages, were doubtless the result of accident, as the ancients were ignorant of the means for their systematic accomplishment. The greatest progress in the art which has been made in modern times, was effected by Van Mons in Belgium, and by Knight in England.

The former, who directed his labours chiefly to the pear, produced many new and excellent varieties, by a constant and successive selection of the best seedlings. He first made a large collection of natural stocks, choosing those which, from the appearance of the wood and leaf, he had reason to believe, would be most likely to produce the best fruit. As soon as the first of these bore, he selected the best, and planted the seeds. Selections were again made from the first fruit of these, and so on in continued succession, the best and soonest in bearing were uniformly chosen. He thus obtained fruit from the eighth generation; each successive experiment yielding an improved result on the preceding. At the fourth generation many of the fruits were good, several excellent, but a smaller number still bad. He had, in the early part of this series of experiments, no less than eighty thousand trees; hence in selecting from so large a number, his chance for fine ones was vastly greater than from a small collection; and hence too the reason why, after seven or eight improving generations, he had obtained so many hundred fine sorts. In the early stages of his operations, he found "that twelve or fifteen years was the mean term of time, from the moment of planting the first seed of an ancient variety of the domestic pear, to the first fructification of the trees which sprung from them. The trees from the second sowing, yielded their first fruit at an age of from ten to twelve years; those of the third generation, at an age of from eight to ten years; those of the fourth generation, at an age of from six to eight; and those of the fifth generation at the age of six years. Van Mons, being actually at the eighth generation, has informed me," says Poiteau, "that he has obtained several pear trees which fruited at the age of four years." When his seedlings were at the age of three or four years, he was able to judge of their appearances, though they had not as yet borne; such only were taken for further trial, as exhibited the strongest probability of excellence. It is hardly necessary to remark that in all these trials, the young trees were kept in the highest state of cultivation. Van Mons maintained that, by planting the seeds of the first crop, the product would be less liable to run back to the original variety, than where the seeds were taken from a crop produced on an old bearing tree; and to this practice he chiefly ascribed his success.

The production of new varieties is greatly facilitated by cross-impregnation, or by intermixing the pollen and stigma of two varieties, for the purpose of procuring something of an intermediate nature. This was performed with great success by Knight. Selecting two varieties for operation, while yet early in flower, and before the anthers had burst and discharged the pollen, he cut out with a fine pair of scissors all the stamens, leaving the stigma untouched. When the stigma became mature, he introduced the pollen (the fine dust of the bursting anthers) of the other variety, either by shaking the flower of the latter, deprived of its petals, over the stigma, or by transferring it on the point of a camel's-hair pencil, from one flower to the other. The seeds of the fruit, thus yielded, partake of the nature of both; and the trees growing from them, bear fruit of various intermediate mixtures.—*Thomas's Fruit-Culturist.*—See the article HYBRIDIZING OF PLANTS.

VARRONIA. A genus of ornamental, exotic, ligneous plants, of the cordia family. About a dozen species, all white-flowered evergreens, varying in natural height from 4 to 30 feet, have been introduced to British collections, principally from tropical America; and about 20 more are known. All the introduced species are propagable from cuttings; most love a soil of sandy loam; and one, the alder-leaved, ranks in its native country as a fruit-tree.

VASCOA. A small genus of ornamental, Cape-of-Good-Hope, yellow-flowered, evergreen shrubs, of the genista division of the leguminous order.

Two species, the perfoliate and the stem-clasping, both about 4 feet high and blooming in July and August, have been introduced to British gardens; and they love a soil of peaty loam, and are propagated from cuttings. The name vascoa was given in honour of the celebrated navigator Vasco de Gama.

VASCULARES. One of the two grand or primary divisions of the vegetable kingdom. It is very nearly identical with the Phænogamia of Linnæus and the Cotyledoneæ of Jussieu; but is preferred to these by later botanists on account of its expressing a more important and more extensively constitutional character. The same plants, when viewed as phænogamous, have true or obvious flowers,—when viewed as cotyledonous, have true or lobed seeds,—and when viewed as vascular, have not only cellular tissue, but a system of tubular and spiral vessels. Though the characters of flower and seed are sufficiently distinct for every purpose of mere classification, yet they exist only in very small parts of a plant, and in parts not present during the greater portion of the year, and are in some instances far too obscure and minute to serve as indications to a merely popular observer; but the character of vascularity pervades the whole structure, and remains patent to observation at all seasons of the year and in all conditions of the plant; and developes broad exterior distinctions which are readily recognised by the most unpractised eye. Many vascular plants, in particular, declare themselves to every peasant by the existence of woody fibre; and both these and all the others proclaim themselves in the veinedness of their leaves. See the articles CELLULARES and BOTANY.

One set of vessels in vascular plants are simple tubes called lymphatics by Decandolle, false tracheæ by Mirbel, and corpus culiferous or globule-bearing tubes by Dutrochet. They have no valves and no lateral intercommunication; they abound in both the hard wood and the soft wood of ligneous exogens, particularly between the concentric layers of different years, but do not occur in either the pith or the bark; they are studded with small globules or molecules, which lie embedded in their walls; and they serve as the channels of the ascending sap, and may readily be seen to pour out from the orifices of their section the bleeding juice of a cut vine.—Another set of vessels are short, oblong, spindle-shaped tubes, swollen in the middle, pointed at the extremities, and often divided by transverse plates. They consist of very firm membrane, but have no globules; they are arranged in longitudinal series along the alburnum and the bark, down to the interior of the root; those of adjoining series touch one another at the middle, but have spaces for other vessels between their intrinsically contracting and mutually receding extremities; and all have lateral communications and a porous wall, and serve to conduct the cambium or elaborated juice from the leaves of all the plant's exterior downward and retrogradingly through all its spray and branches and stem and root.—A third set of vessels are spiral tubes or tracheæ,—fine, filmy, and transparent, twisted in the form of a corkscrew, either from right to left, or from left to right,—occasionally interspersed with the other sets of vessels, but easily distinguishable from them by their spiral form and their filminess,—terminating each in a sort of conical and spiry point,—and furnished with nervous globules similar to those of the cells. The functions and even the structure of these vessels have been a subject of great debate and of wide diversity of opinion among phytologists; and we shall therefore, in the following paragraph, quote a somewhat extended account of them from Keith.—A fourth set of vessels are tubes of similar form and character to the lymphatics, but comparatively very wide in diameter, destitute of globules, and serving to convey the descending and secreted fluids peculiar to each species of plant, such as the yellow juice of the celandine and the milky secretion of the spurges, and therefore called proper vessels. They occur in both ligneous and herbaceous plants; and occupy comparatively large space in some of the most succulent and lactiferous and mucilaginous species.—A fifth set of vessels are articulated cellular tubes, or series of cells so concatenated as to be aggregately tubular, furnished with globules and free from pores,—some of them radiating from the centre of the stem to the circumference of the alburnum, and constituting what are popularly termed the medullary rays of trees and shrubs,—and others extending longitudinally through the plant, within the bark, at right angles to the radiating ones. The office of these vessels is fully more obscure than even that of the spiral vessels; and probably is dependent on the office of the pith; and possibly also has connexion with the function of a supposed sixth set of vessels, of very filmy texture, of anastomising power, and of retiform distribution through all parts of the plant, from the root to the leaves and from the centre to the circumference,—a set of vessels, however, whose very existence, to say nothing of their offices, is yet matter for enquiry.

"Grew and Malpighi, who first discovered and described the spiral vessels," says Keith, "represented them as resembling in their appearance the tracheæ of insects, and designated them by that name,—an appellation by which they are still very generally known. They do not occur often in the root, or, at least, they are not easily detected in it, though Kieser is said to have found them in it, in great abundance. Dutrochet could find none, and denies their existence in the root expressly. For myself, I can safely affirm that I have repeatedly met with them in the root of the lettuce called cos lettuce, though not in any other root that I have ever

examined in search of them. Neither are they to be found in the branch or stem of woody plants, except in the annual shoot; nor in the pith of any plant, except in the several species of nepenthes. But in the stem and branches of herbaceous plants, they are generally to be found without much difficulty, accompanying the longitudinal fibres, and forming part of the bundles. They are very easily detected in the foot-stalk, whether of the leaf or flower. They are discoverable also in the leaf itself; though rarely in the calyx and corolla; and more rarely still in the other parts of the flower. Grew and Malpighi found them both in fruits and seeds. I have myself met with them in the external umbilical cord of the seed of the cherry, at a very early period of its growth,—that is, about the time of the falling of its petals,—but not in any other fruits. In the leaf or leaf-stalk of the artichoke, the spirals are not only remarkably large, but also remarkably beautiful, exhibiting the appearance of spiral coats investing interior fibres, rather than that of a distinct and individual tube, and seeming, when uncoiled, to be themselves formed of a net-like film, consisting of three principal and longitudinal stripes. At present, we find that the botanical adepts are divided on this subject, one party contending that the spires are external to the tubes as they appeared in the case just stated; and the other party contending that the spires are, on the contrary, internal, forming a lining to the tubes, and not a coating. Dr. Brown espouses the former opinion, and Professor Henslow espouses the latter. Is it certain that the organs now under consideration are tubes? In the closely coiled up state in which they exist in the growing plant, they might be said to constitute tubes by the union of their spires. Divide a leaf-stalk of the artichoke or of the elder longitudinally, cutting it partly, and tearing it partly asunder, and place a portion of it under the microscope. Inspect the exposed surface of it carefully and in a strong light, and it will present to your view bundles of spirals in their coiled up and united state. Divide a portion of the same leaf-stalk transversely, cutting it partly, and breaking it partly asunder. Place it under the microscope in a clear and strong light, and multitudes of spirals, not yet divided, but merely drawn out, and partly uncoiled, will be found to connect the fractured surfaces; and if you stretch them even till they give way, the fragments will, as if by an elastic and inherent spring, coil themselves up again, nearly as before; yet the prevailing opinion seems to be that the spire does not in any case constitute a tube, but forms merely a coating or lining to a tube within it or without it. —Much has been said with regard to their functions. Malpighi regarded them as destined to the transmission of air. Grew thought they transmitted, not only air, but sap. Mirbel regards them as being well fitted for the transmission of the ascending sap. Mr. Knight thinks they are altogether incapable of transmitting moisture. Yet Hedwig and Senebier concurred in affirming that a fluid may be seen issuing from their orifices, if the horizontal section of a stem is inspected immediately after its division. Hence they are doubtless capable of conducting a fluid, whether it be the ascending sap or not. The latest hypothesis with regard to their function is that of M. Dutrochet. He shows that they cannot be the channel of the sap's ascent, because they do not exist either in the root or stem, except as aforesaid,—that is, in the annual shoot. He shows also that they contain a fluid *sui generis*,—that is, a diaphanous fluid, which is neither air nor sap. He infers that their function is in accordance with that of the leaves, because it is in the leaves that they occur in the greatest abundance. But leaves are vegetable lungs, and as animals receive a vivifying influence from oxygen in the lungs, so plants, through means of the leaves, receive a vivifying influence from the light of the sun, either directly or in combination with the fluids they contain; which influence the spirals or tracheæ convey to the interior, and are hence to be regarded as organs of insolation."

VASCULAR ORGANS. See VASCULARES.

VAT. A large vessel for holding any fermented alcoholic liquor, such as wine, ale, beer, cyder, or perry, during the process of its preparation.

VATERIA. See TALLOW (PINEY.)

VAUANTHES. An ornamental, Cape-of-Good-Hope, yellow-flowered, annual plant, of the crassulaceous order. It was called by Linnæus *Crassula dichotoma;* but it now constitutes a genus of itself, with the specific name of *chloræflora*. It has a height of about 6 inches; and is only half-hardy.

VEAL. The meat or well-fed carcase of a calf. See the articles CALF and MEAT. The fillet of a cow-calf, under any ordinary conditions of breed and age and feeding and aggregate fitness for the market, is less firm in the groin and more curdled in the fat than that of a bull-calf; and is therefore generally preferred to it. If a shoulder of veal have not a bright red colour in the vein, it is stale; and if it have any green or yellow spots, it is totally unfit for use. The neck and breast, if white and dry, are good; but, if clammy, and greenish or yellowish at the upper end, they are bad. The loin generally taints first under the kidney; and whenever it becomes soft and slimy, it is stale. If the leg be white and firm, it is good; but if it be flabby, and show any greenish or yellowish specks, it is bad.

VEGETABLE. A plant. See the articles PLANT and VEGETABLE PHYSIOLOGY.

But the word vegetables, in the plural number, is popularly used as the proper aggregate designation of culinary plants, or of such as are cultivated in the kitchen garden. The chief of

these in Britain are the following:—Cabbage plants, whose leaves or unexpanded flowers are pickled or made into sauerkraut or eaten boiled,—white cabbage, red cabbage, savoy, borecole, Brussels sprouts, cauliflower, and brocoli. Spinaceous or oleraceous plants, whose leaves are eaten boiled,—spinach, New Zealand spinach, white beet, sea-beet, turnip-tops, orach or mountain spinach, good king Henry or wild spinach, white orach or fat-hen, sorrel, French sorrel, stinging-nettle, herb patience or patience-dock, spotted hawkweed, pilewort, sowthistle, sauce alone or Jack by the hedge, black bryony, and chickweed. Acetaceous or salad plants, whose leaves or whole herbaceous parts are eaten raw as salad, along with vinegar and spice,—lettuce, endive, succory, or wild endive, ox-tongue, dandelion, ox-eye daisy, milk-thistle, yarrow or milfoil, white cabbage, radish, charlock, mustard, rape, garden rocket, water cress, garden cress or wild rocket, French or American cress, yellow rocket or winter-cress, scurvy-grass, ladies-smock, corn-salad or lamb-lettuce, brooklime, burnet, sorrel, garden sorrel, French sorrel, alpine sorrel, wood sorrel, nasturtium or Indian cress, purslane, sea bindweed, sweet cicely, chervil, celeriac, celery, angelica, borage, spearmint, cowslip, primrose, and plantain or star of the earth. Pot or garnishing herbs, whose roots, leaves, or flowers are used to flavour soups and garnish dishes,—horse-radish, parsley, purslane, tarragon, fennel, dill, chervil, sweet cicely, anise, Indian cress or nasturtium, marigold, sea-flower, crocus or saffron, and borage. Alliaceous plants, whose bulbs are used either boiled, raw, or pickled,—onion tree or bulb-bearing onion, rocambole, Welsh onion, chives, leeks, garlick, and shalot. Sweet or aromatic herbs, whose young sprigs are used generally to flavour stuffings or soups,—thyme, lemon-thyme, sage, clary, spearmint, peppermint, pennyroyal, pot marjoram, sweet marjoram, winter marjoram, common marjoram, summer savory, winter savory, sweet basil, dwarf or brush basil, rosemary, lavender, tansy, and balm. Asparagaceous plants, whose young shoots, peeled leaf-stalks, flower-scales, or fruit-flesh are eaten boiled on toast with butter, or are occasionally made into pies,—asparagus, good king Henry, bladder-campion, hop, Alexanders, Persian willow or willow-herb, cardoon, rhubarb, burdock, thistle, celery, sea-kale, artichoke, milk-thistle, cotton-thistle, pompion, water-melon, squash, and vegetable marrow. Esculent-rooted plants, whose roots are mostly eaten boiled, or rarely raw when young, and sometimes made into bread,—potatoes, Jerusalem artichokes, turnips, turnip-rooted cabbage, radish, rampion, beet, parsnip, carrot, skirret, Hamburgh parsley, scorzonera, salsafy, arrowhead, bitter vetch, earth-nut, meadow-sweet, salep, silver-weed, Solomon's-seal, and black bryony. Leguminous plants, whose fruit is eaten boiled, either enclosed in the pod when tender, or shelled, or whose seeds are ground when ripe,—pea, sea-pea, bean, dwarf and running kidney-beans. Pickling plants, whose whole substance, or whose bulbs, leaves, flowers, or fruit are used in pickling,—onions, samphire, marsh-samphire, sea-convolvulus, sea-sandwort, sea-orach, sea-salsola, golden samphire, red cabbage, capers, marsh-marigolds, cauliflower, love-apples, egg-plants, cucumbers, capsicums, cherry-pepper, bell-pepper, and Indian cress or nasturtiums. Edible algæ, or sea-weeds,—sweet fucus or sea-belts, dulse, red dulse, bladder-leeks, ciliated dulse, fringed dulse, pepper dulse, bladder or hunting fucus or gulf-weed, oyster-green, and lava. Edible fungi, — cultivated mushroom, champignon, chanterell, morrel, and truffle. Medical plants, whose whole substance, or whose leaves, flowers, or fruit are used in domestic medicine, — angelica, anise, coriander, carraway, parsley, dill, fennel, agrimony, marsh-mallow, rue, hyssop, balm, sage, arum, assarabacca, ladies'-smock, chamomile, lesser centaury, meadow-saffron, elecampane, liquorice, carrots, wormwood, southernwood, Roman wormwood, scurvy-grass, leeks, garlic, sea-holly, and dandelion. Confectionary plants, which are used in tarts, puddings, or candying,—angelica, celery, elecampane, rhubarb, vegetable marrow, pompion, carraway, coriander, and anise.

Kitchen vegetables, particularly such bulky and common kinds as the succulent roots and the brassicas, form an essential part of the sound and healthy food of human beings,—insomuch that any person who long and entirely wants them is certain to suffer serious derangement of his constitution, or to contract some severe disease; and when used largely and judiciously, with a due regard to the tone of the stomach, and with a proper selection of the most saline and succulent kinds, they act as a prompt remedy for scorbutic complaints and for various kinds of general debility. Any method, therefore, for preserving them long in a fresh state, in voyages at sea, or in other situations where frequent supplies of them cannot be obtained, is of vast importance for the conservation of health. About 10 or 12 years ago, a new and curious method of preserving them was discovered by M. Braconnot, and is said to have proved highly efficient, after being tested by a number of trials. This method is as follows:—Provide a cask furnished with an opening, which fill three-quarters with the vegetables which it is desired to preserve. At the opening, fix an iron wire, to which suspend a match of sulphur, which set on fire. After burning for some time, shake the cask, and put on the vegetables sheets of paper which have absorbed sulphuric acid for a time. Fumigate the cask with burning brimstone at two different times, taking care to preserve the vegetables and sheets of paper from the embers of the match when burning. The vegetables, after parting with the water of vegetation, appear boiled. After this process they are put into stoneware

pots and placed in a cellar, without any other precaution than a covering of parchment. When you wish to use the vegetables, all that is necessary is to let them steep some hours in water, their cooking taking no more time than that given to vegetables recently gathered, and their taste is as agreeable. M. Braconnot extended his trials to many sorts of vegetables, among others to sorrel, Roman lettuce, common lettuce, and asparagus; and they all afforded him satisfactory results. He found, however, that the sulphuric acid was usefully employed only when applied to tender vegetable substances, susceptible of prompt cookery.

VEGETABLE ACIDS. Compounds which possess the properties of an acid, and are derived from the vegetable kingdom. A brief account of them has already been given in the article Acids. They are, for the most part, less liable to spontaneous decomposition than other vegetable principles; and they probably owe their comparative stability to the large proportion of oxygen which they contain. They constitute a highly important class of organic substances; and are nearly four times as numerous as the vegetable alkalies; and differ very widely from one another in transformative power and aggregate chemical behaviour; and, in many instances, play a conspicuous part both in the organic chemistry of nature and in the economical chemistry of art. About one half consist, in various proportions, of oxygen, carbon, and hydrogen; two, the oxalic and the croconic, consist only of oxygen and carbon; two, the indigotic and the carbazotic, consist of oxygen, carbon, and nitrogen; five or six consist of oxygen, carbon, hydrogen, and nitrogen; and the rest either have not been carefully analysed, or consist of some other powerful acid, such as the sulphuric, in combination with alcohol, with ether, or with some other vegetable principle. One class, comprising between one-sixth and one-seventh of the whole, are volatile acids, or may be volatilized without decomposition; and the most interesting of these are the acetic, the lactic, the oxalic, the sebacic, the formic, the benzoic, and the hippuric. A second class, comprising about double the number of the preceding, are fixed acids, which cannot be volatilized or distilled over without decomposition, and which, when exposed to a sufficient degree of heat, are resolved into other acids called pyracids; and the most interesting of these are the malic, the citric, the racemic, the gallic, the meconic, the tannic, the ulmic, and the caffeic. A third class, comprising a rather greater number than the first, are oily acids which result from the boiling of wax or fixed oils with potash or soda, and whose combination with the alkali constitutes soap; and the most interesting of these are the margaric, the stearic, and the ænanthic. A fourth class, about half as numerous as the first, are azotic, or have nitrogen in their composition, and in consequence possess a nearer kindred than the rest to the proximate principles which distinguish the animal kingdom; and the most interesting of these are the carbazotic, the azulmic, and the cholesteric. A fifth class, nearly equal in number to the first, are imperfectly examined acids, whose constitution is obscurely known or is matter of dispute; and the most interesting of these are the pectic, the crenic, the apocrenic, and the gummic. And a sixth class, nearly half as numerous again as the first, are compound acids, which consist of a vegetable principle in combination with a strong mineral or vegetable acid; and the most interesting of these are the xanthic, the tartrovinic, the sulphocetic, stearin, and olein.

VEGETABLE ALKALIES. See Alkaloids.

VEGETABLE CHEMISTRY. Either the chemistry of vegetation, whether with reference to the actions which take place in the interior of plants, or with reference to the agencies which affect and control and determine them from without; or the chemistry of vegetable principles,—both those which are formed by living plants, and afterwards separated from them by artificial processes, and those which result from the excretion or death or decay of plants, or which are artificially formed out of portions of their substance by manipulation or chemical reaction. In the former sense, vegetable chemistry, in its various parts and phases, is very abundantly treated in the articles Organic Chemistry, Agricultural Chemistry, Manure, Food of Plants, Farm-Yard Manure, Salts, Alkalies, Air, Electricity, Ammonia, Azote, Carbonic Acid, and many others; and in the latter sense, it is treated with sufficient fulness and frequency for all the purposes of the various classes of our readers, both in articles on entire classes of vegetable substances, such as Alkaloids, Vegetable Acids, Oils, Resins, Gums, Salts, and Balsams, and in articles on each of the most important principles which are used either in medicine, in domestic economy, or in the arts, such as Sugar, Starch, Alcohol, Protein, and all the chief oils, gums, resins, and salts, and all the chief artificial products of destructive distillation and artificial recombination. "The chemistry of vegetable principles," says Dr. Thomson, "has made considerably greater progress than that of animal principles; chiefly because the former have a greater tendency to crystallize, and, in consequence of this property, can be more easily obtained in a state of purity than the latter. This is the case with most of the vegetable acids and alkaloids, with sugar and some other substances not easily classified. Others are volatile, and are formed or driven off at particular temperatures. Alcohol, ethers, and volatile oils are in this predicament. Pretty frequently several of these volatile bodies occur together; and in such cases we have scarcely the means of obtaining them in a state of purity, unless when they enter into definite and crystallizable com-

pounds with some other substance. It is not unlikely that all the vegetable principles may be found hereafter to be capable of entering into definite compounds with other bodies, and that they will be ultimately possessed of the character of acids or bases. But there are a good many vegetable principles which, so far as our present knowledge extends, do not seem capable of forming any such definite compounds. Thus caoutchouc neither combines with acids nor bases. We must consider such bodies as neutral. There exist also several groups of bodies which have been distinguished by a common name, some of which neutralize acids, and therefore ought to constitute bases, while others belonging to the same group neutralize bases, and therefore ought to constitute acids; while a considerable number of the bodies belonging to the group has been so imperfectly examined, that we do not know whether they be acids or alkalies. This is the case with the group of bodies distinguished by the name of volatile oils. Oil of turpentine saturates muriatic acid, and therefore is a base; while oil of cloves saturates bases, and therefore is an acid. But many of the other volatile oils have been so imperfectly examined, that we could not venture to place them either among bases or acids." "Nearly all bodies of vegetable origin," says Dr. Turner, "are composed of oxygen, hydrogen, and carbon; and in a few of them, nitrogen is likewise present. Every distinct compound which exists ready formed in plants, is called a proximate or immediate principle of vegetables. Thus sugar, starch, and gum, are proximate principles. Opium, though obtained from a plant, is not a proximate principle; but consists of several proximate principles mixed more or less intimately with each other. The proximate principles of vegetables are sometimes distributed over the whole plant, while at others they are confined to a particular part. The methods by which they are procured are very variable. Thus gum exudes spontaneously, and the saccharine juice of the maple-tree is obtained by incisions made in the bark. In some cases a particular principle is mixed with such a variety of others, that a distinct process is required for its separation. Of such processes consists the proximate analysis of vegetables. Sometimes a substance is separated by mechanical means, as in the preparation of starch. On other occasions advantage is taken of the volatility of a compound, or of its solubility in some particular menstruum. Whatever method is employed, it should be of such a nature as to occasion no change in the composition of the body to be prepared. The reduction of the proximate principles into their simplest parts, constitutes their ultimate analysis. By this means chemists ascertain the quantity of oxygen, carbon, and hydrogen present in any compound." See the articles PROXIMATE PRINCIPLE, ANALYSIS, and VEGETABLE PHYSIOLOGY. The methods of analysis introduced not many years ago by Liebig and Dumas opened a new era in vegetable chemistry, and suddenly let in upon it an inundation of new facts and explanations; insomuch that several hundred new vegetable substances were discovered in a very brief time by these two distinguished chemists and their pupils, and many of the most talented young chemists both on the Continent and in Britain were induced to devote their main strength to enquiries in that direction, and such multitudes of accessions began to be made to the knowledge of chemical reactions and combinations within the vegetable kingdom as speedily raised the study of organic chemistry to as broad a platform of investigation and to as lofty an influence over economics and the arts as that of all the combined departments of the general chemistry which had been accumulating its resources for centuries. Agricultural chemistry, therefore, which is but one department of vegetable chemistry, has already become a separate and great science.

VEGETABLE EXCRETION. See EXCRETION OF PLANTS.

VEGETABLE EXTRACT. See EXTRACT.

VEGETABLE JELLY. See PECTIN.

VEGETABLE LIFE. See ORGANIC CHEMISTRY.

VEGETABLE MARROW. The succada gourd, —a variety of the egg-bearing gourd, *Cucurbita ovifera*. It is an annual; and is raised under a hand-glass or in a frame, and afterwards transplanted into a warm aspect, and trained to a trellis or to some similar support. Its fruit is uniformly of a pale yellow colour, and of an elliptic-oblong shape; and when full grown, is about 9 inches in length and 4 inches in diameter. It is by far the best of the gourds for culinary purposes; and, though generally eaten when about the size of a hen's egg, may be used at any stage of its growth. When very young, it does well to be fried with butter; and when half-grown, it is excellent either plain boiled or stewed with rich beef-gravy; and, in either case, it requires to be cut into slices. It takes its name of vegetable marrow from the peculiar tenderness and softness of its flesh.

VEGETABLE MORPHOLOGY. See MORPHOLOGY.

VEGETABLE MOULD. See HUMUS.

VEGETABLE PHYSIOLOGY. The science which treats of the structure, functions, and vital phenomena of plants. It either may be understood quite comprehensively as discussing all matters which concern living plants, in the same wide way in which zoology discusses all matters which concern living animals, and it then may be more properly called phytology; or it may be taken more limitedly as discussing only matters which concern the organisms and the organic operations of living plants, irrespective of specific habits and chemical constituencies and external connexions, in the same limited way in which animal physiology treats only of

the organisms and organic functions of living animals, and it then may be more strictly designated vegetable physiology. Yet the two definitions so run into each other as to be of little or no use for any purpose of either practice or theory; and we therefore may follow them indifferently—now the one and now the other—in all that we have to say.

The philosophers of ancient Greece and Rome had no notions of vegetable physiology which are worth recording; and even the philosophers of modern Europe down to the time of Bacon continued unacquainted with both the anatomy of plants and all the true principles of vegetation. Dr. Hooke, who published in 1667, and who examined wood-charcoal and saw the small cells and the opening of the spiral vessels, was the first person who applied a microscope to the examination of the structure of plants; and Dr. Grew, an English physician, and Malpighi, an Italian anatomist, both of whom published in 1671, were the first observers who conducted such searching and extensive investigations by dissection and microscopical examination as either to lay a true foundation for phytological science, or to amass any considerable materials for rearing its superstructure. "They had no mutual intercourse, and yet their experiments and observations are so nearly alike that the one might seem copied from the other. The characteristics of both are minute and accurate observation, careful experiment, and cautious deduction from a large collection of instances. Hence we find that no organ of the plant escapes their inspection; roots, trunks, branches, leaves, flowers, fruits with their appendages, are all subjected to the most rigid and minute scrutiny, as well as those parts and organs which are discoverable only by the dissection or anatomy of the plant,—the pith, the wood, the bark, the epidermis, together with the fibres, tubes, or membranes into which they are further separable. This enquiry is followed by a careful enquiry into the respective uses of each, in the economy of vegetation,—which is ascertained by watching with the most unwearied assiduity the phenomena of vegetable life,—the functions of the several organs of the plant,—the 'latens processus naturæ, in casu ubi fit inquisitio ex quibus initiis, et quo modo et quo processu herbæ generuntur, a primis concretionibus succorum in terra, a seminibus, usque ad plantam formatam, cum universa illa successione motus, et diversis et continuatis naturæ nixibus.'" Many distinguished philosophers, from the latter part of the 17th century down to the present age, particularly Ray, Camerarius, Geoffrey, Vaillant, Linnæus, Hales, Bonnet, Duhamel, De la Baisse, Cotta, Van Marum, Mustel, Hedwig, Spallanzani, Sprengel, Treviranus, Link, Rudolphi, Mirbel, Knight, Kieser, Dutrochet, Amici, Brongniart, and Brown, followed in the footsteps of Grew and Malpighi and in those of one another, each contributing new materials to phytological science, or correcting the observations of predecessors, till the whole structure and organic economy of a plant, and even of every part of it, have become almost as completely known as those of the highest orders of vertebrated animals, and till either clear notions or luminous and consistent theories have been obtained upon such topics as the processes of nutrition and assimilation, the offices of the spongioles and the stomata, the use of the several kinds of cells and vessels, the structure and development of seeds, the descent of the radicle and the ascent of the plumule, the peculiarities of root and stem and leaves, the several nature of bark and wood and pith, the differences of secretion and excretion, the ascent of the sap and descent of the cambium, the elaboration of liquid from the root with gases from the leaves, the origin of buds and branches, the irritability and vital economics of the general system, and even the obscure and mysterious process of vegetable fecundation.

The early phytologists alluded chiefly to organic phenomena, and but slightly to functional, and not at all to chemical or to vito-chemical. "The first experimenters," says Keith, "seem to have had in view nothing beyond the mere analysis of their constituent parts, or rather of their medical properties,—which they endeavoured to ascertain by means of the processes of infusion, decoction, evaporation, distillation, and combustion, torturing the vegetable subject in every possible way and making much use of the crucible. It cannot be said that their researches were altogether unprofitable; but certainly they did nothing to elucidate the phenomena of vegetation. The key to that mystery may be said to have been first found by Priestley, when about the year 1771 he discovered the extrication of oxygen gas, by the leaves of plants, when exposed under the water to the rays of the sun. The path thus opened up was afterwards successfully explored by Ingenhouz and Senebier, who extended their researches to a variety of other phenomena; and from that time chemical phytology has continued to attract the notice of almost all chemists of distinction; among whom we may particularly mention Lavoisier, Fourcroy, Vauquelin, Gay Lussac, and Thenard, in France,—and in this country, Chenevix, Thomson, Ellis, and Davy. But the individual who, after Priestley, has perhaps the strongest claim to originality in these investigations, is Saussure the younger, who, in the true spirit of the Baconian philosophy, has watched and investigated, not merely the phenomena of vegetable life, but even the phenomena of vegetable death and decomposition, demonstrating the peculiar and indispensable agency of oxygen in the germination of the seed,—the absorption of moisture by the root,—its elaboration in the leaf, by the alternate inhalation and extrication of oxygen and of carbonic acid gas, by night and by day,—the de-

composition of water,—the descent of the cambium and its conversion into wood and bark;—and, lastly, the primary principles of which plants consist, or to which they may be reduced, —carbon, oxygen, hydrogen, azote."

We have discussed the structure of plants in the articles Botany, Acotyledonous Plants, Cellulares, Compositæ, Cruciferous Plants, Cryptogamous Plants, Dicotyledonous Plants, Endogens, Exogens, Leguminous Plants, Monocotyledonous Plants, Organization, and a great many others; the parts, members, and organs of plants, in the articles Air-Vessels, Anther, Aril, Armature, Bark, Berry, Bract, Branch, Bud, Bulb, Calyx, Capsule, Catkin, Cellular Tissue, Corolla, Cotyledon, Culm, Down, Epidermis, Flower, Frond, Fruit, Germ, Gland, Involucrum, Kernel, Leaf, Nectary, Nut, Ovary, Pericarp, Pith, Pollen, Radicle, Root, Sap, Seed, Spongioles, Spore, Stamens, Stem, Tuber, Vasculares, and many more; the constituents, secretions, and proximate principles of plants, in the articles Albumen, Alburnum, Aroma, Ashes, Balsams, Bloom, Cambium, Chlorophylle, Duramen, Extract, Fibrin, Food of Plants, Gluten, Gum, Lignin, Odour, Oil, Phosphates, Protein, Resin, Starch, Sugar, Vegetable Acids, Alkaloids, Turpentine, and a multitude of others; the general economy of plants, or their form, habit, relations, and exterior susceptibilities, in the articles Acclimatation of Plants, Age of Plants, Aerial Roots, Air-Cells, Air-Plants, Analogy, Annual Plants, Aquatic Plants, Barren Flowers, Biennial Plants, Blanching, Etiolation, Grafting, Habit, Herb, Hybridizing of Plants, Morphology, Offset, Parasites, Pollen, Rotation of Crops, Seed, Tree, and many more; the exterior chemistry of vegetation, or the controlling influences which are exerted over the life and energy of plants by external agencies and outward circumstances, in the articles Aeration, Air, Agricultural Chemistry, Altitude, Atmosphere, Carbonic Acid, Ammonia, Azote, Caloric, Climate, Food of Plants, Humus, Gypsum, Irrigation, Light, Lime, Manure, Pulverization, Soil, Sowing, Temperature, Water, and many others; the organic functions and vital actions of plants, in the articles Absorption in Plants, Æstivation, Ascent of Sap, Cambium, Endosmose, Elaboration, Excitability of Plants, Excretion of Plants, Feundation, Germination, Growth, Irritability,-Morphology, Nutrition, Organic Chemistry, Secretion, Vasculares, and many more; and the diseases of plants in the articles Aphis, Blight, Canker, Ear-Cockle, Decay, Dropsy, Ergot, Extravasation, Fascia, Gall, Gangrene, Honey-Dew, Knot, Mildew, Smut, and a number of others. Any further notice of these multitudes of topics, either in groups or in a connecting manner, and much more seriatim, would be useless repetition; and, in the sequel of the present article, we shall merely notice two or three prominent facts and speculations respecting vegetable physiology which happen to have been either touched but slightly or not touched at all in other parts of our work.

The peculiar organic action of root crops, in its connexion with fallowing effects and with the economy of efficient rotations, is a subject of great practical interest to farmers; and is briefly but luminously discussed in the following terms by Messrs. Way and Ogston:—"Root crops are means, when judiciously employed, of increasing the fertility of the land,—of rendering it, that is, capable of bearing larger crops of the more valuable produce, wheat and the other cereals, which form the great staple of food for man. Now, how do they effect this? Whence the efficacy of the turnip and the mangold wurzel. What peculiar properties do these roots possess, that their cultivation should form so important a feature in modern agriculture? They are most powerful, most industrious agents in the collection and preparation of food, both mineral and vegetable, for the use of other crops. They are continually employed in abstracting by their leaves from the air the constituents of which their own vegetable substance is made up; they never cease to collect by their roots, and to bring to the surface, the mineral matters which are essential to their own growth and to that of the crops which follow them; and both these forms of matter, the organic or vegetable, and the inorganic or mineral, are (when the crop has been consumed by sheep) in great part left in the soil in the condition most favourable for the purposes of the succeeding plants. It is chiefly, however, to the accumulation of vegetable matter, that we are to attribute the influence of the root crop generally in improving the soil; for although the turnip does certainly add to the available stock of mineral ingredients of the surface soil, its own growth is very mainly dependent upon the sufficiency of their supply; and to obtain a very liberal return, we must be proportionately liberal in our grants of the materials which are indispensable to the construction of the crop. Root crops, from the great development of their gas-collecting leaves, are comparatively independent of the soil for vegetable nourishment. They may in reality add to, rather than take from, the quantity of vegetable matter in the soil, even when entirely removed; for land has been found after several years' cropping with turnips, all the produce being carried off, absolutely richer in organic matter than it was at first, the plant having returned to the soil more than it had taken from it. How much more is this the case when a large portion of the organic matter, after passing through the body of the sheep, is returned in a highly comminuted state to the land. It cannot, however, be too often insisted upon, that, whilst we may fully restore by a green or root crop all the organic wealth of which the soil has been de-

prived by the grain of a crop of corn, we have no such resource for a renewal of its mineral ingredients. The phosphoric acid, the potash, and the magnesia of a plant must be obtained from the soil, and the soil alone. But even in this respect much may be done; it may be safely predicted that a time will come when, in the cultivation of land already brought into a state of high fertility, the application of artificial manures, except in rare cases, will be looked upon as an unnecessary and unjustifiable waste of money. At the present stage of agricultural practice, the only necessary loss of its mineral ingredients which the land sustains, is comprised in that portion which is sent into our large towns in the different grains and in the bones of animals, and that other small (but unfortunately often too considerable) portion which is lost by the drainage of liquid from the stables and manure heap. The purchase of bones to restore the phosphate of lime removed by the growing of sheep and the milk of the cows, should hardly perhaps be looked upon in the light of the application of artificial manures, because nothing can be more reasonable than to give back what we have taken from the soil; and the measures now in progress for rescuing the sewerage of our large towns, and an improved system in the manufacture and preservation of natural manures at the homestead, will leave but little on the credit side of the land. But allowing a certain and considerable yearly diminution of the mineral elements of fertility in land, we have yet, so to speak, an almost infinite supply of these bodies in the soil itself, provided we knew how we might economically avail ourselves of it. This (the item of *expense*) is after all, the turning point. Most soils, if sufficiently exposed by repeated stirrings and cultivation to the action of the natural agents, water and air, would yield up abundant materials for the growth of luxuriant crops of roots, and through their means of corn. We know from the constitution of the rocks from which they have been produced, that all soils containing any clay, must contain also considerable quantities of potash; and there is every reason to believe that no sandy or chalk soil is absolutely deficient in this alkali. Again, the experiments of Dr. Daubeny and Professor Fownes have led us to believe that phosphoric acid is a constituent of the chalk and limestone strata, as well as of the older rocks; and the recent investigations of Dr. R. D. Thomson and of Mr. Sullivan, go a great way to prove that this acid, so important to agriculture, is present in all the great mineral masses of the globe, whether of ancient and igneous origin, such as granite, gneiss, and all volcanic rocks, or the more modern aqueous deposits of which so large a portion of the soil of England consists. The presence of phosphoric acid in the older rocks however is the important point, because its existence (as insoluble phosphate of lime) in the sedimentary deposits formed from the debris of the first, follows almost as a natural consequence. But though it is quite possible that, from the universal prevalence of the most important mineral constituents of crops, sufficient working of the soil would enable us to dispense with the addition of any artificial manures, it may be, and is, far more economical at the present time to supply the requisite dose of mineral matter directly than to seek to furnish it from the natural resources of the soil by a costly expenditure of mechanical force. It must be observed, however, that there are other ways of bringing into play the dormant energies of the land, besides deep and subsoil ploughing and trenching. Some plants have an extraordinary capacity and disposition to seek food at great depths in the soil—not vegetable food, for there is none in such situations, generally speaking, to be had, but mineral food. For this they will send down their roots, in many cases, to many times the depth which the most enthusiastic advocate of subsoiling would hope to attain; and in their subsequent growth at the expense of so distant a source of nourishment, they effect a far more important chemical addition to the surface soil than the subsoil plough could accomplish. The perfection of a fallow crop, either root or otherwise (other circumstances of facility of cultivation, amount and feeding properties of the crop being equal), would be that which, whilst requiring for the completion of its own structure a considerable quantity of valuable mineral ingredients, should be possessed of an energy and power of obtaining them quite independent of any extraneous supply in the shape of artificial manures. In other words, a scientific review of the conditions of vegetable growth, apart from circumstances of practical detail, would indicate as the best fallow crop a plant with large spreading leaves, strong penetrating roots, and nutritive qualities in the feeding of stock, provided that at the same time its ash were in quantity and composition such as would benefit the cereals for which it is intended to prepare the food. Of this latter point there would be little fear, supposing that the plant was really superior in feeding properties; for an examination of the evidence at present existing in reference to the ash of plants, amply demonstrates that those parts of plants (such as the seeds of the cereals) which owe their high nutritive powers to the large quantity of nitrogenized bodies (gluten, albumen, &c.) they contain, are also proportionably rich—invariably so—in phosphates of lime, magnesia, and potash. Let it not be thought from the foregoing remarks, that we can take only one narrow contracted view of the relation which the culture of the root crop bears to the whole rotation, or that we seek to explain the advantages of existing practices and modern improvements, solely upon chemical principles. A practical farmer will tell us, that there are twenty

ways in which the root crops are beneficial to his land,—that they are means in his hands for altering the texture of the soil,—that they afford him opportunity of cleansing and well stirring it, &c. This is very true; but after all, it will be found that their most important function is, as before said, the collection and preparation of food for the cereals. The root crops may be called the nurses of the tender and helpless corn plants; like nurses, they themselves require food, but their organs are of a nature to render them less dependent upon the character of that food. Food is, indeed, the first consideration to plants as well as animals. Give a man plenty of wholesome nutritious food, and he will be comparatively safe from the attacks of disease, and indifferent to the inclemency of the weather. Stint him in the supplies of this first necessary, and you leave him an easy prey to both. Is it otherwise with plants? Surely not—they too must be fed; if nature does not supply them liberally enough, the care of man must make good the deficiency; but until he knows what they require, his efforts can hardly fail of being in many cases abortive, or, where successful, attended with unnecessary waste. And here we come to the point from which we started; the cereals require two kinds of manuring, mineral and vegetable—the roots require principally only one, the first of these. Supply your roots with mineral nourishment, and whilst by the increase of their produce you are enabled (so to speak) to grow a larger quantity of mutton and beef and milk, you will ensure also a more abundant return of the more valuable crops, for which the turnip and mangold wurzel eventually become the mineral as well as vegetable sustenance."

The connexion of heat with vegetable life and growth is intimate and manifest, yet involves questions of much intricacy, and is so interwoven with accompanying connexion of light, electricity, moisture, and chemical reaction as to present many and strong obstacles to searching investigation. A power is evidently possessed by the living plant of preventing the freezing of its sap amid a temperature far below that at which the inmost juices of the same plant when dead would become frozen; but what that power consists in, or through what precise means it operates, further than the theoretic certainty of its essential connexion in some way or other with life, is utterly unknown. Plants, indeed, in some ways or through some organ or in some particular stages or functions of their growth, are capable of generating very considerable quantities of heat, and sometimes evolve it in sufficient quantity to be perceptible, and may be supposed to form it by the inhalation of oxygen and the burning of carbon in a particular organ or organs in some such method as is done by animals in the organs of respiration; and though the texture of such organ or organs is so exceedingly minute as to have hitherto eluded actual observation, their existence may be satisfactorily inferred, not only from the general fact of generated heat being evolved, but from the particular one that oxygen is inhaled by petals as distinctively as carbonic acid is inhaled by leaves, and especially is absorbed in large quantity by flowers at the instant of fecundation.—Yet the temperature which mainly affects plants is not that which originates within themselves, but that which is suffused around them in the soil and in the atmosphere. A certain degree of exterior temperature is necessary to every plant for the germination of its seeds, the development of its flowers, and the maturation of its fruits; and as this very largely depends upon climate, it both controls the native adaptation of different species of plants to different zones and altitudes of the world, and powerfully modifies the phenomena of vegetation in any one species when removed from its native region to one which is either considerably colder or considerably hotter. The seeds of tropical plants, when sown in temperate climates, germinate much later than in their native regions,—and when sown in gardens, require such a considerable elevation of temperature as can be obtained only in greenhouses or on hotbeds or in stoves; and those of cold countries bordering on the frigid zones, when sown in temperate climates, germinate much earlier than in their native regions, —and when sown in gardens, require to be deposited in the coldest and most shady spots of the open ground. A difference of temperature, in any one district, in one and the same season in different years, likewise exercises a great influence on the epochs of germination, so that, not unfrequently, the seeds of the same plants germinate much earlier when the spring arrives soon, and a mild rainy winter had preceded it, but much later when the heat of spring has been delayed by a severe winter. The unfolding of the leaf buds, and the development of the flowers are also subject to the same changes which are observable in the germination of seeds. According to observations made, at the request of Schübler, by the naturalists assembled at Berlin in the autumn of 1828, during the following summer at Parma in Lombardy, and in various places farther to the north, the same plants flower at Zurich 6 days later than at Parma, at Tubingen 13 days later, at Jena 17, at Berlin 25, at Hamburgh 33, at Greifswald 36, and at Christiana no less than 52 days later than at Parma. In higher latitudes, in districts situated in the north of Germany, the development of vegetation is less retarded than in more southern positions; for the delay of the development of efflorescence between Hamburgh and Christiana amounts to only 3·4 days for one degree's approach towards the north, while that between Southern Germany and Smyrna, which is in the same parallel as the most southern portions of Europe, amounts for the same space to 7·4 days.

The ripening of the fruit also is controlled both by differences in the thermal nature of the season for one and the same place, and by the difference of climate in different latitudes. The wheat-harvest begins in the neighbourhood of Naples in June, in Central Germany in July, in the south of England and in the middle districts of Sweden on the 4th of August; and the barley-harvest takes place at Naples in June, in Central Germany about the end of July or beginning of August, in England on the 14th of August, and in the middle districts of Sweden on the 4th of August. Owing to the comparatively higher temperature which prevails in summer in Sweden, and to the more rapid vegetation there than in England, the wheat-harvest does not take place sooner in the south of England that at Upsala, but occurs about the same time; and barley is 10 days later of ripening in England than in Sweden. For July, in England, has a mean temperature of 60·8° Fahr., and about 62·6° Fahr. at Upsala; and August in England has a mean temperature likewise of about 60·8° Fahr., and in Sweden about the same, namely 60·26° Fahr. If we adopt the observations made during two years in Saxony, we find as the mean result that, from efflorescence to ripeness of fruit, 56 days are required for wheat, 59 for rye, 31 for barley, 45 for oats, and 68 for the potato. According to the observations made in Würtemberg, which were continued for several years, the same period of vegetation required 56·4 days for rye, 42½ for Triticum spelta, 51½ for winter barley, 25 for summer barley, and 25½ for oats.—Mere solar heat, however, never operates alone on vegetation, but always in accompaniment with heat generated by chemical action in the plant and in the soil, and with light, electricity, moisture, and the numerous agents which are brought into play in the course of vital energy and of chemical recombination; and therefore the phenomena of variable seasons and variable climates are very far from being in uniform accordance with those of variable atmospheric temperature. The commencing and most precarious stage of vegetation, from the germination of the seed to the full expansion of the foliage, is, for the most part, at least in such climates as ours, gone through in comparative lowness and unsteadiness of atmospheric heat; and the completing and least derangeable stage, from the formation of the fruit to the falling of the leaf, is gone through in comparatively high and steady temperature of both the atmosphere and the soil. And instead of vegetating seasons of different character capriciously following one another in the same manner as the atmospheric ones, an early immediately following a late and this again immediately following an early, as they would do if they were controlled by mere temperature, a series or succession of early ones is generally followed by a series or succession of late ones. Mr. Gorrie remarks that the vegetating season about Edinburgh commences about the 20th of March, and ends about the 20th of October,—that there 40° is the lowest temperature at which corn will vegetate, and 56° the mean temperature of a good vegetating season,—but that in the Carse of Gowrie, nearly half a degree further north, a good vegetating season seldom occurs, though vegetation there is as forward as in the vicinity of Edinburgh; and this, he adds, is a proof that the progress of vegetation is not dependent solely on temperature. He notes too, as general results, that the wettest seasons are the coldest, and that if very dry seasons are warmer and earlier, vegetation is less vigorous, in consequence of a deficiency of moisture at the roots.—The ways in which heat operates are at once numerous, complex, and recondite; and comprise action throughout the plant in connexion with vital energy, action within the organisms in connexion with electricity and chemistry, action upon the leaves and the epidermis in connexion with light and atmospheric agents, and action within the soil in connexion both with the chemical resolution and recombination of the principles of nutrition, and with the vito-chemical functions of the several parts of the seed and the roots. We have not space to attempt illustrations of these intricate actions; and shall simply refer, in the words of a periodical writer, to a small department of one of them as an instructive instance of the whole. "Solar heat," remarks this writer, "liquefies and refines the vegetable juices; in proportion to that heat, therefore, will be their ascent. Heat also renders liquids capable of holding a larger quantity of salts in solution. These salts form the valuable constituents of vegetables, and are, as it were, their frame-work. We have here an explanation of the rapidity of vegetation in warm weather, and also of the fact that warm seasons mature the finest grain; because in these seasons the ascending sap will hold the greatest amount of salt in solution. The most durable vegetable fibre is generally the product of warm climes; and we have the fact explained upon these principles, because in these climes it will be composed of the greatest amount of least soluble salts."

A remarkable law of vegetation, of great consequence to be well known and understood by cultivators, is the counteractive force of luxuriant growth upon early maturation. In the animal kingdom, the chief influences which accelerate growth at the same time accelerate reproduction, so that the period of puberty is uniformly earlier in domesticated than in wild animals, and in those which are fed plentifully with food, than in those which are scantily supplied; but in the vegetable kingdom, the reverse of this arrangement, to a very considerable extent at least, prevails. Where plants are furnished with an abundant supply of food, their reproductive energies are slowly developed, and flowers and fruits are late in appearing; and when the sup-

ply of nourishment is scanty,—when the plant is starved and death is threatened,—the reproductive energies act with readiness, and flowers and seeds are freely produced. In other words, the scantier the supply of nourishment, the earlier will a plant propagate its kind. Hence seeds which are new or fresh produce plants with more luxuriant foliage, and less inclined to run into flower and fruit, than such as have been kept for some time and are partially spoiled. Pease, for example, are well known to be apt to run to straw where the ground is rich or moist; so that the employment of old ones for seed is, in such cases, the only suitable remedy. But where luxuriance of leaf and great size are the objects sought in any species of garden or farm produce, the newest and most vigorous seeds are eminently suitable,—especially, for example, with turnips and cabbage; old seed producing plants too much disposed to run to flower. The law we have mentioned operates also on the growing plant itself; and occasions a variety of practices in horticulture which, though obviously depending on it, are in general but imperfectly understood by the practical gardener. The transplanting of fruit-trees, for instance, hastens the production of flower-buds. A tree which for years has shown no tendency to produce flower-buds, but which has been exclusively occupied in the extension of its roots and branches, will, upon being shifted from its place, soon exhibit symptoms of a change. The roots by this process have been in part injured, the supply of sap to the tree during the following season has in consequence become diminished, and the plant, ceasing in a great measure to increase its size, hastens to propagate its kind, by the production of flower-buds, and the subsequent display of blossoms and fruit. Again, when a rank growing fruit-tree is engrafted on a slow growing stock, or, in other words, when a tree requiring much sap is compelled to receive its supply through a tree having but a scanty supply, the engrafted branch will come earlier into fruit than if it had always been supplied with abundant nourishment; and this method of accelerating the production of fruit, and termed 'dwarfing,' is particularly serviceable in enabling the cultivator of new varieties to become early acquainted with their respective merits. When fruit-trees are prone to run to wood, gardeners are accustomed to lay bare a portion of their roots during winter; and thereby many of their fibres are destroyed, and the vigour of all greatly diminished; so that the sap during the following summer is transmitted to the branches in less quantity, and the production of fruit-buds is the consequence. In the cultivation of flowering plants, a knowledge of this law and its extensive application may prove of great importance. Sir James Edward Smith, in his Introduction to Botany, mentions that the *Solandra grandiflora*, a Jamaica shrub, was for a number of years cultivated in the English stoves, and propagated extensively by cuttings, each plant growing many feet in length every season, from the abundance of moisture and nourishment, without showing any signs of fructification. At length a pot of it was accidentally left without water in the dry stove at Kew; and, in consequence of this unintentional neglect, the luxuriant growth of its branches was greatly checked, and a flower came forth at the extremity of each. By a similar mode of treatment, the same effect has since been frequently produced; and when the law is once properly understood, its application to a variety of cultivated plants, which are slow in showing flower, must be obvious. In the ordinary cultivation of farms, also, numerous examples of it are frequently occurring. The crops growing on the thinnest parts of the soil, where the nourishment is consequently diminished, are always the first to exhibit their flowers, and to be ready for the sickle; and on ill-managed farms, the harvest is usually much earlier, other things being equal, than in those where the crops are under the influence of a better system. In the management of plantations, the indications of this law may often prove of great value; for wherever we see a tree, in a very young state, exhibiting its flowers and producing fruit, we may anticipate its early decay. The premature formation of fruit-buds is the consequence of a scanty supply of nourishment, arising, it may be, from the roots having been injured, but generally from the plant being placed in an unfavourable soil. The balsam fir, for example, which thrives well on a moist soil, will, if planted on a thin dry soil, begin in a few years to produce cones,—then the bark appears covered with blisters which, when opened, pour forth a limpid resin, and the tree, after languishing a few years, dies. In looking at those decorated villas near a large town, which to the citizen appear so captivating, one may frequently discover the real character of the soil by the premature flowering of the ornamental shrubbery.

The effect of gravitation on the growth and habit of plants, has been the subject of profound speculations and ingenious experiments, on the part of some of the most distinguished phytologists; and, though probably over-estimated or confounded with other effects by its principal advocates, seems to be not only real but powerful. "It can scarcely have escaped the notice of the most inattentive observer of vegetation," says Mr. Knight, "that in whatever position a seed is placed to germinate, its radicle invariably makes an effort to descend towards the centre of the earth, while the elongated germen takes precisely the opposite direction; and it has been proved by Duhamel, that if a seed during its germination be frequently inverted, the points both of the radicle and germen will return to the first direction. Some naturalists have supposed these opposite effects to be produced by gravitation; and it is not difficult to conceive that the

same agent, by operating on bodies so differently organized as the radicle and germen of plants are, may occasion the one to descend and the other to ascend. I conceived that if gravitation were the cause of the descent of the radicle, and the ascent of the germen, it must act either by its immediate influence on the vegetable fibres and vessels during their formation, or on the motion and consequent distribution of the true sap afforded by the cotyledons; and as gravitation could produce these effects only while the seed remained at rest, and in the same position relative to the attraction of the earth, I imagined that its operation would become suspended by constant and rapid change of the position of the germinating seed, and that it might be counteracted by the agency of centrifugal force. Having a strong rill of water passing through my garden, I constructed a small wheel similar to those used for grinding corn, adapting a wheel of a different construction, and formed of very slender pieces of wood, to the same axis. Round the circumference of the latter, which was eleven inches in diameter, numerous seeds of the garden bean, which had been soaked in water to produce the greatest degree of expansion, were bound at short distances from each other. The radicles of these seeds were made to point in every direction, some towards the centre of the wheel, and others in the opposite direction, others at tangents to its curve, some pointing backwards and others forwards relative to its motion, and others pointing in opposite directions in lines parallel with the axis of the wheels. The whole was enclosed in a box and secured by a lock, and a wire-grate was placed to prevent the ingress of any body capable of impeding the motion of the wheels. The water being then admitted, the wheels performed something more than 150 revolutions in a minute, and the position of the seeds relatively to the earth was as often perfectly inverted within the same period of time, by which I conceive that the influence of gravitation must have been wholly suspended. In a few days the seeds began to germinate; I soon perceived that the radicles, in whatever direction they were protruded from the position of the seed, turned their points outwards from the circumference of the wheel, and in their subsequent growth receded nearly at right angles from its axis. The germens, on the contrary, took the opposite direction, and in a few days their points all met in the centre of the wheel. Three of these plants were suffered to remain on the wheel, and were secured to its spokes to prevent their being shaken off by its motion. The stems of these plants soon extended beyond the centre; but the same cause which first occasioned them to approach its axis still operating, their points returned and met again at its centre. The motion of the wheel being in this experiment vertical, the radicle and germen of every seed occupied during a minute portion of time in each revolution precisely the same position they would have assumed had the plants vegetated at rest; and as gravitation and centrifugal force also acted in lines parallel with the vertical motion and surface of the wheel, I conceived that some slight objections might be urged against the conclusions I felt inclined to draw. I therefore added to the machinery I have described another wheel, which moved horizontally over the vertical wheels; and to this, by means of multiplying wheels of different powers, I was enabled to give many different degrees of velocity. Round the circumference of the horizontal wheel, whose diameter was also eleven inches, seeds of the bean were bound as in the experiment which I have already described, and it was then made to perform 250 revolutions in a minute. By the rapid motion of the water-wheel, much water was thrown upwards on the horizontal wheel, part of which supplied the seeds upon it with moisture, and the remainder was dispersed in a light and constant shower over the seeds in the vertical wheel, and on others placed to vegetate at rest in different parts of the box. Every seed on the horizontal wheel, though moving with great rapidity, necessarily retained the same position relative to the attraction of the earth, and therefore the operation of gravity could not be suspended, though it might be counteracted in a very considerable degree by centrifugal force; and the difference I had anticipated between the effects of rapid vertical and horizontal motion soon became sufficiently obvious. The radicles pointed downwards about ten degrees below, and the germens as many degrees above, the horizontal line of the wheel's motion, centrifugal force having made both to deviate eighty degrees from the perpendicular direction each would have taken had they vegetated at rest. Gradually diminishing the rapidity of the horizontal wheel, the radicles descended more perpendicularly, and the germens grew more upright, and, when it did not perform more than eighty revolutions in a minute, the radicle pointed about forty-five degrees below, and the germen as much above, the horizontal line; the one always receding from, and the other approaching to, the axis of the wheel. I would not, however, be understood to assert that the velocity of 250 or 80 horizontal revolutions in a minute will always give accurately the degrees of depression and elevation of the radicle and germen which I have mentioned; for the rapidity of the motion of my wheels was somewhat diminished by the collection of fibres of confervæ against the wire grate, which obstructed in some degree the passage of the water; and the machinery having been the workmanship of myself and my gardener, cannot be supposed to have moved with all the regularity it might have done had it been the work of a professed mechanic. But I conceive myself to have fully proved that the radicles of germinating seeds are made to descend, and their germens to ascend, by some

external cause, and not by any power inherent in vegetable life; and I see little reason to doubt that gravitation is the principal, if not the only, agent employed in this case by nature. I shall, therefore, endeavour to point out the means by which I conceive the same agent may produce effects so diametrically opposite to each other.—The radicle of a germinating seed (as many naturalists have observed) is increased in length only by new parts successively added to its apex or point, and not at all by any general extension of parts already formed; and the new matter which is thus successively added, unquestionably descends in a fluid state from the cotyledons. On this fluid, and on the vegetable fibres and vessels while soft and flexible, and whilst the matter which composes them is changing from a fluid to a solid state, gravitation would, I conceive, operate sufficiently to give an inclination downwards to the point of the radicle; and as the radicle has been proved to be obedient to centrifugal force, it can scarcely be contended that its direction would remain uninfluenced by gravitation. I have stated that the radicle is increased in length by parts successively added to its point; the germen, on the contrary, elongates by a general extension of its parts previously organised, and its vessels and fibres appear to extend themselves in proportion to the quantity of nutriment they receive. If the motion and consequent distribution of the true sap be influenced by gravitation, it follows that when the germen, at its first emission or subsequently, deviates from a perpendicular direction, the sap must accumulate on its under side; and I have found, in a great variety of experiments on the seeds of the horse-chestnut, the bean, and other plants, when vegetating at rest, that the vessels and fibres on the under side of the germen invariably elongate much more rapidly than those on the upper side; and hence it follows that the points of the germen must always turn upwards. And it has been proved that a similar increase of growth takes place on the external side of the germen, when the sap is impelled there by centrifugal force, as it is attracted by gravitation to its under side when the seed germinates at rest. This increased elongation of the fibres and vessels of the under side is not confined to the germens, nor even to the annual shoots of trees, but occurs and produces the most extensive effects in the subsequent growth of their trunks and branches. The immediate effect of gravitation is certainly to occasion the further depression of every branch which extends horizontally from the trunk of the tree, and when a young tree inclines to either side, to increase that inclination; but it at the same time attracts the sap to the under side, and this occasions an increased longitudinal extension of the substance of the new wood on that side. The depression of the lateral branch is thus prevented, and it is even enabled to raise itself above its natural level when the branches above it are removed; and the young tree, by the same means, becomes more upright, in direct opposition to the immediate action of gravitation, nature, as usual, executing the most important operations by the most simple means.—It has, however, been objected by Duhamel (and the greatest deference is always due to his opinions) that gravitation could have little influence on the direction of the germen were it, in the first instance, protruded, or were it subsequently inverted, and made to point perpendicularly downwards. To enable myself to answer this objection I made many experiments on trees of the horse-chestnut and of the bean, in the box I have already described; and as the seeds there were suspended out of the earth, I could regularly watch the progress of every effort made by the radicle and germen to change their positions. The extremity of the radicle of the bean, when made to point perpendicularly upwards, generally formed a considerable curvature within three or four hours when the weather was warm. The germen was more sluggish; but it rarely or never failed to change its direction in the course of twenty-four hours; and all my efforts to make it grow downwards by slightly changing its direction were invariably abortive. — Another, and apparently a more weighty objection to the preceding hypothesis (if applied to the subsequent growth and form of trees) arises from the facts that few of their branches rise perpendicularly upwards, and that their roots always spread horizontally; but this objection may, I think, be readily answered. The luxuriant shoots of trees, in whatever direction they are first protruded, almost uniformly turn upwards, and endeavour to acquire a perpendicular direction; and to this their points will immediately return if they are bent downwards during any period of their growth, their curvature upwards being occasioned by an increased extension of the fibres and vessels of their under sides, as in the elongated germens of seeds. The more feeble and slender shoots of the same trees will, on the contrary, grow in almost every direction; probably because, their fibres being more dry, and their vessels less amply supplied with sap, they are less affected by gravitation. Their points, however, generally show an inclination to turn upwards; but the operation of light, in this case, has been proved by Bonnet to be very considerable. The radicle tapers rapidly as it descends into the earth, and its lower part is much compressed by the greater solidity of the mould into which it penetrates. The true sap, also, continues to descend from the cotyledons and leaves, and occasions a continued increase of the growth of the upper parts of the radicle; and this growth is subsequently augmented by the effects of motion, when the germen has risen above the ground. The true sap is, therefore, necessarily obstructed in its descent, numerous lateral roots are generated, into which

a portion of the descending sap enters. The substance of these roots, like that of the slender horizontal branches, is much less succulent than that of the radicle first emitted, and they are, in consequence, less obedient to gravitation; and therefore, meeting less resistance from the superficial soil than from that beneath it, they extend horizontally in every direction, growing with most rapidity, and producing the greatest number of ramifications, wherever they find most warmth, and a soil best adapted. As these horizontal or lateral roots surround the base of the tree on every side, the true sap, descending down its bark, enters almost exclusively into them; and the first perpendicular root, having executed its office of securing moisture to the plants whilst young, is thus deprived of proper nourishment, and, ceasing almost wholly to grow, becomes of no importance to the tree."

VEGETATION. See Vegetable Physiology.

VEGETO-ALKALIES. See Alkaloids.

VELLA. See Cress-Rocket.

VELLEIA. A genus of ornamental exotic plants, of the goodenia family. Three species, all yellow-flowered, evergreen herbs of between 3 and 8 inches in height, have been introduced to British greenhouses from Australia; and some other species are known.

VELLING. Ploughing up or paring the turf or surface of the ground preparatorily to its being burnt.

VELTHEIMIA. A genus of ornamental, tuberous-rooted, South-African plants, of the day-lily family. Three species, the green-leaved, the glaucous, and the intermediate, all about two feet high, and carrying light flesh-coloured flowers at an early period in spring, have been introduced to the greenhouses of Britain; and they love a soil of rich mould, and are propagated from offsets.

VENISON. The flesh of deer. See the articles Deer and Meat.

VENTILATION. The frequent or constant circulation of pure air in confined apartments, occupied by man, by the lower animals, or by living plants, in sufficient quantity to prevent the accumulation of noxious gases. The necessity and principles of it are widely different in the case of animals and in that of plants; but they are the same in the case of man and in that of the domesticated animals,—the same for human dwellings and for stables and cattle-houses; and while we shall illustrate them in two sets, the one applicable to human beings and the other applicable to plants, we must be understood as saying, with reference to horses, cattle, dogs, and all other domesticated animals, substantially the same things which we say with reference to human beings.

The carbonic acid naturally present in the atmosphere exists just in sufficient quantity to supply food to plants without inflicting any injury on animals; but whenever it acquires considerable increase, in a confined apartment, it becomes highly noxious to every breathing creature. Now during the combustion of wood or coal or any other ordinary fuel, or during the decomposition of straw or any other dead vegetable matter, carbonic acid is formed by the combination of the extricated carbon of the fuel or litter with the oxygen of the air. This acid is formed also by the oxygen consumed in respiration, combining with the carbon in the venous blood, which, having become carbonised in its progress through the arteries for the purposes of life, goes to the lungs to be decarbonised. Thus carbonic acid is given out by the breath, as well as by the exhalant pores of the body, it being supposed that much uncombined oxygen enters the blood, and does not unite with carbon until it reaches the capillary arteries. This formation of carbonic acid in the body engenders animal heat; and oxygen being a supporter of the combustion originated by electrical action—indeed the only supporter of combustion for living creatures—if the formation of carbonic acid actually take place in the capillary vessels, we must, according to the views of Dr. S. Smith, be burning carbon at every pore of our bodies. Though grateful and beneficial to the stomach, though constituting one of the principles of spirit, wine, and every vinous beverage, and though existing as a most wholesome ingredient in the water we drink, carbonic acid is a most deadly poison to the lungs, and, unless largely diluted with atmospheric air, causes instant death to him who breathes it. One adult human being emits through the lungs and pores of the body about 40,000 cubic inches of carbonic acid every day,—an amount the carbon of which would be equal to nearly three quarters of a pound of pure charcoal. Thus four individuals, living and breathing in a room eight feet by twelve, and eight in height, would, in the twenty-four hours, evolve in its space 160,000 cubic feet of carbonic acid, or three pounds of solid charcoal,—a quantity that would deprive the whole of them of life, if all ingress of atmospheric air were prevented. Nor is this all. Certain other gases are constantly emitted from the bodies of living animals, in the form of exhalation or insensible perspiration; and are the chemical products or recombinations of useless, injurious, or morbid and rejected portions of their food and organisms; and escape from their pores, or are thrust out of their system, in a manner strictly analogous to excrementition; and act more or less poisonously on every species of animals, but most of all on individuals of the same species as those by whom they are emitted. The chief of these gases are sulphuretted hydrogen, phosphuretted hydrogen, and ammonia,—substances constituting animal fetor. It is a remarkable fact that hydrogen, which, by itself, is a quiet odourless gas, an antiseptic, a non-conductor of the electric principle, and a positive

electric, is, nevertheless, one of the elements in all compounds generating putrid disease. The sulphuretted hydrogen is a union of hydrogen gas with sulphur, forming an invisible gas heavier than common air in the proportion of 36·764 to 30·8115, and so dreadfully poisonous that one part of it, mixed with 249 parts of air, would destroy a horse if breathed by that animal. Professor Donovan states that a greenfinch died instantly in air containing one fifteen hundredth part of its volume of this gas; and that if the body of a rabbit be enveloped in it, though the head of the animal be exposed to the pure air, it will die in a quarter of an hour. Some individuals give out so large a quantity of this gas, as to discolour white paint. Its odour, when isolated, is that of rotten eggs, it being precisely to the emission of sulphuretted hydrogen that these owe their odious stench. Hydrogen and phosphorus form several combinations equally offensive. The phosphuretted hydrogen is a transparent colourless gas, having, when free, an odour resembling that of putrid fish. Ammonia is largely generated in all animal bodies, and plays a most important part in the dangerous action of animal exhalations upon the human frame. The constituents of it are hydrogen and nitrogen; and the latter of these is the immediate agent of all decomposing action upon organised matter, from the vinous fermentation which, by the decomposition of sugar produces alcohol and vinegar, to the decomposition of dead animal structures by putrefaction. In all these cases the process is the same,—and so is the ultimate result; the action leading, through various changes, to complete dissolution and dispersion of the elements, which enter into new combinations. The nitrogen, in its efforts to liberate itself, having first acted upon the gluten contained in the mucilage of sugar or grape juice, or in malt,—this, in the form of yeast, continues its action upon the sugar, which is converted into wine, afterwards into vinegar, and ultimately into an unwholesome putrid liquor free from either alcohol or vinegar. In like manner, the nitrogen acts as a ferment to dead animal matter, which once in a state of putrefaction communicates its condition not only to any other dead animal matter in contact with it, but to living beings within its influence, producing those dreadful fevers and putrid sores which, in all our large towns, sweep away so many human beings every year; and in some other countries generating that horrible disease called the plague, from which the habits of superior civilisation have freed our island, but to which we were formerly subject from the extremely unclean state of our houses and our persons. The exhalations, then, from human beings, are deadly poisons to human beings, and, in the case of the four individuals shut up in a close room, as we have supposed further up, would engender typhus fever, even if there were nothing to dread from the deadly effects of the carbonic acid and the absence of oxygen. All this shows the necessity of perfect ventilation in our dwelling-houses and public establishments.

When a small close room is occupied for an hour or two by even a single individual, and one too of the most cleanly habits, of the most delicate and fragrant person, any one entering it from the external air will perceive a faint, fetid odour, which certainly does not proceed from the odourless carbonic acid, or the odourless nitrogen; and when several individuals are assembled in such an apartment, the fetid smell is strong and particularly offensive, though they themselves may become insensible to the nuisance. Pastilles are burnt, or perfumes used, to 'purify the air of the room,' as it is alleged; but such expedients only increase the danger; because the pastilles are made of charcoal, sandal-wood, and other perfumes; and the burning of these produces no other effect than to diminish the quantity of oxygen, and increase that of carbonic acid. The atmosphere of a bedroom in which an adult human being has slept, will, in the morning, be found impregnated with a fetid odour, which, from the idiosyncracy of some individuals, is extremely offensive; and this odour is increased by the pernicious practice of not only closing the door and windows, but stopping up the chimney as well, so as to prevent the escape of the offensive gas, at the same time that the fresh air has no power of entering. A large body of assembled men and women, whether consisting of lords and courtly dames at a court drawing-room, or of a mixed congregation in a church, or of the unwashed multitude in a mob, emit the same offensive effluvia, despite of musk, or ambergris, or that most exquisite perfume Ede's hedyosmia, each of which, like every other toilette perfume, carries in its sweets the poisonous carbon. The stench given out by human beings is an agent of death independent of carbonic acid, and one of more fatal import, too, because charged with the germs of infection. It is, in fact, a true putrid ferment, bringing to matter, still possessed of the vital power, the principle of ultimate decomposition. This principle, the cause of the fetor emitted, is a most malignant and destructive poison when reabsorbed by the system; it is nothing less, though in a modified form, than the principle given out by the putrefaction of dead animal matter.

Besides the ultimate elements of animal matter, oxygen, hydrogen, nitrogen, and carbon—elements belonging as much to the snail and the worm as to the flesh of man, or to that of the dog, the tiger, and the elephant, or any other breathing thing—sulphur, phosphorus, ammonia, potash, soda, lime, and many other chemical substances, exist in the human animal structures. Many of these matters are taken into the body with the food, for the purposes of life; and others are obtained by respiration, and by

absorption through the skin. The combinations of sulphur, phosphorus, and nitrogen with hydrogen, are fully sufficient to explain the fetor of animal exhalations. The deadly poisonous sulphuretted hydrogen is largely emitted by some persons in a state of disease, especially by those who have undergone excessive mercurial treatment. As it blackens white lead, the appearance of discoloration on the white paint of a room pretty surely indicates, in the absence of any other apparent cause, an excess of this gas from some individual who has occupied or visited the apartment. The same compound blackens the trinitrate of bismuth, from which the pearl powder of the shops is manufactured. Ladies using this pigment upon their skin should ascertain that they are free from an abnormal generation of sulphuretted hydrogen; otherwise the pearl powder may change from white to a livid lead colour, or even black,—an effect often unjustly attributed to the bad quality of the article. All these offensive and poisonous compounds of hydrogen concur in giving fetor and imparting to animal exhalations a poisonous action distinct from carbonic acid, in the same manner that they create the stench and fermentation of dead flesh. Both kinds of exhalations, those from living bodies and those from dead flesh, are the bearers of putrid and pestilential disease; and a congregation of filthy human beings in a confined space, and deprived of sufficient air, is as certain to generate putrid fever, as the infection from putrid dead bodies. This is the cause of the gaol pestilence, and of the various typhus fevers prevalent in the densely-inhabited dwellings of the poor.

It has been found that young persons in good health are sweeter and evolve generally a less amount of fetid animal exhalations than the middle-aged and the old. The cause of this is obvious: these exhalations in clean and healthy individuals proceed, in a considerable degree, from the excess of nourishment not required for the support of the system, and which is therefore got rid of by the insensible perspiration of the skin. Young people are still growing, if not in height, at least in the various structures of the body, which is not in full maturity till about the age of forty years. A greater amount of nutriment is therefore required to supply in them the secretions of formation. After the age of forty, there are no secretions of formation, but only of continuance; therefore less chyle is required for the purposes of the animal frame. Yet not only is the same quantity of food taken, but often a great deal more. At the maturity of life, and as the body descends the vale of years, people indulge more in alimentiveness; hence an increase of fetid animal exhalations; hence, also, acid digestion and its attendants,—gout, gravel, and a variety of other diseases. That which the system cannot use, it must get rid of; and where, from excess in quantity, the process of getting rid of it is impeded, disturbance must ensue. From this it may be inferred, that the space occupied by young people is, in general, somewhat less impregnated with animal effluvia, than that containing the middle-aged and the advanced in life.

But in addition to the fetid exhalations of healthy persons, there are the still more pernicious exhalations of bodies actually diseased, and of many others which, if not in a state of positive disease, are at least in an unhealthy condition, from excess of pleasure, intemperance in food and drinking, injudicious mercurial treatment, bad habits, or constitutional scrofula in some form or other. Thus, in crowded assemblies, besides the carbonic acid generated, and the exhalations of the healthy portion of the company, the impurity of the air is further increased by the offensive emanations from tuberculated lungs, foul ulcers, and loathsome diseases,—by the fumes of half-digested wine, spirits, ale, and porter,—by the odour of smoked cigars and the meerschaum,—the whole forming a tainted and disgusting compound breathed over and over again by all present. Is it, then, surprising, after dancing to excess in such an atmosphere, after remaining in and breathing it during a considerable number of hours, the muscles fatigued by exertion, the pores of the skin opened and relaxed, every organ of the body affected by the foul air and the unnatural heat, that a delicate girl should be injured by a sudden and violent change of temperature, and from the bracing effect of the fresh air of which she had been so long deprived, should imbibe the germs of a disease that proves so fatal to the young and lovely? Even the most robust are affected by such causes, which no human being can encounter with impunity, but which, on delicate constitutions, are sure to plant the standard of dissolution.

The necessity of ventilation is, therefore, manifest. Air fresh from household contamination ought to be freely admitted in sufficient quantity to carry off all animal exhalations. Carbonic acid, though heavier than air, being expanded by the heat of inhabited apartments, becomes lighter, flows out when its escape is possible, and gives place to a fresh and pure atmosphere. Such ventilation is indispensable not only in crowded rooms and assemblies, but in every apartment occupied by even a single individual. The same degree of ventilation found so useful in public hospitals for the cure of disease, is equally useful in private dwellings for its prevention. The admission, into any room, of the pure atmosphere at a proper temperature never brings disease—quite the reverse; it often removes the cause of disease; and it is a striking fact that the absence of the fresh pure air is the real cause of those various indispositions that are imputed to its presence. Assuredly when the body is overheated, and the vascular action of the skin ren-

dered almost powerless by long sojourn in a close, hot, animalised and carbonised apartment, though only two or three individuals should be present, the lungs and the skin are brought to such a state of morbid susceptibility, that the invigorating and healthy action of the pure atmosphere produces inflammation, often followed by death. It is just like suddenly giving a large quantity of food to a person starved: the effect of treatment so injudicious is death. To restore the body to its normal condition, the air must be administered as gradually as food after starvation; but in both cases the germs of fatal disease often sprout forth ere the remedy can operate. There can be no doubt, then, of the necessity of keeping the air of every inhabited apartment in a state of constant renovation and purity; and that many of the diseases now prevalent, especially those affecting the respiratory organs, and those bearing a typhoid type, are the result of inadequate ventilation. Nor must it be believed that these evils are confined to the small and crowded dwellings of the poor; they are common in the spacious mansions of the wealthy where there is no excuse for them, and where by double doors, green baize, gilt leather, list, and various other contrivances, as much pains are taken to exclude the vital air as would be taken to shut out the pestilential sirocco, or the simoom of the desert. The prevention of cold, and the preservation of a proper temperature, are by no means incompatible with perfect ventilation—quite the reverse; a proper temperature may be best maintained by keeping up a stream of air gently undulating through the apartment, instead of shutting up this so closely that each time the door is opened, a torrent of cold air rushes in, and, until the equilibrium is established, does considerable mischief, by giving colds to those susceptible of taking them,—such susceptibility, in healthy persons, being caused solely by ignorance and bad habits.

There is still a question of great importance, —what amount of space in cubic feet ought to be assigned, in sleeping apartments, to each adult human being? Not less, we reply, than 1,000 cubic feet. Even more would be preferable. A room 18 feet long, 16 broad, and 9 feet high, with a door, a proper-sized window, and a free chimney—closing a chimney being highly injurious—should not be inhabited by more than two individuals. The average allowance in hospitals is from 500 to 600 cubic feet,—a space much too small. In union workhouses the average is only from 200 to 300 cubic feet,—a parsimony of space which greatly increases the demand for pauper medical relief, by rendering the sleeping apartments of the indigent inmates highly insalubrious. The amount of space allowed in stables and cowhouses ought, of course, to correspond in amplitude to the amount allowed in human bedrooms. And the ventilation there, as well as in all apartments occupied by man, should be provided for systematically, by means specially applicable and so contrived as to maintain an equable temperature in every nook and at all hours, and not by make-shifts or by chinky walls or ricketty doors and windows. The fresh air should enter in constant, gentle, minute currents, in equal proportion to the corresponding outflow of foul air, and in such direction or through such contrivances as to maintain the same temperature in the most distant as in the nearest parts of the apartment. Alternations of fresh air and of foul, sudden vicissitudes of cold and heat, and partial currents of cold air through corners or sides of apartments elsewhere full of stagnant warm air, are almost as injurious to both man and beast as a general prevalence of carbonaceous and fetid vapours.

The ventilation of plant-houses does not require to make any provision for either a supply of oxygen to plants or the carrying away of putrefactive fetor from them,—for, during all the period of light, they inhale carbonic acid from the air, and abstract its carbon, and give back its oxygen, so as to reverse the result of animal respiration; and such free or excessive ventilation as is practised in the great majority of hothouses is more frequently injurious than advantageous, and far more suitable to animals than to plants. "Considering the manner in which glass-houses of all kinds are constructed," says Dr. Lindley in his Theory of Horticulture, "the buoyancy of the air in all heated houses would enable it to escape in sufficient quantity to renew itself as quickly as can be necessary for the maintenance of the healthy action of the organs of vegetable respiration. It is, therefore, improbable that the ventilation of houses in which plants grow is necessary to them, so far as respiration is concerned. Indeed, Mr. Ward has proved that many plants will grow better in confined air than in that which is often changed. By placing various kinds of plants in cases, made, not indeed air-tight,—for that is impossible with such means as can be applied to the construction of a glass-house,—but so as to exclude as much as possible the admission of the external air, supplying them with a due quantity of water, and exposing them fully to light, he has shown the possibility of cultivating them without ventilation, with much more success than usually attends ordinary glass-house management. In forcing-houses, in particular, ventilation, under ordinary circumstances, in the early spring, must be productive of injury rather than benefit. Many gardeners now admit air very sparingly to their vineries during the time that the leaves are tender and the fruit unformed. Some excellent stoves have no provision at all for ventilation; and we have the direct testimony of Mr. Knight as to the disadvantage of the practice in many cases to which it has been commonly applied. 'It may be objected,' says this great horticulturist, 'that

plants do not thrive, and that the skins of grapes are thick, and other fruits without flavour, in crowded forcing-houses; but in these it is probably light, rather than a more rapid change of air, that is wanting; for, in a forcing-house which I have long devoted almost exclusively to experiments, I employ very little fire heat, and never give air till my grapes are nearly ripe, in the hottest and brightest weather, further than is just necessary to prevent the leaves being destroyed by excess of heat. Yet this mode of treatment does not at all lessen the flavour of the fruit, nor render the skins of the grapes thick; on the contrary, their skins are always most remarkably thin, and very similar to those of grapes which have ripened in the open air.' While, however, the natural atmosphere cannot be supposed to require changing in order to adapt it to the respiration of plants, it is to be borne in mind that the air of houses artificially heated may be rendered impure by the means employed to produce heat. Sulphurous acid gas escapes from brick flues, ammoniacal vapour from fermenting manure; and there may be many unsuspected sources of the introduction of vaporous impurities; an inconceivably minute quantity of which is enough to deteriorate the air, so far as vegetation is concerned. Drs. Turner and Christison found that 1-10,000th of sulphurous acid gas destroyed leaves in 48 hours; and similar effects were obtained from hydrochloric or muriatic acid gas, chlorine, ammonia, and other agents, the presence of which was perfectly undiscoverable by the smell. We also know that the destructive properties of air poisoned by corrosive sublimate, perhaps by its being dissolved in the vapour of a hothouse, are not at all appreciable by the senses. Ventilation is necessary, then, not to enable plants to exercise their respiratory functions, provided the atmosphere is unmixed with accidental impurities, but to carry off noxious vapours generated in the artificial atmosphere of a glazed house, and to produce dryness or cold or both.

"When the external air is admitted into a glazed house containing a moist atmosphere, it, under ordinary circumstances, is much colder than that with which it mixes; the heated damp air rushes out at the upper ventilators, and the drier cold air takes its place; the latter rapidly abstracts from the plants and the earth, or the vessels in which they grow, a part of their moisture, and thus gives a sudden shock to their constitution, which cannot fail to be injurious. This abstraction of moisture is in proportion to the rapidity of the motion of the air. But it is not merely dryness that is thus produced, or such a lowering of temperature as the thermometer suspended in the interior of the house may indicate; the rapid evaporation that takes place upon the admission of dry air produces a degree of cold upon the surface of leaves, and of the porous earthen pots in which plants grow, of which our instruments give no indication. To counteract these mischievous effects many contrivances have been proposed, in order to insure the introduction of fresh air warm and loaded with moisture,—such as compelling the fresh air to enter a house after passing through pipes moderately heated, or over hot water pipes surrounded by a damp atmosphere, and so on, the advantages of which of course depend upon the objects to be attained. If ventilation is merely employed for the purpose of purifying the air, as is often the case in hothouses and in dung-pits, it should be effected by the introduction of fresh air damp and heated. If it is only for the purpose of lowering the temperature, as in greenhouses, or in the midst of summer, the external air may be admitted without any precautions. But it is very commonly required in the winter, for the purpose of drying the air in houses kept at that season at a low temperature; such, for instance, as those built for the protection of heaths, and many other Cape and New Holland plants: in these cases it should be brought into the house as near the temperature of the house as possible, but on no account loaded with moisture. One of the principal reasons for drying the air of such houses is, to prevent the growth of parasitical fungi, which, in the form of mouldiness, constitute what gardeners technically call 'damp.' These productions flourish in damp air at a low temperature, but will not exist either in dry cold air or in hot damp air. If the air of cool greenhouses is allowed to become damp, the fungi immediately spring up on the surface of any decayed leaves, or other matter which may be present, when they spread rapidly to the young and tender parts of living plants; and when this happens they consume the juices, choke the respiratory organs, and speedily destroy the object they attack. [See the article Mould.] Ventilation is also required in the winter in such places as dung-pits or frames, especially those in which salad, cucumbers, and similar plants are grown. In those cases, the object is to dry the air, in order that the plants may not absorb more aqueous particles than they can decompose and assimilate. Although plants of this kind will bear a high degree of atmospherical moisture in summer, when the days are long and the sun bright, and when, consequently, all their digestive energies are in full activity, yet they are by no means able to endure the same amount in the short dark days of winter, when, from the want of light, their powers of decomposition or digestion are comparatively feeble. Hence, no doubt, the advantage of growing winter cucumbers in forcing-houses, instead of dung-frames. One of the causes of success in the Dutch method of winter forcing is, undoubtedly, their avoiding the necessity of winter ventilation, by intercepting the excessive vapour that rises from the soil, and which would otherwise mix with the air. For this purpose

they interpose screens of oiled paper between the earth and the air of their houses; and in their pits for vegetables they cover the surface of the ground with the same oiled paper, by which means vapour is effectually intercepted, and the air preserved from excessive moisture.

"In forcing-houses, ventilation is thought to be required at the time when the fruit is ripening, for the purpose of increasing the perspiration of the plants, and, consequently, of assisting in the elaboration of the secretions to which fruit owes its flavour. But, even for this, its utility is, perhaps, overrated,—and it is quite certain that it may be easily carried to excess; for, if it is so powerful as to injure the leaves by over-drying the air, an effect the reverse of what was intended will be produced; that is to say, the quality of the fruit will be deteriorated. Upon this subject Mr. Knight has made the following observations:—'A less humid atmosphere is more advantageous to fruits of all kinds, when the period of their maturity approaches, than in the earlier stages of their growth; and such an increase of ventilation, at this period, as will give the requisite degree of dryness to the air within the house, is highly beneficial, provided it be not increased to such an extent as to reduce the temperature of the house much below the degree in which the fruit had previously grown, and thus retard its progress to maturity. The good effect of opening a peach-house, by taking off the lights of its roof during the period of the last swelling of the fruit, appears to have led many gardeners to overrate greatly the beneficial influence of a free current of air upon ripening fruits; for I have never found ventilation to give the proper flavour or colour to a peach, unless that fruit was, at the same time, exposed to the sun without the intervention of glass; and the most excellent peaches I have ever been able to raise were obtained under circumstances where change of air was as much as possible prevented, consistently with the admission of light (without glass) to a single tree.'

"It is not improbable that one of the advantages of ventilation depends upon a cause but little adverted to, but which certainly requires to be well considered. It was an opinion of Mr. Knight, that the motion given to plants by wind is beneficial to them by enabling their fluids to circulate more freely than they otherwise would do; and in a paper printed in the Philosophical Transactions for 1803, he adduces, in support of his opinion, many experiments and observations; of which the following is sufficiently striking:—'The effect of motion on the circulation of the sap, and the consequent formation of wood, I was best able to ascertain by the following expedient. Early in the spring of 1801, I selected a number of young seedling apple trees, whose stems were about an inch in diameter, and whose height between the roots and first branches was between 6 and 7 feet. These trees stood about 8 feet from each other; and, of course, a free passage for the wind to act on each tree was afforded. By means of stakes and bandages of hay, not so tightly bound as to impede the progress of any fluid within the trees, I nearly deprived the roots and lower parts of the stems of several trees of all motion, to the height of three feet from the ground, leaving the upper part of the stems and branches in their natural state. In the succeeding summer, much new wood accumulated in the parts which were kept in motion by the wind; but the lower parts of the stems and roots increased very little in size. Removing the bandages from one of these trees in the following winter, I fixed a stake in the ground, about 10 feet distant from the tree, on the east side of it; and I attached the tree to the stake at the height of 6 feet, by means of a slender pole, about 12 feet long; thus leaving the tree at liberty to move towards the north and south, or, more properly, in the segment of a circle, of which the pole formed a radius; but in no other direction. Thus circumstanced, the diameter of the tree from north to south in that part of its stem which was most exercised by the wind exceeded that in the opposite direction, in the following autumn, in the proportion of thirteen to eleven.' Now, if the effect of motion is to increase the quantity of wood in a plant, it is evident that ventilation, which causes motion, must tend to produce a healthy action in the plants exposed to it; and such a state must also be favourable to the development of all those secretions upon which the organization of flowers, the setting of fruit, and the elaboration of colour, odour, flavour, &c., so much depend. Some suggestions by Mr. Knight, as to the manner in which this result can be artificially produced, will be found in the *Hort. Trans.*, vol. iv. p. 2 and 3; but the subject has as yet attracted little attention."

VENUS'S COMB. See Shepherd's Needle.

VENUS'S FLY-TRAP. See Muscipula.

VENUS'S HAIR. See Maidenhair.

VENUS'S LOOKING-GLASS. See Prismatocarpus and Bellflower.

VENUS'S NAVELWORT,—botanically *Omphalodes*. A genus of ornamental, hardy, herbaceous plants of the borage family. The name alludes to the navel-like form of the seeds.—The evergreen species, *Omphalodes sempervirens*, called by Linnæus *Anchusa sempervirens*, grows wild on rubbishy spots of ground in Britain. Its root is perennial; its foliage is evergreen; its stem is about 30 inches high; and its flowers have a blue colour, and bloom from May till July. Two evergreen perennial species, and four annual species, some with white flowers, others with blue flowers, all very handsome and more or less nearly allied to the hound's-tongues, have been introduced to Britain from the southern parts of Continental Europe; and all thrive well on any common soil.

VERATRIA. See Veratrum.

VERATRUM,—popularly *White Hellebore.* A genus of tall, ornamental, herbaceous plants, of the melanthium family. The white species, *V. album*, is a native of the mountains of Switzerland, Italy, Greece, and Russia, and was introduced to Britain in 1548. Its root is perennial, fusiform, and fleshy, and has strong fibres gathered into a head; its stem is annual, thick, cylindrical, erect, hairy, branching, and from 3 to 6 feet high; its leaves are sheathing, yellowish green, oblong-ovate, plaited longitudinally, and about 10 inches long and 5 broad; its inflorescence has the form of long terminal spikes, consisting of small alternate spikelets, each accompanied with a lanceolate bract; its flowers have a pale greenish-yellow colour, and bloom from June till August; and its fruit are capsules, with many compressed membranous seeds. The whole of the plant is very acrid and poisonous; and the root eminently partakes of the same properties, and has a strong, disagreeable odour, and a bitterish, very acrid, and very prolonged taste, but, in a dried state, wants all the odour and much of the taste, and is used in medicine. The pieces of the dried root in drug shops are either transverse slices of the thick parts or longitudinal slices of the fibrous parts, and have an exsiccated and corrugated appearance, and break with a short starchy fracture; and they have been found by analysis to consist of lignin, gum, starch, acidulous gallate of veratria, a yellow-colouring matter, elaine, stearine, and ammonia. The veratria is a peculiar alkaline principle, but occurs also in colchicum, and appears to be the chief seat of medicinal power, both in veratrum and in colchicum. Powdered veratrum root is a violent sternutatory, emetic, and cathartic, and cannot be safely used, in any form or for any purpose, in either human or veterinary medicine, without the utmost caution. It serves as a sternutatory in cases of lethargy and gutta serena, but requires to be greatly diluted with starch, powdered liquorice root, or some other mild powder; it is useful in the form of ointment, as an external applicant, in some bad cases of ulcerated surface, yet, even in this form, is liable to excite griping and purging; and it acts with more or less advantage, in substance or in tincture, as an internal administration, in cases of leprosy, scabies, epilepsy, and mania, but, if given in overdose, produces hypercatharsis, excessive vomiting, tremors, vertigo, syncope, convulsions, and death,—and even when given in moderate doses, is liable to act with very dangerous violence. A safe dose of it to a strong man cannot exceed two grains, and can be prescribed only by a very skilful physician. The best antidote to an overdose of it is a strong infusion of nut-galls. In veterinary medicine, the powder, in doses of from 20 to 30 grains, acts well as a powerful sedative on the horse, and is sometimes very serviceable in various inflammations, and particularly in inflammation of the lungs; but if given in slight overdose or at an improper moment, it may produce vertigo, tremor, hypercatharsis, and death,—and, it, therefore, ought never to be administered by an unskilful or inattentive practitioner, and far less by a groom or a quack.—Five other species of veratrum, varying in height from 2 to 6 feet, all hardy, perennial-rooted, annual-stemmed herbs, one with white flowers, one with dark purple flowers, and the other three with green flowers, have been introduced to Britain.

VERBASCUM. See Mullein.

VERBENA,—popularly *Vervain.* A diversified genus of corolliflorous exogens, constituting the type of the natural order Verbenaceæ. This order has a botanical place in the vicinity of the Labiatæ and the Scrophularineæ; but is exceedingly diversified in its outward habit and general appearance,—and comprises ugly weeds and brilliant beauties, lowly annuals and imposing shrubs, creeping herbs and lofty trees. A large proportion of the species inhabit wastes, waysides, and woods in Southern Europe and within the tropics. About 160 hothouse species, about 60 greenhouse species, and nearly 40 hardy species, besides very many varieties and hybrids, occur at present in the gardens and botanical collections of Britain; and they are distributed among about 30 genera,—some of the most remarkable of which are verbena, clerodendrum, aloysia, vitex, and tectona.

One species of the genus verbena grows wild in Britain, about 40 have been introduced from other countries, and a few more are known. Some species also which formerly belonged to it are now assigned to three other genera; and many of the most beautiful varieties and hybrids belonging to it have almost as distinct characters, at least to a popular observer, as if they were separate species. Some of the species are hardy annuals; some, hardy biennials; some, hardy, annual-stemmed, erect perennials; some, frame or greenhouse, evergreen, erect herbaceous perennials; and some, either half-tender annual-stemmed perennials, or half-tender evergreen undershrubs, or evergreen herbaceous creepers. Their height varies from an inch or so to 6 or 8 feet; and the extent of the creeping kinds is, in some instances, comparatively great, but depends much on situation and culture. Some have undivided leaves; some, trifid leaves; and some, variously cut and emarginated leaves. A considerable number are mere weeds; and the rest vary in ornamental character from simple beauty to the most dazzling brilliance. The colour of the flowers is generally pervading and uniform in any one species or variety; but it comprises so wide a range as white, sulphur, cream, carmine, pink, red, crimson, scarlet, purple, violet, lilac, and blue throughout the genus.

The indigenous species, or common vervain, *Verbena officinalis*, inhabits road-sides, dry waste grounds, and dry pastures, in the vicinity of dwell-

ing-houses and villages. Though pretty common in almost every district of England, and often very abundant by the side of footpaths, it scarcely ever occurs at a greater distance from a human dwelling than a quarter of a mile; and it used to be called the Simpler's joy on account of its indicating the near neighbourhood of a house. Its root is perennial, woody, and somewhat creeping; its stem is annual, ascending, leafy, roughish with minute bristles, and from 18 to 27 inches high; its leaves are deeply cut; its inflorescence is a sort of panicle composed of several slender spikes; and its flowers are inodorous and bluish or purplish, and bloom from June till September. This plant has scarcely any aromatic or other sensible quality; and though now known to be of little or no value for any medicinal or economical purpose, and to possess the rank as well as the appearance of a mere weed, it formerly had a place in the materia medica, and also bore high fame for some remarkable uses of superstition. Its root, too, was worn about the neck on a string as a charm against the king's evil.

Some of the most interesting of the exotic species are the veronica-leaved, *V. veronicæfolia*, a hardy blue-flowered annual, of 2 or 3 inches in height, blooming in July and August, and introduced from Mexico in 1825; the hispid, *V. hispida*, a hardy, purple-flowered annual of about a foot in height, blooming in July and August, and introduced from Peru in 1816; the elegant, *V. elegans*, a hardy, blue-flowered biennial, of 2 or 3 inches in height, blooming in July and August, and introduced from Mexico in 1826; the hairy-spiked, *V. lasiostachya*, a hardy, purple-flowered biennial, of about 2 feet in height, blooming in July and August, and introduced from California in 1826; the many-spiked, *V. polystachya*, a hardy, annual-stemmed, red-flowered perennial, about 4 feet high, blooming in July and August, and introduced from Mexico in 1820; the sister, *V. sororia*, a hardy, annual-stemmed, purple-flowered perennial, about 2 feet high, blooming in July and August, and introduced from Nepaul in 1824; the strong-veined, *V. venosa*, a frame herbaceous evergreen, about 30 inches high, carrying rose-coloured flowers from May till September, and introduced from Buenos Ayres in 1830; Tweedie's, *V. Tweediana*, a greenhouse herbaceous evergreen, carrying scarlet flowers in autumn, and introduced from Brazil in 1834; the cut-leaved, *V. incisa*, a greenhouse herbaceous evergreen, about 2 feet high, carrying red flowers from June till September, and introduced from Panama in 1836; the fair, *V. pulchella*, a frame suffruticose evergreen, about a foot high, carrying whitish flowers from June till September, and introduced in 1834; the rooting, *V. radicans*, a frame trailing evergreen, about 6 inches high, carrying lilac flowers from June till September, and introduced from Chili in 1832; the germander-like, *V. teucrioides*, a greenhouse herbaceous evergreen, about 2 feet high, carrying white and pink flowers in autumn, and introduced from South America in 1837; the melindres, *V. melindres*, a greenhouse trailing and climbing evergreen, capable of being trained over a large surface, carrying a profusion of brilliant, scarlet corymbosely arranged flowers, and comprising a number of very distinctly charactered varieties.

But some of the still more recently introduced species, together with the best varieties of the old ones and all the choicest hybrids, are the most attractive both to amateur florists and to popular observers; and they constitute, not only a very numerous collection of flower-garden ornaments, but one of the most dazzlingly beautiful in the world. If a selection rather than a collection be wanted, the following may be mentioned as among the best entitled to favour:—Chandler's atrosanguinea is the brightest of the scarlets, and a very free and robust grower. *V. ignea*, is the next in colour, but is rather difficult to keep through the winter; and Croucher's maxima is nearly as dark, with a better habit of growth. *V. Hislopii* is a bright scarlet, with something of the breed of teucrioides in it; and *V. melindres superba*, and *V. latifolia*, are kinds known and esteemed by every one. All the varieties of Tweediana are good; but *V. T. superba* is the best. Of the rose-coloured or pink kinds, Barnsii is the best, as the old incisa is a very straggling grower, and fades very much under a strong sun. Among the purple kinds, *V. Stewartii* is the best; but *V. Charlwoodiana*, *Hendersonii*, and *triumphans* are so much like it, that it is difficult to distinguish the flowers when off the plants; the two first are probably the best, though all four are worth cultivation. The orange-scarlet varieties are a new class of colours; and of these Kyle's *speciosa* and Croft's *formosa elegans* are most worthy of notice. The first has large flowers, with a white centre; and *formosa elegans* is very appropriately named, for it certainly is elegantly beautiful. *V. variegata* is a salmon scarlet, and *mirabilis* is in the same way, but not quite so bright. Of the white varieties, *V. teucrioides* is very much surpassed by Youell's Princess Royal and the Queen. Princess Royal is a very pure white, more so than the Queen, and a plant of excellent habit. The varieties of *V. teucrioides* are very numerous, and most of them sweet scented. *V. T. rosea* is a purplish rose colour; and Girling's *eximia* is a flower of the same character, but two or three shades darker. *Burleyana* might be called variegated, as the flowers open of a deep rose or ruby colour, and change to pale rose, so that there are several colours upon a plant at the same time. *V. Ingramii*, is a fine variety with deep rose-coloured flowers tinged with salmon. *V. Taglionii* is very fine, with immense corymbs of flowers of a silvery palish colour; Rosy Queen, and Mortloch's superb, are of nearly the same colour, and all three

very good. *V. Iveryana* is a rosy purple, very good; and *V. Bishopii* is a purplish rose-coloured kind, which makes a good bed. Of the lavender-coloured varieties, *V. Niellii* is very good, but of a loose habit. *V. Hydeana* is a pale bluish lilac, very distinct; and *V. Vangardii* is of nearly the same colour. *V. Laconii* is a deep bluish lilac, and a very good variety.

The soil required by some of the old kinds is poor, light, and sandy, and that required by others, as well as by some of the hybrids, is rich and loamy, with a large admixture of mould; but any common garden soil, particularly of a light loamy nature, if kept in careful drainage, will suit excellently for most. The annuals and biennials, even the hardiest, are best raised from sowings on a gentle hotbed; the perennials are most readily multiplied from seeds or from radical divisions; and the hybrids and fine varieties increase rapidly from cuttings, planted in sand under a glass, and, in the case of the tender kinds, in a little heat. All the kinds succeed well in the open ground during the summer and autumn months; and most of the chief beauties do admirably either in beds, in patches, or in pots. The trailing and stoloniferous sorts require to be pegged down; and the climbing kinds must be trained on fancy wire trellises.

VERBERINA. A diversified genus of exotic plants, of the sunflower division of Compositæ. Fifteen species have been introduced to the gardens and botanical collections of Britain, principally from the two Indies and the hot parts of Continental America. They vary in height from 2 to 10 feet. Three are evergreen shrubs, five are evergreen herbs, three are annual-stemmed perennial-rooted herbs, and four are annual-rooted herbs; five have alternate leaves, and the rest have opposite leaves; two have respectively white and orange flowers, and the rest have yellow flowers; a few are ornamental, and the rest have a weedy appearance. The marigold-like species, *V. calendulacea*, a yellow-flowered annual of about 2 feet in height, introduced upwards of a century ago from Ceylon, is regarded in India as a medicinal plant, every part of it having a pleasant and somewhat aromatic taste, and either a decoction of it, or the powder of its seeds and leaves, being prescribed in cases of jaundice and of visceral obstruction. The cultivated species, *V. sativa*, a yellow-flowered annual of about 6 feet in height, introduced from India in 1806, is cultivated in its native country for the sake of the oil produce of its seeds. Most of the kinds thrive well in any common soil.

VERDIGRIS,—chemically *Subacetate of Copper*. A green mineral-like substance, used sparingly as a drug in medicine, and extensively as a pigment in the arts. A coarse and common kind of it is manufactured on a large scale in the South of France, by covering plates of copper with the refuse of the grape after the juice has been expressed for making wine,—and afterwards collecting the accretion which forms on the plates, and beating it in wooden mortars, and pressing it down in bags of white leather; but this always contains a greater or less degree of vegetable extractive, and of the stalks and husks of the grapes. A much better kind is prepared in Britain by covering copper plates with cloth soaked in pyroligneous acid, or by exposing copper plates to the fumes of vinegar. Pure verdigris has a beautiful bluish green colour, a foliaceous texture, and a hard and pulverulent consistence; it is quite inodorous, and seems at first contact with the tongue or palate to be nearly insipid, but leaves a strong metallic taste in the mouth; and it consists, according to Dr Ure, of 52 per cent. of acetic acid, 39·6 of peroxide of copper, and 8·4 of water. It is an useful external application, both in human and veterinary medicine, as a mild caustic for cleaning foul ulcers, reducing the callous edges of sores, and consuming fungous growths; and it serves also, in the form of ointment, as a remedy for chronic ophthalmia; but, in internal exhibition, though recommended as a good tonic in such cases as epilepsy in the human subject and farcy in the horse, it is very uncertain and extremely dangerous, and can seldom be wisely preferred by even the most skilful practitioner to some other drug. A safe dose of it for a strong man rarely can amount to half a grain; and an overdose of it proves rapidly fatal, producing hypercatharsis, excessive vomiting, convulsion, palsy, coma, and death. The best known antidotes are albumen and the ferrocyanate of potash.

VERDITER. A blue pigment, found native in Hungary, and also manufactured by decomposing nitrate of copper with chalk. It is an impure carbonate of copper.

VERJUICE. An acid liquor, used as a chief ingredient in a cooling beverage, and for some of the same purposes as vinegar. It may be prepared from gooseberries, from crab apples, from such grapes as are too coarse for yielding good wine, from such acidulous apples as are least fit for cyder, and from any other fruit of similarly sour character, containing a large proportion of either malic, citric, or tartaric acid. A good method of preparing it from ripe gooseberries or grapes is to express the juice without bruising the seeds,—to strain the expressed juice through a cloth, to bottle it, and to expose it uncorked for six or seven days to the sun,—to replace every morning with fresh liquid as much matter as has become converted into froth,—and, when the fermentation has ceased, to decant the liquor into other bottles, and to cork them, and place them in a cool cellar till they are wanted for use. Verjuice thus prepared is in great request in France as the sapid and cooling ingredient of a refreshing summer beverage,—a little of it being well mixed with a little sugar or syrup, and then poured into a glass and filled up with water; and in a state of ready mixture with sugar, it is

sold by the confectioners of Paris under the name of Sirope de Groseilles.

VERMIFUGE. Any medicine which expels intestinal parasites from man or horse or other subjects. One of the best vermifuges for man is turpentine,—for the horse, calomel and aloes,—and for the dog, tin. See the article Worms (Intestinal).

VERMILION. The powdered bisulphuret or deuto-sulphuret of mercury. It is found native in the form of a ruddy sand in some silver mines. and is afterwards purified by repeated washings and other processes; and it is also manufactured on a large scale in the solid form of cinnabar, and afterwards reduced to powder. It is well known as a beautiful and delicate pigment. See the articles Mercury and Cinnabar.

VERMIN. Parasites infesting any of the larger animals. See the articles Louse, Lousiness, and Parasites (Animal).

VERMIN. Any animals, small or great, invertebrate or vertebrate, which prey upon the crops or produce of the garden or the farm. The principal molluscous vermin, together with the best methods of keeping them down or destroying them, are noticed in the article Slug; the principal annelidous ones, in the articles Worm and Earth-Worm; the principal insect ones, in the articles Insect, Ant, Aphis, Butterfly, Moth, Beetle, Fly, Caterpillar, Larva, Grub, and Wire-worm; the principal feathered ones, in the articles Crow, Rook, Game, and Hedge-Birds; and the principal mammalian ones, in the articles Mouse, Field-Mice, Rat, Mole, Hedge-Hog, Weasel, and Polecat. A method of destroying most kinds of vermin by means of any strong ammoniacal liquor is mentioned in the article Ammonia. A writer in the English Agricultural Journal describes a method of destroying rats and mice with phosphorus, which may be regarded as an acceptable addendum to the methods noticed in our article Mouse. "Two years ago," says he, "rats of an extraordinary size and fierceness trooped about this old house at night, with a clatter which a little imagination and the stillness of the hour magnified into charges of cavalry. Young pigs were torn from the sows, and devoured, despite their formidable defence; nor was it possible to calculate anything like the quantity of grain consumed by them. Several plans were tried for entrapping and poisoning; but our ingenuity fell so far short of their marvellous sagacity, that no sensible impression was made upon their hosts, notwithstanding unremitting perseverance. However, having declared a war of extermination against the whole race, I rejoice in being now able to communicate to my agricultural friends in England an easy and certain mode of getting rid of this intolerable nuisance. A little manœuvring may be judiciously used to attract the enemy to a suitable position—suppose any unoccupied room in an outhouse, where they particularly abound. Here they should be fed with any favourite food—fish or malt I believe they are fond of—and then with, not a preparation of arsenic, which they are much too clever to touch, but pills, the size of pease, made of equal portions of wheaten flour and powdered sugar, intimately mixed with one sixtieth part of that weight of dissolved phosphorus—say one quarter ounce phosphorus to one pound of flour and sugar. Cold water should be added to make the mass manageable, and the pills finely rolled in dry flour, and kept secluded from light and air. A couple of pills may be thrown into each rat hole, or any quantity left on a plate in a dark situation, by which the double object is attained of attracting the animals by the luminousness of the phosphorus and preserving it from too rapid evaporation. The pills should be replaced as often as eaten, and that without grudging, as although the slain may not be found, it may be relied on that 'every bullet has had its billet.' Still, in a day or two, many rats will be seen running to water, where they die from excessive drinking. No domestic animal appears to be in danger of eating this preparation, except fowls. Dry weather is most favourable to its successful application, as damp, whether of situation or atmosphere, dissolves and consequently weakens the phosphorus."

VERNAL GRASS. See Anthoxanthum.

VERNONIA. A genus of ornamental exotic plants, of the thistle division of the composite order. About 20 species have been introduced to the gardens and botanical collections of Britain, principally from various parts of America; and nearly 30 more are known. A few of the introduced species are herbs, with sessile and subspicate flowers; a greater number are hardy perennial-rooted, annual-stemmed herbs, with paniculate or corymbose flowers; and five or six are tropical evergreen shrubs. Most have a height of between 3 and 9 feet, and carry purple-coloured flowers, and bloom from the early part or middle of autumn till November; but one of the shrubs, the axillary-flowered, has lilac-coloured flowers, and blooms throughout the greater part of the year. The greater number thrive well in any common soil; and the shrubs are propagated from cuttings, and the perennial-rooted herbs by radical division.

VERONICA. See Speedwell.

VERTIGO. See Megrim.

VERVAIN. See Verbena.

VERVAIN (Bastard). See Stachytarpheta.

VESICARIA. A genus of ornamental exotic plants, of the cruciferous order. The name is derived from a word signifying "a bladder," and alludes to the inflations of the silicles. Four species have been introduced to Britain from Southern Europe and the Levant; and twice as many more are known. Two of the introduced species are hardy evergreen herbs of about a foot in height, the other two are respectively a bien-

nial and an evergreen undershrub; and all the four are yellow-flowered, and bloom in the latter part of spring and early part of summer, and love a soil of sandy loam, and require to be propagated from seeds.

VESICATORY. Any substance or application which blisters or raises vesicles.

VESICLE. An inflated hollow excrescence, in either plant or animal, similar to a blister or a bladder.

VESTIA. An ornamental, deciduous, yellow-flowered, greenhouse shrub, of the nightshade family. It was introduced to Britain from Chili, above 34 years ago; it constitutes a genus of itself, and is specifically called *lycioides* or the boxthorn-like; it has a height of about 3 feet, and blooms in June; and it thrives best in a soil of sandy peat.

VETCH,—botanically *Vicia.* A large genus of ornamental herbaceous plants, constituting the type of a tribe of sarcolobous leguminosæ. This tribe comprises the pea, bean, vetch, chick-pea, tare, everlasting pea, bitter vetch, ochrus, and platystylis genera. The vetch genus has nine united stamens and one free stamen, and is distinguished from all other genera most nearly allied to it by its style having a tuft of hair under the stigma. Nine species of it grow wild in Britain, about 70 have been introduced from other countries, and nearly 40 more are known. Three or four of the species in Britain are erect perennials, about 20 are climbing perennials, and almost all the rest are climbing annuals; nearly one half have pedunculated flowers, and the rest have subsessile flowers; two or three require greenhouse protection, and all the rest are hardy; a good many possess high agricultural value as forage plants, principally under the popular misnomer of tares, and both these and all the others, with scarcely an exception, display a very considerable degree of floral beauty.

The common tare or cultivated vetch, *Vicia sativa,* grows wild by the side of hedges, on the sides of roads, on heaps of rubbish in the vicinity of quarries, and in wettish stony spots of cultivated fields, in many parts of Britain. But, in its wild state, it is much more dwarfish, and has a more slender habit of growth, and has much smoother stalks and leaves than in its cultivated varieties; and, in the latter, it exhibits much diversity of character, and possesses wide diversity of constitutional tone, and is very susceptible of modification from the influences of climate and culture. Its root is annual; its stems are climbing and normally about 3 feet high; its leaflets are oblong, and terminate abruptly with a small point in the middle; its stipules are small and toothed; its flowers are generally in pairs, and have no foot-stalks, and are of a red or purplish colour, and normally bloom in May and June; and its pods are more or less downy or hairy. The most distinct wild varieties of it are the corn vetch, *V. s. segetalis,* and the grove vetch, *V. s. nemoralis;* and the best known cultivated varieties are the winter tare and the summer tare; but all, as well as other varieties, sport and diversify and undergo modifications and almost reverses of their distinguishing characters, when grown and treated for a time in other circumstances than those to which they naturally belong. The winter tare is usually smaller in size, and has more smooth and cylindrical pods, and presents a nearer resemblance to the normal wild plant than the summer tare; and it is suitable to be sown in autumn, and offers complete resistance to the frosts and storms of winter; yet, if repeatedly sown in spring, it rises into comparative luxuriance, and loses most or all of its hardiness, and ceases to be suitable for autumnal sowing. Subvarieties of it, therefore, differ somewhat widely from one another in hardiness and earliness; and a recently introduced subvariety, known in some parts of England under the name of the racers, is said to excel all others, not only in hardiness and earliness, but in bulk of produce and in adaptation to intermixture with rye for the spring-feeding of sheep. The summer tare cannot resist severe frost or other severe winter weather, and requires to be sown in spring; yet it is much more extensively cultivated than the winter tare, and is raised in widely different ways, and for considerably different purposes, or with reference to considerably different modes of application, whether of its herbage or of its seeds. The subvarieties of it are even more diversified than those of the winter tare, particularly in size and luxuriance; and, in many places, the larger kinds are popularly designated vetches, while the smaller kinds are designated tares. The seeds of the winter tare and those of the summer tare, to say nothing of the seeds of the several subvarieties of each, are so like each other as to be indiscriminable by even the most practised judges,—so that much care and confidence are requisite in transactions about them between venders and purchasers. The seeds of another variety, however, the white tare or the Canadian lentil or the Napoleon pea, *V. s. alba,* are very readily distinguishable by their having a white or cream colour and a much milder taste. This variety has a more dwarfish habit, and produces a much greater quantity of seeds than the other varieties; and is cultivated chiefly for the sake of its seeds, and far more extensively in France and in Canada than in Britain. Its seeds are used for human food, both green and ripe, in soups and other dishes, in the same manner as pease; and they are also ground into flour, for intermixture with the flour of wheat, for making bread. A specimen of the herbage of the winter tare was found by Sinclair to be more nutritive than that of the summer; and, when cut at the time of flowering, upwards of one-sixteenth of its entire weight consisted of nutritive principles, between one-

fifth and one-sixth consisted of woody or unassimilable matter, and the rest was water. The cultivation of the chief varieties of the common tare will be discussed after we have disposed of the other species.

The tufted vetch, *Vicia cracca*, is a somewhat abundant native of hedge-banks, plantation-sides, thickets, osier grounds, and low bushy meadows in many parts of Britain. Its roots are perennial, small, and creeping; its stems are furrowed, downy, climbing, and from 2 to 5 feet high, and choke up other plants with their long many-branched tendrils; its leaflets are numerous, elliptico-lanceolate, downy or silky on both surfaces, and of a hoary light bluish green colour; its stipules are half arrow-shaped and mostly entire; its flowers are numerous, and grow in dense clusters, or closely imbricated, elongated, one-sided racemes, and have a bluish or purplish colour beautifully variegated with tints of bright bluish violet, and bloom from June till August; its peduncles or floral footstalks are longer than the leaves; and its pods are smooth and scarcely an inch long, and contain each 4 or 5 dark globular seeds about the size of those of the lentil. This vetch is a good forage plant, and can be profitably cultivated for both its herbage and its seeds; but has not come into much favour among British farmers, probably on account of its pertinaciously climbing habit, and of the difficulty of gathering it. Dr. Anderson speaks highly of it; and Dr. Plot praises it and the wood vetch as the most suitable of all known plants for starved or weak cattle. It yields a considerable bulk of fodder, and is greedily eaten by cattle, and has the important recommendation of containing a much smaller proportion of water than the common tare. Forty-three grains of its nutritive matter comprise 20 of sugar, 12 of mucilage, and 11 of insoluble and saline principles. This vetch thrives best on soils of medium character between stiff and loose, or between clayey and sandy; yet it succeeds well on such light sandy soils as afford sufficient anchorage for its long foraging roots, and on such strong clay soils as are well drained and do not allow a stagnation of moisture about the roots in the months of winter and spring. A specimen of it grown on 360 square yards of the Meadowbank Nursery in the vicinity of Edinburgh began to bloom and had an average height of 2½ feet on the 12th of June, and was ripe and had an average height of from 4 to 5 feet on the second week of August, and was cut at the latter date and thrashed on the 16th of September, and yielded 30lbs. of clean seed, 24 stones of dried haulm, and 2 stones of chaffy refuse separated in the process of thrashing and cleaning. Two very distinct varieties of the tufted vetch occur as ornamental plants in flower gardens,—the one, *V. c. floribus albis*, with white flowers,—and the other, *V. c. floribus rubris*, with red flowers; and an important and very distinct agricultural variety of it is mentioned by Mr. Lawson as having been obtained from France, and as possessing broader and smoother dark green foliage than the normal plant, and yielding a greater quantity of seed, and being about a week later in blooming.

The wood vetch, *Vicia sylvatica*, grows wild in stony places among trees and bushes, on the stony borders of woods and sides of hedges, on the rocky parts of shores and beaches, and even sometimes on strong damp poor clayey soils, in many districts of Britain. It is one of the most elegant of our indigenous plants, and serves well to decorate certain parts of shrubberies, or to train over fences and large trellises. It has similar habits to the tufted vetch, but is more impatient of exposure, and thrives best when supported by shrubs and bushy young trees. Its root is perennial and very slightly creeping; its stems are numerous, much branched, widely spreading, and commonly from 4 to 7 feet high; its tendrils also are large and branched, and combine with the ramose character of the stems to carry the plant over a great extent of supporting surface; its leaflets are elliptical, smooth, and of a light green colour; its stipules are small, sublunate, and bristle-pointed; its flowers have the same kind of arrangement as those of the tufted vetch, and display beautiful variegations of white and blue streaked with grey, and bloom in July and August; and its pods are similar in size to those of the tufted vetch, and have a bright brown colour, minutely dotted. In its natural habitats, particularly in moist woods, it produces a bulk of herbage six times greater than either the tufted vetch or the bush vetch; but when transplanted to any open situation, it produces comparatively little; and, though capable of being advantageously raised from seeds on poor and waste spots where few other forage plants will thrive, and of there producing an amount of herbage somewhat in keeping with its wild luxuriance in moist woods, yet it ripens its pods so irregularly, and drops them as they become ripe so freely, that a good supply of its seeds cannot easily be obtained, and requires to be secured by the slow process of gathering the pods by hand as they arrive one after another at maturity. This plant is superior to many of the commonly cultivated vetches in nutritiveness, and is eaten more readily than any of them by horses, cattle, sheep, and alpacas. A variety of it has white flowers.

The bush or hedge vetch, *Vicia sepium*, grows wild about hedges and in woody places in many parts of Britain; but though naturally loving shady spots, on superior and rather dry soils, in situations favourable to its climbing on bushes and dwarf trees, it thrives well in cultivated fields, and adapts itself to a somewhat wide range of soils, and is by no means so dependent on other plants for support as the tufted and the wood vetches. Its root is perennial and slightly creeping; its stems attain an average height of

about two feet; its leaflets are broad and roundish, smaller toward the point of the leaf, and most abundant toward the point of the shoot; and its flowers stand on such short footstalks as to be subsessile, and grow in clusters of four or six together, and are more numerous at the point of the shoots than in other situations, and have generally a red or violet or dull purplish colour, lightest and slightly striped on the standard, and bloom in May and June. This plant is in general much relished by cattle, and seems well adapted for sowing in mixture with the best wood grasses in such shady places as are not suitable for the clovers; but, as in the case of the wood vetch, a good supply of its seeds cannot easily be obtained. A variety of it occurs with white flowers.

The yellow vetch, or yellow-flowered sea-side vetch, *Vicia lutea*, grows wild on stony and gravelly spots of the sea-coasts of Britain. Its root is fibrous, and varies in duration from annual to slightly perennial; its stem is branching and two or three feet high, and, except when supported by other plants, has a very decumbent or prostrate habit of growth; its flowers have a dull yellowish colour, and bloom from June till August; and its pods are solitary, sessile, reflexed, flattened, broad, and hairy. This plant may be profitably cultivated on such stony and gravelly soils in the vicinity of the sea, as are not capable of bearing any considerable produce of the common clovers.

The narrow-leaved vetch, *Vicia angustifolia*, grows wild in the corn-fields of some parts of Britain, yet seems a doubtful native, and probably was originally introduced from the woods and shady grounds of Germany. Its root is annual; its stems are from 15 inches to 4 or 5 feet high; its leaflets are narrow, smoothish, and of a dark green colour, and terminate abruptly at the points; its flowers are sessile, and grow singly or in pairs, and have a reddish colour, and bloom in May and June; and its pods, when ripe, have a shining black colour. This plant possesses considerable adaptation to field culture for forage; and yields a large bulk of herbage; and is not so easily injured by frost or so liable to early decay toward the end of the season as any of the common summer tares or as any of the clovers; and it is also much less juicy or watery than the summer tare, and therefore not so subject to injury from a long continuance of wet weather.

The other indigenous species are the lathyrus-like, *V. lathyroides*, an annual of from 15 to 24 inches in height, inhabiting fallow-fields, and carrying purple flowers from April till June; the hybrid, *V. hybrida*, an annual of about 20 inches in height, inhabiting thickets, and carrying yellow flowers from June till August; and the smooth-podded, *V. lævigata*, a perennial of from 15 to 24 inches in height, inhabiting sea-shores, and carrying pale yellow flowers in July and August. But the two last are comparatively rare in England, and do not occur in Scotland; and neither they nor the other possess any agricultural importance.

The biennial vetch or Siberian tare, *Vicia biennis*, is a native of Siberia, and was introduced to Britain in 1753. Its root is commonly annual on stiff wet soils, and biennial on porous and comparatively dry land; its stems are slender and branching, and have a height of from 2 to 8 feet; its leaflets are small, smooth, and sharp-pointed, and amount to about 10 or 12 in each leaf; its tendrils are long and for the most part branching; its flowers grow in clusters of about 8 or 10 on long footstalks, and have a light purplish pink colour, and bloom from July till September; its pods are smooth, flattish, and from 1 inch to 1½ inch long and about ¼ inch broad; and its seeds are small, round, and of a dark dull green colour. This vetch was recommended by Miller as an agricultural plant of great promise, so long ago as 5 or 6 years after its introduction to Britain; and it has since been strongly recommended by very competent judges; and it is cultivated on the light soils of some parts of France and Germany; and it possesses the valuable recommendations of growing to a comparatively great height, and yielding a large bulk of herbage, and remaining green throughout the winter in defiance of the most severe weather; yet, to the astonishment of many scientific agriculturists of Britain, it seems never yet to have got a fair trial among our practical farmers. "Those who cultivate it in Germany," says Mr. Lawson, "find it advisable to sow it in mixture with one or other of the melilots, as from its tall and slender habit of growth, unless supported, it is apt to become lodged and much damaged in damp weather; and for this purpose the biennial species of the genus melilotus are exceedingly well adapted, owing to their strong upright habit of growth and similarity of duration."

The bastard tufted vetch, *Vicia pseudo-cracca*, is a native of the South of Europe, and was introduced to Britain in 1820. Its root is annual; its stems naturally attain a height of about 2 or 2½ feet; its foliage is smoother and finer than that of the true tufted vetch; and its flowers have a palish purple colour, and bloom in June and July. This plant makes some agricultural promise; and if it got a due trial, it probably might be found to yield a somewhat large bulk of fodder during the interval between the begun decay of the pastures in autumn and the profitable commencement of the use of turnips and other winter-feed.

The hairy vetch, *Vicia villosa*, is a native of Germany, and was introduced to Britain in 1815. It has an annual root, and naturally attains a height of about 3 feet; and it very much resembles the tufted vetch in at once foliage, flowers, and general appearance; but it is more hairy, and has a more branching habit, and produces a much greater quantity of pods. Mr. Gorrie, who obtained on account of it the High-

land Society's silver medal for the introduction of new or valuable plants into the field culture of Britain, and who sent seeds of it to Mr. Lawson which produced plants of the average height of 8 feet, says, "This plant is quite hardy, and stands the winter; and if sown in October or early in March, it will come into flower in the beginning of July, at which time, although the plants originally should stand 9 inches separate, it will form a dense mass of succulent herbage, of which cattle and horses are exceedingly fond." And Mr. Lawson says, "The *V. villosa* is of slender growth, and relying, like the *V. cracca*, for support on whatever stronger plants may be growing beside it; for which purpose the sweet melilot, *Melilotus cærulea*, or some such strong-growing annual, might be introduced with advantage in the case of this and the other slender-growing annual vetches. It also possesses the same advantages as the *V. cracca*, of containing less watery matter than the common tare, and being greedily eaten by cattle or horses, either in a green or dry state. Compared with the common tare, the *V. villosa*, when sown in spring, comes away rather slower at first; but its actual weight, or bulk of produce from a given space of ground, when fully grown, may be reckoned nearly double that of the other."

The dark purple-flowered vetch, *Vicia atro-purpurea*, is a native of the north of Africa, and was introduced to Britain from Algiers in 1815. Its root is annual; its stems are naturally about 3 or 3½ feet high; its leaflets are slightly villous, and have a dark green colour; its floral footstalks are many-flowered, and not so long as the leaves; its flowers have a dark purple-coloured corolla and setaceous and very villous calyx-teeth, and bloom in June and July; and its pods are short, broad, and pretty well filled, and contain each 3 or 4 seeds. This plant seems to possess good agricultural adaptations in such climates as Italy and the south of France, and probably in the warmest parts of the south and centre of England, but possibly is not hardy enough to be at all suitable farther north.

The Narbonne or broad-leaved vetch, *Vicia narbonensis*, is a native of France, and was introduced to Britain toward the close of the 16th century. Its root is annual; its stems are thick, soft, hollow, much branched, and naturally about 3 feet high, and do not rely much on other plants for support; its leaflets amount to about six on each leaf, and are entire, large, and roundish; its flowers have a reddish purple colour, and bloom in June and July; and its pods are either sessile or have very short footstalks, and grow either singly or in twos or in threes, and are large, flattish, and of a darkish colour when ripe. This plant is cultivated in many parts of Continental Europe, in the same manner in which the common tare is cultivated in Britain. When sown in spring, it yields a close and large crop of succulent fodder, of a strong beany taste, not well liked at first by cattle; and when sown in autumn, it stoutly withstands the severities of our winter, and grows very rapidly in spring, and yields a good bulk of spring forage, which cattle relish better than they afterwards do the first bites of clover.

The three-coloured vetch, *Vicia tricolor*, was introduced to Britain in 1818. Its root is annual; its stems vary in height from about 15 inches to about 3 feet or upwards; and its flowers are sessile, and have a jet black colour on the alæ, a dull brown toward the posterior extremity, and a green colour on the other parts of the corolla, and bloom from June till August. It has a more dwarfish habit than some of the other agricultural annual vetches, but produces a greater quantity of seeds. It was recommended by Mr. Loudon as a plant well worth the attention of farmers; yet, for forage purposes at least, it does not seem to be at all equal to some of the other vetches.

The saw-leaved vetch, *Vicia serratifolia*, is a native of Hungary, and was introduced to Britain in 1723. It so closely resembles the Narbonne vetch as to be considered by some botanists only a variety of it; and its duration, height, floral colour, time of blooming, and several other properties are the same; but its leaves and stipules are deeply sawed or indented, while those of the Narbonne vetch are quite or nearly entire. It is cultivated in the fields of some parts of Continental Europe.

The broad-podded or large-podded vetch, *Vicia platycarpus*, is a native of Germany, and was introduced to Britain in 1723. Its root is annual; its stems are strong, nearly upright, and from 15 to 24 inches high; its leaves resemble those of the Narbonne vetch; its flowers have a purple colour, and bloom in July and August; and its pods are sessile, solitary, large, broad, and inflated. This species and the saw-leaved and the Narbonne differ more or less from all the other species in their comparative independence of support for climbing, in their somewhat strong and robust habit of growth, and in the thickness and succulency of their stems; and they may be regarded as possessing an intermediate character between the common tare and the bean. The broad-podded species, however, yields a much less bulk of produce than either of the other two.

The most likely of the remaining species to adapt themselves to the purposes of the husbandman are the pea-shaped vetch, *V. pisiformis*, a perennial of commonly about 2 feet in height, carrying pedunculated pale yellow flowers in July and August, and introduced from Austria in 1739; the hedge-vetch, *V. dumetorum*, a perennial of commonly about 3 feet in height, carrying pedunculated purple flowers in May and June, and introduced from France in 1752; the Bengal vetch, *V. Bengalensis*, an annual of commonly about 3 feet in height, carrying dark

purple flowers in June and July, and introduced from India in 1792; the intermediate vetch, *V. intermedia*, an annual of commonly about 3 feet in height, carrying subsessile purple flowers in June and July, and introduced from the South of Europe in 1818; the two-coloured vetch, *V. bicolor*, an annual of commonly about two feet in height, carrying subsessile white and purple flowers from June till August, and introduced in 1820; and the Hungarian vetch, *V. pannonica*, an annual of commonly about 20 inches in height, carrying subsessile white flowers in June and July, and introduced from Hungary in 1658.

Most of the annual vetches suitable for field crops are well adapted to cultivation in the intermediate year between different sorts of grain crops, for the double purpose of ameliorating the land and affording a supply of fodder. It has even been contended that vetches may be made the means of enabling the arable farmer to support as much live stock as the grazier,—that, while they remain on the ground, they yield a larger bulk of the best kind of green food per acre than the richest and most productive grass lands,—that they may be taken from the ground at so early a period in the summer as, on the friable loamy soils, to admit of a clean crop of turnips being obtained from the same land in the same year, and of those of the more heavy kinds being sown with wheat,—that while they are capable of being raised with success on most kinds of soils and situations, they support and fatten cattle and sheep of different sizes and breeds in an expeditious manner,—that, in addition to all this, they afford a good preparation for other sorts of green crops, and in that way keep up the successions of such kinds of food for the fattening of additional quantities of animals, and, in consequence, produce abundance of manure in situations where it could not otherwise be procured,—and that, in short, by a judicious combination of vetches with turnips, clover, and sainfoin, the poor downs, sheep-walks, and other waste lands, may be rendered from ten to thirty times more valuable than they are at present. Now though these observations may be unduly sanguine, yet we cannot doubt that the vetch may be beneficially cultivated both for improving the land, and for supporting a larger stock, and that it ought to be more generally grown in most situations, in proportion to the extent of the stock that is kept. When, however, it is grown for the sake of its seed, or when it is allowed to stand till it approaches ripeness, it is one of the most impoverishing of all our commonly cultivated leguminous crops.

Most kinds of soils in ordinary cultivation are more or less suitable for vetches. Gravelly loams of medium dryness are the most generally suitable; and all other loamy sorts, from kinds bordering on thin gravel to kinds bordering on stiff clay, will do. The richer any soil is, provided it be not rankly fertile, the better it is for any vetch crop which is to be cut down in a green state; but a soil of an inferior description is requisite for the seed produce of a vetch crop, as a rich soil sends the herbage of the plant into such excessive luxuriance as to occasion a deficiency in the yield of seed.

The preparation of the land for vetches is done by most farmers in as slim and niggard a fashion as if it were almost wholly superfluous; and certainly less preparation is really necessary in this case than in that of most other farm crops. Yet if a good or especially a very large amount of produce be desired, the soil must be intrinsically rich, and must be well cleaned from both annual and perennial weeds, and must be reduced to a somewhat fine state of pulverization, and, in some cases, must receive a tolerably liberal supply of manure. The quality of the preparation, in fact, very mainly determines the quantity of the produce. Stubble land intended for winter tares ought to be ploughed immediately after the harvesting of the corn crop, and then pulverized by harrowing, and then ridged up before the sowing of the seed; and, though it may do well enough without manure if it be a very rich loam or a rich kindly clay in good condition, yet it ought by all means to be manured either if it be naturally a poor soil, or if it be a rich one in an exhausted state; and should the farmer be so stingy or so hard-pressed as to give it only one ploughing, the manure should be applied on the stubble, —and in the case of sufficient preparation, it should be applied in the second ploughing, at the ridging up of the land. The preparation for spring tares or any other spring-sown vetches should closely resemble that for broadcast pease or for any similar spring-sown green crop; and ought to comprise as much working and cleaning and manuring as a due regard to the aggregate circumstances of the farm will permit. The first ploughing should be given in autumn; and at least a second ploughing, together with harrowing, rolling, and weeding, ought in due course to follow. Manure is requisite on all light and exhausted soils; and should be applied either in a rough and fresh state in autumn, or in a short and well-rotted state before the seed-furrow,—the former method, of course, being the most economical. When the niggard practice of only one ploughing is persisted in, the ploughing should not be given till after the commencement of winter.

The time of sowing depends on the kind of the vetch, the nature of the soil and situation, and the intended use of the crop.—The sowing of the indigenous perennial vetches, in all lands and situations analogous to those of their wild condition, ought to be done as soon as their seeds are ripe, or previous to the advanced stage of autumn; but, on richer lands or in more genial situations, may be deferred till spring. The sowing of winter tares for purposes of forage, on poor soils in late exposed situations, may be as

early as the beginning or middle of August,—on better soils or in more genial situations, in the latter part of August or early part of September,—and on prime soils in the best situations, so late as some time in October. In every case, it should be done in sufficient time to let the plants become perfectly established in the soil before the commencement of winter weather; and, in most cases, especially on well-conducted farms with a large amount of winter stock, it ought to be done at successive periods, through as long a range of time as possible, in order to provide a due succession of green food for spring consumption. The sowing of summer tares for purposes of seed must be done early, else the amount of produce will be deficient; and for purposes of forage, should be done at intervals from February till the end of May,—and has, in some instances of rich soil and warm situation, been advantageously done at so advanced a period as the early part of June. The intervals of time between the sowings, and also the extent of ground sown at each sowing, should be greater in the latter part than in the early part of the succession. The broadcast method, when carefully and evenly practised, is generally the best for forage; and the drill method is generally preferable for seed. No rolling of winter tares immediately after sowing is allowable; but a good harrowing should be given to cover the seeds from being picked up by birds; and, in spring, if the land and the weather be sufficiently dry, a light rolling may be given to the young crop destined for forage in order to smoothen the ground for the scythe; and when this cannot be done, the crop will generally require to be cut with the sickle. A close heavy rolling, immediately after sowing, is commonly suitable for spring tares and other spring-sown vetches, and puts the ground into a fine state for the action of the scythe.

A mixture of some other plants with vetches is desirable or even requisite to prevent them from lying on the ground, and from becoming injured by rains; and, in the case of annual crops grown for forage, serves the additional purpose of making the produce both more abundant and more agreeable. The most suitable intermixing plants are rye for forage winter tares, oats for summer forage tares and for other spring-sown annual forage vetches, melilot for the biennial vetch, pease or beans for summer tares and other annual vetches intended to seed, and beans for winter tares intended to seed and for all the perennial vetches whether intended to seed or to be cut green. Wheat might do as well as rye for the mere supporting of forage winter tares, but is not so well relished by cattle and sheep in its green state as rye, and does not yield such a profusion of early spring feed as any of the prime forage varieties of rye. Barley, on the other hand, might do as well as oats, in the case of summer tares, for the purposes of fodder, but does not afford so good support to the vetch plants by the strength of its culms. Beans greatly improve the quality of vetches, particularly with reference to their seeds, by keeping them well up from the ground, and exposing them fully to the circulation of the air and the play of the sunshine,—and they also facilitate the process of harvesting them; and though their seeds necessarily become mixed with those of the vetches, they are so very different from them in size as to be easily separated in the course of winnowing and riddling. New sowings of beans every year, of course, are requisite for intermixture with the perennial vetches; and, either in the broadcast method or with narrow drill intervals, in consequence of the soil becoming hard and exhausted, the beans will not possess due vigour beyond the second or third year, but will afterwards be dwarfish and feeble; and, in the case at least of the wood vetch, this evil might be partly remedied, by making the drills two feet apart, and working and manuring the intervals for the reception of the beans every year.

The quantity of vetches proper to be sown depends on the kind of the vetch, the character and condition of the soil, the destination of the crop, and the kind and degree of intermixture of other plants. The proper quantity of either winter tares or summer tares, sown alone, in medium or ordinary circumstances of soil and situation, may be from 3 to 4 bushels if the crop be intended for forage, and about $2\frac{1}{2}$ if the crop be intended to ripen its seeds; and the proper quantity of intermixture in average or ordinary circumstances for forage crops, is from 2 to $2\frac{1}{2}$ bushels of winter tares and $1\frac{1}{2}$ bushel of rye, and from $1\frac{1}{2}$ to $2\frac{1}{2}$ bushels of summer tares and 1 bushel of Hopetoun or potato oats. If the quantity sown be too small, the crop may be thin and deficient; and if the quantity sown be too large, the crop may be so crowded in the roots and so feeble in the stems as easily to rot off in wet weather.

The after-culture of vetches which have been sown broadcast consists merely in pulling out the larger weeds, and should be done at an early stage of the crop's growth; and that of such as have been sown in drills, particularly when they are intended to ripen their seeds, consists in the thoroughly cleaning and aerating use of the hand-hoe and the horse-hoe. But, in general, vetches grow so very densely and exert of themselves so smothering an action upon weeds, that they require much less after-culture than most other kinds of green crop. The cutting of forage vetches may be done after the pods have begun to form, but long before the seeds approach to ripeness or even before they are properly formed; or if the cutting take place at an earlier stage of the growth, a second crop will be produced. But in the proportion in which the crop is in an advanced stage at the time of being cut, it impoverishes rather than ameliorates the soil for the cereal crop that is to follow; and to allow

a vetch crop of the early season to stand over for a second cutting may be to forego the far higher advantage of raising a turnip crop on the ground which it occupies. A crop or patch of vetches which stands till its seeds are ripened should be cut and harvested in the same manner as pease.

"In making tares into hay," says Dr. Dickson, "more attention is necessary than in those of most of the artificial grasses, as wet is more injurious to them, and they require more sun and air; but in other respects they demand the same cautious management in order to preserve the foliage from being lost. The time for cutting for this purpose is when the blossoms have declined, and they begin to fall flat. When well made, the hay is of the most nutritious quality. In the application of tare crops, there can be little hesitation in pronouncing that of soiling them with horses or other stock on the farm, as the most advantageous and beneficial method. The vast advantage of this mode is rendered particularly evident by the great loss in converting them into hay. In the practice of soiling much loss may be sustained by cutting the tares at too early a period. An intelligent agricultor is of opinion that the farmer's stock should be wholly supported on them from the time they begin to blow till the blossoms begin to fall off, and the formation of pods takes place. On account of the risk from wet, he recommends that all the stock of a farm should be soiled on them green, as it will have the good effect of taking it off the grass land long enough to allow of its being mown for hay; and by this means the meadow hay be much increased in quantity, and there will not be so much occasion for pasture, the tares abundantly supplying its place. Besides, at the time the cattle return from green tares, the grass land, in the mean time having been mown, may be ready to receive them. It is further observed that, as it would be wasteful in the extreme to turn live stock into a field of tares, as their treading and lying down would do great mischief to the crop, even by feeding it in small patches hurdled off, the most advisable method would be to mow the tares of the first half acre, and to carry the produce into the stables, cow-houses, and fold-yards, or on to poor land to be consumed by stock, then to hurdle the growing tares from such cleared ground, into which put the stock and feed them all with the tares, given to them in racks, removing the hurdles and the racks forward daily to the edge of the growing tares, which will manure the land uniformly, and deposit all the urine in the soil. In the Gloucester Report another good method is recommended, 'which is to feed them through rack hurdles, which are made the same as the common five-railed ones, only leaving the middle rail out, and nailing upright pieces across, at proper distances, to admit the sheep to put their heads through. A swath of vetches being mown in the direction you wish to plough the land, a sufficient number of these hurdles, allowing one to five sheep, are set close to it: at noon the shepherd mows another swath and throws it to the hurdles, and the same at night; next morning, a swath being first mown, the hurdles are again set: thus moving them once in the twenty-four hours, by this trifling additional trouble the vetches are eaten clean off, and the land equally benefited.' In Gloucestershire and Worcestershire, they sow tares as pasturage for horses, and eat them off early enough to allow of turnips being sown the same season. In wet seasons, where the tare crops are large, the stems are, however, apt to become rotten upon the ground; in this condition such food often proves prejudicial to horses; in such cases it will therefore be imprudent to cut them any longer for the purpose of soiling. In Sussex tares are of such infinite importance that not one-tenth of the stock could be maintained without them: horses, cows, sheep, hogs, all feed upon them. The last sort of animals are soiled upon them without any other food. This plant maintains more stock than any other plant whatsoever. Upon one acre Mr. Davies can maintain four horses in much better condition than upon five acres of grass; upon eight acres he has kept twelve horses and five cows for three months without any other food. No artificial food whatever is equal to this excellent plant. They find this crop to be a hearty and most nourishing food for all sorts of cattle. Cows give more butter when fed with this plant than with any other food whatsoever. By one crop of vetches succeeding another, Mr. Halstead, in the same district, insures a crop the whole summer of the best food that can be given to cattle; after this he sows turnips, and then wheat. Where large stocks of sheep are kept, tares are exceedingly useful; for they come in at a time when rye and turnip crops are eaten off, and before the clovers and other grasses are in sufficient forwardness for being turned upon, and afford a seasonable supply of food for ewes and lambs. It is recommended to wait till the tares have gained a sufficient increase of stem before the sheep are turned in, and then to divide the ground by hurdles, in the same manner as is practised above. By this means there will be little waste, and the ground be enriched in a much higher degree than if the stock had been suffered to ramble over the whole crop. As from the great closeness and shade which is produced in these crops the land becomes much improved and rendered more clean and mellow, such plants should constantly be cultivated wherever the soils and situations will admit, especially if the keeping of much live stock be the object. In cold exposed situations, where vegetation is late in the spring months, they are not so proper: it may sometimes under such circumstances be more advisable to raise clover crops, as it will not be so much later as to render it much less valuable, and at the same time be more certain.

Tare crops form an excellent preparation for wheat in all the more strong and heavy sorts of soil, and for both grain and turnips in those of the light kinds; but as they have much effect in rendering the lands on which they grow more light, open, and porous, they may sometimes, in the latter case, bring it into too loose a state for the successful culture of that crop, as it requires a rather close texture of the land."—*Withering's Botany.—Smith's English Flora.—Sinclair's Hortus Gramineus.—Lawson's Agriculturist's Manual.—Loudon's Works.—Dr. Dickson's Practical Agriculture.—Sproule's Treatise on Agriculture.—Annals of Agriculture.—Reports to the Board of Agriculture.—Quarterly Journal of Agriculture.—Journal of the Royal Agricultural Society.—Museum Rusticum.—Young.—Low.—Stephens.*

VETERINARY MEDICINE. This useful branch of general knowledge in former years, and even now, by the vulgar, called farriery, has of late received the more appropriate and deserving title of veterinary art. In a medical point of view, it may be regarded as naturally allied to the science of human medicine; in other respects, however, its objects tend quite another way; and it is only by a happy amalgamation of acquirements of both descriptions, that veterinary science can be practised with its fullest advantages. The veterinary art, according to the present acceptation of the phrase, comprehends a knowledge of the external form, as well as the internal structure and economy, of our domestic quadrupeds, — their appropriate management,—the nature, causes, and treatment of their disorders,—and the art of shoeing such of them as may be found to require it. The word veterinary is an anglicism derived from the Latin adjective *veterinarius*,—which, by some of the ancient writers, in particular by Columella, was used substantively, to denote a farrier, horse-doctor, or one who lets horses to hire; its radical being the verb *veho*, to carry,—whence veterinarius came to signify anything connected with, or relating to, beasts of burden.

Veterinary science shared the common fate of literature in general during the interval known as the dark ages; and it was not until some time after the period of the universal revival of letters, and other arts and sciences, that the veterinary art once more came to be deemed worthy the attention of men of respectability and education. To the French in an especial degree are we indebted for this meritorious rescue of our art from the trammels of ignorance and superstition. Solleysel, Bourgelat, and Lafosse, shone first in the hemisphere of revived veterinary science, and have left behind them lights which will for years to come serve us as beacons through many obscure and trackless regions. In 1762, the first veterinary school was instituted, the one at Lyons; in 1766, that at Alfort was opened. A similar institution was founded at Berlin in 1792; and, in the year following, the London veterinary college was opened for the reception of pupils and patients, under the direction of Sainbel, its first professor, a Frenchman who had come over from France for the specific purpose of introducing the study of the art among us, and who succeeded, under the auspices of the Odiham Agricultural Society, in founding a college and creating himself professor. See the articles Agricultural Schools and Hippopathology.

An enlightened age has discovered that the study of the medical department of this art can be rationally conducted only upon a knowledge of anatomy and physiology. These are the rocks which the farriers are continually splitting and blundering against; the neglect of this the cause that has led to so much mystery, superstition, and mal-practice among them. When we consider what a complicated machine an animal body altogether is, and how exceedingly its intricacy and importance must be enhanced by the circumstance of its being possessed of vitality, we can only feel astonishment we hardly know how to express, that such a set of ignorant men as farriers and grooms in general are, should have the assurance to pretend to be able to set that machine aright again every time it is out of order, concerning which they possess not one particle of knowledge, in regard either to its construction or its action, when it is in a sound and healthy state. But the truth is, it is this very ignorance which carries them through the darksome wilderness into which want of common reflection alone on the part of their employers could have induced them to enter.

VIBORGIA. A small genus of ornamental, yellow-flowered, Cape-of-Good-Hope, evergreen shrubs, of the genista division of the leguminous order. Two species, the silky and the obcordate, have been introduced to British collections; and they have a height of between 2 and 4 feet, and bloom in July and August, and thrive best in a soil of loamy peat.

VIBRIO. See Ear-Cockle.

VIBURNUM. A genus of ornamental, erect, white-flowered shrubs, of the honeysuckle family. Two species grow wild in Britain, about 30 have been introduced from other countries, and a few more are known. Five or six of the species in Britain are tender or half-tender evergreens, four or five are hardy evergreens, and the rest are hardy deciduous shrubs. They vary in height from 2 to 20 feet; and most love a soil of peaty loam, and are propagated from layers. Three are described in the articles Laurustinus, Guelder-Rose, and Cassine; and two or three more of the best known may be noticed here.

The common viburnum, or wayfaring tree, or pliant mealy tree, *Viburnum lantana*, inhabits the hedges and thickets of Britain and of most other parts of Northern Europe. It commonly has a height of about 10 or 12 feet, and sometimes attains a height of 20 feet or upwards; but, in culture, may be kept down to any height desired. In places where it abounds, it is little esteemed for ornament; but in places where it is rare, it attracts and delights almost as much as the most admired exotic of the shrubbery. The branches are rather few; and, in winter, are covered with a smooth greyish bark, inclining to brown; and are long and exceedingly tough, sometimes shooting six feet from the bottom in the course of a single year, and generally making prime bands for fagotting. The young branches, as they shoot, are white and downy; and their ends, especially in winter, feel soft and woolly. The leaves are opposite, heart-shaped, serrated, of great size, full of large veins, dark green above, and white and cottony below. The flower-buds begin to form in the preceding summer, and increase throughout the autumn and winter, and eventually have the appearance of rough buttons; and about May they begin to divide, and are developed into floral umbels or bunches. The flowers are wholly out in June, and make a pretty good show; and the fruit, which succeed them, are highly ornamental berries, and have at first a fine red colour, and afterwards a deep black. Two well-marked varieties of this species are in cultivation,—the large-leaved and the variegated-leaved; and both are more esteemed in shrubberies than the normal plant.

The saw-leaved or tooth-leaved viburnum, *V. dentatum*, is a native of Virginia, and was introduced to Britain in 1736. Its branches, leaves, and flowers are not so large as those of the common viburnum; but they have a more elegant appearance. It has commonly a height of about 5 feet, but sometimes grows so high as 10. The bark is smooth, and of a light colour. The leaves are opposite, and stand elegantly on longish footstalks, and are roundish, strongly veined, and beautifully serrated, and have a fine light green colour, and are tolerably large, though by no means so much so as those of some of the other species. The flowers come out in very large round bunches at the end of the branches, and bloom in June and July, and are rarely succeeded by fruit in Britain.

The naked or entire-leaved viburnum, *V. nudum*, is a native of North America, and was introduced to Britain in 1752. It has much the appearance of a laurustinus, but is deciduous, and almost twice as tall. The bark of the younger branches is smooth and of a deep red colour; and that of the older branches, though also smooth, has a dark brown colour. The leaves are opposite, entire, ovate-lanceolate, pretty large, much veined, of a beautiful shining green colour above, and paler below. The flowers come out in large umbels at the ends of the branches, and bloom from May till July, and have a handsome appearance, and resemble those of the common laurustinus, but are rather smaller; and they are succeeded by berries, which seldom or never ripen in Britain.

The plum-leaved viburnum or black haw, *V. prunifolium*, is a native of North America, and was introduced to Britain in 1731. It is hardy and deciduous, and commonly about 8 or 10 feet in height. The bark is smooth and reddish. The leaves are chiefly opposite, and stand on shortish footstalks, and are oval, and finely serrated, and not so large as those of most of the other species, and have a pleasant light green colour. The flowers come out in large umbels at the ends of the branches, and bloom in May and June. And the berries have somewhat the appearance of haws, though of a black colour, and occasion the plant to be commonly called the black haw; but they seldom come out in Britain.

VICIA. See VETCH.

VICTORIA REGINA. A magnificently flowering plant, one of the wonders of the vegetable world, belonging to the water-lily family. It was long ago described and figured by the German botanist M. Poppig, under the name of *Euryale amazonica;* but it is very rare, very tender, and very refractory to artificial treatment, and seems to have become generally forgotten among botanists; and, in 1837, it was rediscovered by M. Schomberg, and, by permission of the British Queen, was called *Victoria regina*. "On the 1st of January 1837," says M. Schomberg, "while contending with the difficulties nature opposed to our progress up the river Berbice (in British Guiana), we arrived at a point where the river expanded and formed a currentless basin. Some object on the southern extremity of this basin attracted my attention; it was impossible to form any idea what it could be, and, animating the crew to increase the rate of paddling, shortly afterwards we were opposite the object which had raised my curiosity,—a vegetable wonder. All calamities were forgotten; I felt as a botanist, and felt myself rewarded. A gigantic leaf, from 5 to 6 feet in diameter, salver-shaped, with a broad rim of a light green above, and a vivid crimson below, rested upon the water. Quite in character with the wonderful leaf was the luxuriant flower, consisting of many hundred petals passing in alternate tints from pure white to rose and pink. The smooth water was covered with them; and I rowed from one to another, and observed always something new to admire. The leaf on its surface is of a bright green, in form almost orbiculate, with this exception opposite its axis, where it is slightly bent in. Its diameter measured from 5 to 6 feet. Around the margin extended a rim about 3 to 5 inches high; on the inside light green, like the surface of the leaf; on the outside, like the leaf's lower part, of a bright crimson. The stem of the flower is

an inch thick near the calyx, and is studded with sharp elastic prickles, about three quarters of an inch in length. The calyx is four leaved, each upwards of 7 inches in length and 3 in breadth at the base; they are thick, white inside, reddish brown, and prickly outside. The diameter of the calyx is 12 to 13 inches; on it rests the magnificent flower, which, when fully enveloped, covers completely the calyx with its hundred petals. When it first opens, it is white, with pink in the middle, which spreads over the whole flower the more it advances in age; and it is generally found the next day of a pink colour. As if to enhance its beauty, it is sweet-scented. Like others of its tribe, it possesses a fleshy disk; and petals and stamens pass gradually into each other, and many petaloid leaves may be observed which have vestiges of an anther."

VICUGNA, or VICUNA. See ALPACA.

VIEUSSEUXIA. A genus of ornamental, bulbous-rooted, Cape-of-Good-Hope plants, of the iris tribe. Eleven species, all about a foot high, and most blooming in May and June, have been introduced to the greenhouses of Britain. About one half have flowers of some shade of red or purple; and the rest have them either white, cream-coloured, yellow, greenish, or variegated. All love a soil of sandy peat; and the majority are propagated by radical division. Most were formerly comprised in the iris and moræa genera.

VIGNA. A beautiful, twining, yellow-flowered, hardy annual plant, of the kidney-bean division of the leguminous order. It is a native of North America, and has long been known in Britain. It attains a height of about 4 feet; and blooms in July and August. It constitutes a genus of itself, and is specifically called *glabra* or the smooth.

VILLARSIA. A genus of ornamental aquatic and marsh plants, of the gentian family. The water-lily-like species, *Villarsia nymphoides*, called by Linnæus *Menyanthes nymphoides*, is a floating, yellow-flowered perennial, of the rivers of some parts of England, somewhat resembling the buck-bean, and blooming in June and July. The cordate species, *V. cordata*, is a hardy, floating, yellow-flowered perennial, introduced in 1820 from North America. Four or five other floating species, and three or four upright, evergreen, marsh species, all more or less tender, and most carrying either yellow or white flowers, have been introduced to the botanical collections of Britain from South America, Southern Africa, and Australia. The cordate species is propagated from offsets; and all the others from suckers.

VILLOUS. Covered with soft, close, long, loose, hairs, of a silky, woolly, or shaggy appearance. The epithet is botanical.

VIMINARIA. A small genus of ornamental, yellow-flowered, Australian, evergreen shrubs, of the sophora division of the leguminous order. Two species, the stripped and the side-flowering, both about 3 feet high, and blooming from June till September, have been introduced to Britain; and they love a soil of sandy peat, and are propagated from cuttings.

VINCA. See PERIWINKLE.

VINE,—botanically *Vitis*. A genus of thalamiflorous, exotic climbing plants, constituting the type of the natural order *Ampelideæ*. This order is botanically akin to the geranium and the bead-tree families; and, as to the habit of very many of its plants, is ill or not at all represented by the common grape vine. About 20 hardy ligneous species, 7 or 8 greenhouse species, and nearly 40 hothouse species, at present in the gardens and botanical collections of Britain, belong to it, and are distributed among the genera vitis, ampelopsis, cissus, and leea. Upwards of a dozen of these species are true vines; and about as many more unintroduced ones are known. All the vines are ornamental; and all likewise produce grape-like fruits; but the grapes only of *Vitis vinifera*, are pleasantly esculent, or produce good wine-making juice,—those of the best of the others having a disagreeable foxy flavour, which is not removed by cultivation. Three of the introduced species are tropical evergreen climbers, and the rest are hardy or half-hardy deciduous climbers. Those from North America generally love a soil of sandy peat, and those from other countries a soil of rich mould; and, excepting the wild vine or *V. labrusca*, all are most readily propagated from cuttings. The typal species is the subject of our article GRAPE-VINE; and two or three of the best known of the other species may be noticed here.

The wild vine, or wild Virginian grape, *Vitis labrusca*, is a native of many parts of North America, and was introduced to Britain in 1656. Its stems commonly climb to a height of 10 or 12 feet; its leaves are large, indented, downy below, and nearly divided into three lobes, but nevertheless of a heart-shaped appearance, and very massive and handsome; its flowers come out in bunches, like those of the grape vine and have a herbaceous colour; and its fruit are spherical, black, and rough-flavoured. But a variety introduced in 1805, *V. l. baccis albis*, has white fruit. If the wild vine be wanted as an ornamental climber in the open ground, it should be planted among trees or pretty large shrubs; for, by the assistance of its well-holding tendrils, it will attain a great height; and, if the shrubs which grow near it be low-growing ones, it will entirely overtop them, and, in summer, almost conceal them with its foliage. This species is most readily propagated by layering.

The crumpled or parsley-leaved vine, *Vitis laciniosa*, is a native of Canada, and was introduced to Britain in 1648. It commonly attains a height of 20 or 25 feet; and it has herbaceous coloured flowers, and blooms in June and July. Its stem is very thick, and its shoots are strong, so that when it is planted for an ornamental out-of-door climber, it must be placed in the vicinity

of tall and very powerful trees, as it would quite choke and overwhelm slender trees or mere shrubs. Its leaves are finely divided; and, when seen at a little distance, resemble those of parsley, but are larger.

The summer vine or fox grape, *Vitis æstivalis*, is a native of Virginia, and was introduced to Britain in 1656. Its stem attains about the same height as that of the crumpled vine; its leaves are large, heart-shaped, indented, and smooth on both surfaces; its flowers are green, and come out in vine-like bunches; and its fruit are black, and have in a high degree the odious flavour like the smell of a fox. A variety of this species, *V. æ. sinuata*, is only about half the height of the normal plant, and has sinuate leaves.

VINEGAR. Impure and diluted acetic acid. It was known in very early times and in far distant countries, and was used by the ancients in mixture with water as a cooling beverage, and made a figure in commerce long before the economical use of any other acid. Various and widely different kinds of it seem also to have been early known. A kind called pesca or sera, almost or quite identical with weak soured wine, is supposed to be the vinegar which was offered to Ruth by Boaz and to the Saviour by the Roman soldiers; and a very sour or strong kind seems to be referred to in the two passages in Proverbs, "As vinegar to the teeth, and as smoke to the eyes, so is the sluggard to them that send him"—"And as vinegar upon nitre, (or rather upon natron or native soda,) so is he that singeth songs to an heavy heart." The latter passage also intimates that the Hebrews knew well the neutralizing power of an alkali upon an acid,—or at least the power of soda to destroy the sourness of vinegar; and a passage in the Pentateuch,—"He shall drink no vinegar of wine or vinegar of strong drink, neither shall he drink any vinegar of grapes"—intimates that they made their vinegar from different sources, and had extensive practical acquaintance with both the acetous and the vinous fermentations.

The varieties of vinegar, as to both method of preparation and intrinsic quality, multiplied with the progress of art and the discoveries of science, till they have become absolutely innumerable. All originate in the process described in our article Acetous Fermentation; and all consist of acetic acid and water, together with one or more or many vegetable principles or extracts either spontaneously present or artificially intermixed. See the articles Acetic Acid and Pyroligneous Acid. All the common vinegars of commerce, with the exception of the clear or pyroligneous ones, are made variously from wine, cider, malt liquor, infusions of malt, saccharine vegetable juices, watery solutions of sugar, and some other and similar liquids; and the chief vegetable principles which they contain are mucilage, extractive, bitartrate of potash, and some acids, essential oils, and colouring matters. "Vinegar," say our commercial people, "can be made in a cheap manner from refuse materials which are frequently thrown away as useless,—such as the husks of grapes, decayed raisins, the lees of wine, grounds of ale, grounds of beer, all the summer fruits of England, even blackberries, and all the refuse washings of a sugar-house, cider-pressings, and the like,—anything, in fact, which contains sugar, or which with the aid of water, air, and warmth, will pass into the acetous fermentation."

The best common vinegar of vinous countries is made from the lees of wine worked up with new wine; and the best of Britain is made from an infusion of malt, and always has a deeper colour than any good wine vinegar. But four very good kinds of household vinegar, perfectly suitable for pickling and for other domestic purposes, may easily be made from respectively honey, brown sugar, British wines, and sour ale, according to the following recipes:—First, as to honey or white vinegar, dissolve three quarters of a pound of honey in rain-water, and put it into a seven-gallon cask, with a quart of malt spirit; shake it well, then fill up the cask with rain-water; shake it again and place it near the kitchen fire, where it must stand without being moved or shaken. Let it remain five months in this place, and the vinegar will be made. Draw it off by piercing the lower part of the cask; and let it run until the concretion which is formed at the top, and is termed 'mother of vinegar,' begins to appear. You may then begin the process again without cleaning the cask.—Second, as to vinegar from sugar:—To eighteen gallons of water put eighteen pounds of very coarse brown sugar; let it boil in an iron boiler, removing the scum until no more rises; pour it into a large tub to cool, and when cold enough to work, put into it a large piece of toasted bread saturated with yeast, washing the toast well in the liquor; after it has fermented three days, beat the yeast well into the liquor, put it into a cask and place it near the kitchen fire, laying a bit of wood over the bung-hole. If in four months it is not sour enough, let it remain a month longer; then rack it off into a fresh cask, and throw into it a handful of shred isinglass; this will fine it, when it may be drawn off and bottled. Half this quantity, or even five or seven gallons, may be made, but the vinegar is always best when made in the first proportion.—Third, as to vinegar from British wines:—Take a new five-gallon cask, and pour into it, boiling hot from the fire, a quart of the best and strongest white wine vinegar, which you have boiled for this purpose in a stone pitcher; bung the cask close, and roll it about until the whole of its surface has been covered with the vinegar, and this latter has become cold; let it stand six hours, then take it out and place the cask in a convenient place by the side of the kitchen fire; bung it up tightly, then bore a hole close to one of the ends where the head is inserted; into this hole

introduce a funnel, and with its aid pour into the cask two quarts of the strongest white wine vinegar; on that day week add a quart of any British white wine that may be dead or sour or unfit for drinking, but which is still on the lees; in a week more add another quart of wine, and so on every eight days, until the cask is full. Let it now remain a fortnight, and the whole five gallons of vinegar will be found of the same strength as that first put in. Now draw off two-thirds, and bottle it; and begin again adding a quart of wine every week.—Lastly, as to vinegar from malt:—Put ten gallons of very stale ale into a cask near the kitchen fire, or in any other warm place; pound five drachms of cream of tartar, the same quantity of alum, and six drachms of bay salt, very fine; boil three quarts of the ale in an iron saucepan, and, whilst boiling, throw into it the powdered materials; the instant they are dissolved, pour the boiling liquid back into the cask; put a double fold of wet brown paper over the bung-hole. In a very short time the contents of the cask will be converted into vinegar.

A few of the best known or most approved fancy vinegars, so flavoured by aromatic herbs and pungent vegetable substances as to impart peculiar piquancy to pickles and sauces, may be made according to the following recipes:—For garlic vinegar, peel some cloves of garlic, then weigh out two ounces; just break the garlic in a mortar, and put it into two quarts of vinegar, to which add also a dozen cloves, and a nutmeg cut into very thin slices. In a month the vinegar will be fit for use; it may indeed be used in a fortnight, but it will not be so good. The jar must be closed with cork and bladder.—For vinaigre printannier, or spring vinegar, about the beginning of June, gather a quantity of cresses, chervil, pimpernel, parsley, and some marigold flowers; dry them in the sun, and put them into a two-gallon stone jar with a wide mouth, which fill up to the brim; put in also six onions, ten shalots, and as many cloves of garlic all peeled,—likewise a dessert-spoonful of white mustard seeds, twenty cloves, half a drachm of mace, a drachm of Jamaica pepper, the same quantity of black pepper, and a lemon sliced with its rind; fill the jar with strong vinegar, tie a bladder over it, and let it stand in the sun during a fortnight,—or if the season be rainy, let it stand by the kitchen fire. At the expiration of that time, run it through a jelly-bag, pressing the bag well out, and bottle it in pint bottles. Cork the bottles well, and tie bladders over the corks.—For shalot vinegar, skin a dozen and half of shalots, and cut them into halves; put them, with a small blade of mace and half of a sliced nutmeg, into two quarts of vinegar; close the jar with cork and bladder, and in a month it will be fit for use.—For cucumber vinegar, peel and slice twenty large cucumbers; put them into a stone jar, and add half-a-dozen onions cut into quarters, four shalots, three cloves of garlic, three ounces of salt, half an ounce of pepper, half a teaspoonful of cayenne, and a lemon sliced with its peel; pour two quarts of vinegar upon these ingredients and let them stand a week, the jar being covered with bladder; then place the vessel in a boiler of hot water, and make a few holes in the bladder with a large skewer; let the water boil during an hour; take out the jar, let the vinegar get quite cold, and pass it through a jelly-bag, which must be well pressed. Put the vinegar into pint or half-pint bottles, and tie the bladder over the cork.—For chili vinegar, bruise three dozen of small green chilis with a little salt; put them into a half-gallon jar, which fill two thirds full of large capsicums; fill the jar with vinegar; let it stand a month, then bottle it in small bottles; put a couple of dozen more chilis bruised with salt, and fill up the jar again with vinegar, which at the end of another month may also be bottled.—For tarragon vinegar, fill up loosely a one-gallon stone jar with the fresh leaves of tarragon just gathered; then fill the jar with vinegar; cork the vessel, tie a piece of bladder over it, and let it stand by the kitchen fire, or, if the weather be fine, in the sun, during a month, when it must be run through a jelly-bag, and bottled for use.—For vinegar of roses, fill a gallon jar with rose leaves just gathered, and put in also two ounces of lump sugar in lumps; then fill the vessel with the very best white wine vinegar; close the jar with cork and bladder, and let it stand in a warm place during a month; run it through a jelly-bag, and bottle it in small bottles.—For orange flower vinegar, put a quarter of a pound of orange flowers into a jar; pour upon them two quarts of vinegar; let it stand a month; then strain and bottle it.—For vinegar of elder flowers or clove gilliflowers, dry in the sun during three days, two ounces of either of these flowers; pour upon them a quart of vinegar and let it stand six weeks.

The vinegar suitable to be used in medicine is either distilled wine vinegar, distilled malt vinegar, or purified and diluted pyroligneous acid. The last of these, also, under the name of white or clear vinegar, is very suitable for many culinary purposes, and has, for a number of years past, very generally superseded all other vinegars in matters of every kind which require the presence of the mere acetic acid without the aroma or sapidity or qualifying action of intermixed vegetable principles. Wine or malt vinegar is used in human medicine internally as a tonic, a refrigerant, a diaphoretic, a diuretic, and an antidote to narcotic poisons, and externally as a moderate stimulant and astringent; any common kind of vinegar is much used in veterinary medicine, either alone, diluted, or in mixture with other substances, as an application to bruises, strains, swellings, and other topical in-

juries and maladies; and wood vinegar, or diluted pyroligneous acid, is used in human medicine externally as a rubefacient, an epispastic, an escharotic, and an antiseptic.

VINERY, or Grape-House. A vinery with two furnaces is generally 50 feet in length, and 14 or 15 feet in width within; the height of the back wall being 10 or 12 feet, and of the parapet about 18 inches. When one furnace only is employed, the length of the house should never exceed 30 or 35 feet. The parapet wall is generally supported on small arches or lintels, so that the vines which are planted inside the house may send abroad their roots in search of suitable nourishment. Sometimes the vines are planted without, and introduced through slanting apertures. Very commonly the roof is formed of sashes, which can be let down for the admission of air. In a grape-house described by Mr. Knight, (*Hort. Trans. Lond.* vol. i. p. 100,) the air is admitted at the ends, where all the sashes are made to slide; a free current may thus be made to pass through the house. Besides, about 4 feet of the upper end of every third light of the roof is made to lift up, being attached by hinges to the wood-work on the top of the back-wall; and in this way, air is given in hot and calm weather, without any additional shade. See the article Ventilation.

In planting a new grape-house, the young vines are put in in February or March, and little or no fire heat is given; they make strong shoots the first year, but only such as are wanted for the trellis are preserved, perhaps three on each plant, and in general these are trained straight towards the roof, ten or twelve inches separate from each other. In September, if the wood be not properly ripened, a little fire heat is given for this purpose. Next year a good deal of fruit begins to appear; but only a few bunches are permitted to come forward, in order to prove the kinds. In the third year, if well managed, they fill the roof; and if the wood be thoroughly ripened, they may be considered as established plants.

We shall here mention an incomparably more speedy mode of storing a new grape-house, which may be adopted wherever a vinery previously exists in the garden, or where there is a friend's vinery in the neighbourhood. In the end of June or beginning of July, when the vines have made new shoots from ten to twelve feet long, and about the time of the fruit-setting, he selects any supernumary shoots, and, loosening them from the trellis, bends them down so as to make them form a double or flexure in a pot filled with earth, generally a mixture of loam and vegetable mould; taking care to make a portion of last year's wood containing a joint pass into the soil in the pot. The earth is kept in a wet state; and at the same time a moist warm air is maintained in the house. In about a week or ten days, roots are found to have proceeded plentifully from the joint of last year's wood, and these may be seen by merely stirring the surface of the earth, or sometimes they may be observed penetrating to its surface. The layer may now be safely detached. Very frequently it contains one or two bunches of grapes, which continue to grow and come to perfection. A layer cut off in the beginning of July generally attains, by the end of October, the length of fifteen or twenty feet. A new grape-house, therefore, might in this way be as completely furnished with plants in three months, as by the usual method, above described, in three years. Supposing the layers to be made on the first of July, they might be cut, and removed to the new house on the 9th: by the 9th of October, the roof would be completely covered with shoots, and next season the house would yield a full crop of grapes. It is not meant that they should be allowed to do so, if permanently bearing plants be wished for: on the contrary, they should be suffered to carry only a very moderate crop, as it is pretty evident that the roots could not sustain the demand of a full one; or at any rate, that the plants would necessarily show their exhausted state by barrenness in the following season. By this means the more delicate kinds, as the frontignac, may be quickly propagated: we have seen layers of the Gibraltar or red Hamburgh made in the beginning of July, reach the length of thirteen feet before the end of the month, yielding at the same time two or three bunches of grapes. The more hardy, such as the white muscadine, form still stronger plants in that space of time. Little difficulty is experienced in removing the plants from the pots into the holes prepared for them: if there be fears of preserving a ball of earth to the new roots, the pots may be sunk with them, and then broken and removed; or the plants may be kept in the pots till autumn, when they may very easily be taken out of them without detriment. When it happens that too much bearing wood has been trained in, the plants are relieved, and sufficient sun and air admitted, by thus removing two or three shoots; and supposing these to contain each several bunches, of some fine sort of grape, they are not lost, but may be ripened, by setting the pots on the side-shelves, or flue trellis of the pinery, or any hothouse.

The proper management of the grape-house has now become an important part of the duty of a gardener. To lay down particular rules in this place is impossible; a few general hints only can be given. A great deal of useful information on this subject may be found in the excellent 'Treatise on the Culture of the Vine,' by Mr. William Speechly, London, 1789; and in the 'Forcing Gardener,' by Mr. Walter Nicol, Edinburgh, 1809. These and similar books the gardener should study, as containing the results of experience; but many cases will occur, in which he must depend on his own practical know-

ledge, and be guided solely by his own judgment.

The forcing of the earliest grape-house is often begun in January. Till all the buds be broke, air is daily admitted by the sashes, and the heat is kept moderate, so that the thermometer may indicate only 50° or 55° in the mornings and evenings when the sun has no influence. The temperature is then gradually raised, in the course of a fortnight or three weeks, to about 70°. When the flowers appear, it is increased nearly to 75°, and the house is frequently steamed, by sprinkling water on the flues, or on the walk when the sun shines, grapes being found to set best in a strong moist heat. The gardener now selects his bearing wood for next year, and trains the shoots to an upper trellis, a foot above the other, and the wires of which are perhaps two feet apart; while he nips off all lateral and superfluous produce, and at the same time shortens the bearing shoots at an inch beyond the uppermost cluster. While the berries are swelling, water is moderately given. Nicol, indeed, recommends that it should be given liberally till they begin to ripen; but this has been considered as likely to deprive the grapes of their proper raciness and flavour.

The thinning of the bunches deserves attention. This is sometimes neglected; but in many kinds, without this attention, the berries in the middle of the bunch are apt to get mouldy and to rot; and in all cases where thinning is practised, the berries become larger and more equal in size. In the operation of thinning, particular care should be taken that the left hand, with which the bunch is held, be kept cool, and also quite free from perspired matter. For this purpose, the gardener should have a vessel with pure cold water beside him, into which he may now and then dip his hand, to keep it cool and clean. Without this precaution the berries often suffer from being handled, acquiring a rusty diseased look, and not swelling freely.

When the grapes approach maturity, all are agreed that no more watering is proper. Most, however, freely admit air. In general, a proportion of the foliage, especially on the stubs on which the clusters hang, is removed. The fruit ought to remain till it be fully ripe; but this the impatience of the owners seldom permits. When the fruit is all gathered, the stubs which bore it are cut off, and the new shoots are let down from the upper trellis to their proper places. Watering both of border and foliage is now resumed, and the house is usually left fully exposed to the atmosphere. The general pruning is performed from the middle to the end of October, and time is thus given for the healing of the wounds before forcing be again commenced. At this pruning the loose part of the outer bark on the old wood is carefully peeled off, and the whole plant and the trellises are washed with some penetrating liquid, calculated to destroy the minute eggs of insects. For about a fortnight after this severe pruning, the house is kept shut, but it is afterwards freely exposed as before.

The management of the late grape-house entirely resembles that of the early, making due allowance for the difference of season. It is not intended for *forcing* the fruit, but merely for supplying the deficiencies of our natural climate in spring and autumn. As the vinery may remain without its glass-covers for many months in the year, in some places, especially in the south and west of England, the peach-house is formed exactly of the same dimensions; and, when the peach season is over, the glass frames are transferred to the vinery, and, if the blossoms have escaped, a crop of ripe grapes, of the best sorts, is thus procured in September or October, and the new wood is thoroughly ripened.

VINEYARD. A plantation of vines.

VINQUISH. See Pining.

VINTAGE. The harvesting of a vineyard, or a crop of grapes.

VIOLET, — botanically *Viola*. A large and interesting genus of ornamental thalamiflorous plants, constituting the type of the natural order Violarieæ or Violaceæ. This order is very nearly akin to the Polygaliæ, to the Droseraceæ, and especially to the Passifloræ; and is distinguished from the Polygaleæ by its stipulate leaves, its two-celled anthers, and its unilocular fruit,—from the Droseraceæ by its involutive exfoliation, its stipulate leaves, its solitary style, and its lengthened embryo,—and from the Passifloræ by its stigmas being one and not three, by its anthers being attached along their whole length and not fixed merely by the middle, by its stamens being hypogynous and not perigynous, by its fruit being capsular and not berried, and by its seminal albumen being compact and shining and not pitted. The majority of its species are hardy herbaceous plants, inhabiting the cold or temperate zones of both hemispheres, growing in many instances at great altitudes above the level of the sea, all remarkable for neatness, many for brilliant floral beauty, and some for exquisite and luscious odour. Yet a considerable number, constituting a tribe, are suffrutescent plants, and natives of the tropics. The chief medical properties of the order are emetic, and seem to reside principally in the roots. About 150 species, belonging to 12 or 13 genera, occur in British collections; and about 120 of them are hardy herbs, and the rest are pretty equally divided between the greenhouse and the stove.

Between two-thirds and three-fourths of all the Violaceæ in Britain belong to the violet genus; and, excepting about 8 or 10, all these are hardy herbs,—principally perennial-rooted and annual-stemmed. The garden kinds, comprising a countless number of most brilliant hybrids and varieties, are noticed in the article Pansy. Nine of the other kinds or true species are natives of

Britain, and the rest have been collected from almost all parts and latitudes of the north temperate zone, as well as from some subtropical countries, in both the eastern and the western hemisphere. All deserve to be cultivated, either for their beauty or for their perfume. The small perennial kinds do best in pots, in a mixture of peat, loam, and sand; and the larger and hardier perennial kinds, as also the few annual kinds, do well either in rock-work or in the front of flower-borders. The American species thrive best in peat or vegetable mould, and may be propagated either from seeds or by division of the root; the greenhouse and stove species generally grow best in a mixture of loam and peat, and are propagated variously by layers, cuttings, and divisions according to their respective nature; and the hardy perennial kinds, for the most part, love a soil of peaty loam, and are most readily propagated by radical division.

The sweet-scented violet, *Viola odorata*, is an indigen of shady places in Britain. It is a low creeping evergreen, sending out runners which root at small intervals, and throwing up tufts of leaves and flowers. Its roots are fibrous; its leaves stand on slender footstalks, and are heart-shaped and crenated, and have a lively green colour on the upper surface, and a paler colour and downy appearance on the under; its floral footstalks are quadrangular, channelled, delicate, and about two inches long; and its flowers have a green five-sepalled calyx and a deep violet coloured corolla, with a large spur protruding from one of the petals, and bloom from March till May, and emit a most delightful fragrance. Seven very distinct varieties, with respectively purple, white, blue, double purple, double white, double blue, and double pale flowers, are cultivated in flower-gardens; and the normal plant is extensively cultivated, for the use of apothecaries and city herbalists, in the neighbourhood of Stratford-on-Avon and in some parts of Kent. An alkaloid, called violine, exists as a malate in the root, stem, leaves, and flowers, and has similar properties to emetine, and acts as a strong poison. The petals have a place in the Edinburgh and Dublin pharmacopœias; and were formerly regarded as anodyne and pectoral; but are now used in pharmacy only for preparing a syrup, which has gently purgative properties, and is given to infants. They have a very slightly bitter taste, and, when chewed, give a blue tinge to the saliva. The infusion of them, and also the syrup, serve in chemistry as useful and delicate tests of the presence of uncombined acids and alkalies, an acid changing their blue colour to a red, and an alkali changing it to a green.

The other indigenous species are the dog's violet, *V. canina*, a perennial-rooted, deciduous, blue-flowered creeper, about 3 inches high, inhabiting the heaths of Britain, and blooming from April till June; the three coloured violet, or fancy violet, or heart's ease, *V. tricolor*, an upright, yellow and purple-flowered annual, about 6 inches high, inhabiting the corn-fields of Britain, and blooming from April till September; the corn-field violet, *V. arvensis*, an annual, very similar to the preceding; the yellow flowered violet, or mountain yellow violet, or true wild pansy, *V. lutea*, an upright, annual-stemmed, yellow-flowered perennial, about 3 inches high, inhabiting the meadows and pastures of Britain, and blooming from May till August; the marsh violet, *V. palustris*, an upright, annual-stemmed, blue-flowered perennial, about 3 inches high, inhabiting the mossy bogs of Britain, and blooming in May and June; the hairy violet, *V. hirta*, an upright, annual-stemmed, blue-flowered perennial, about 6 inches high, inhabiting the chalky soils of England, and blooming in April and May; the milk-coloured or cream-coloured violet, *V. lactea*, an upright, annual-stemmed, crimson-flowered perennial, about 6 inches high, inhabiting the moist heaths of England, and blooming in May; and the pleasing violet, *V. amœna*, an upright, annual-stemmed, purple-flowered perennial, about 3 inches high, inhabiting the mountains of Scotland, and blooming in June and July.

Some of the most interesting of the introduced exotic species are the sweet or fragrant, *V. suavis*, a hardy, evergreen, pale blue-flowered, sweet-scented creeper, about 3 inches high, introduced from the Ukraine in 1823, and blooming in September; the palmate, *V. palmata*, a hardy, erect, annual-stemmed, purple-flowered perennial, about 6 inches high, introduced from North America in 1752, blooming in May and June, and comprising a variety with variegated white and purple flowers; the pedate, *V. pedata*, a hardy, erect, annual-stemmed, blue-flowered perennial, about 6 inches high, introduced from North America in 1759, blooming in May and June, and comprising a variety with fan leaves and light purple flowers; the winged-leaved, *V. pinnata*, a hardy, erect, annual-stemmed, violet-flowered perennial, about 6 inches high, introduced from the South of Europe in 1752, and blooming in May and June; the hooded, *V. cucullata*, a hardy, erect, annual-stemmed, blue-flowered perennial, about 3 inches high, introduced from North America in 1772, and blooming from May till July; the butterfly, *V. papilionacea*, a hardy, erect, annual-stemmed, blue-flowered perennial, about 3 inches high, introduced from North America in 1800, and blooming in May and June; the clandestine, *V. clandestina*, a hardy, erect, annual-stemmed, brown-flowered perennial, about 3 inches high, introduced from North America in 1800, and blooming in May; the Japan, *V. Japonica*, a hardy, creeping, blue-flowered, fragrant evergreen, about 6 inches high, introduced from Japan in 1818, and blooming from April till June; the mountain, *V. montana*, a hardy, erect, annual-stemmed, light blue flowered perennial, about a foot high, introduced from Switzerland in 1683,

and blooming in May and June; the peach-leaved, *V. persicifolia*, a hardy, erect, annual-stemmed, cream-flowered annual, about a foot high, introduced from Germany in 1817, and blooming in June and July; Broussonnet's, *V. Broussonetiana*, a frame, erect, annual-stemmed, blue-flowered perennial, introduced from Teneriffe in 1817, and blooming in June and July; the two-flowered, *V. biflora*, a hardy, erect, annual-stemmed, yellow-flowered perennial, about 3 inches high, introduced from Switzerland in 1752, and blooming in April and May; the spurred, *V. calcarata*, a hardy, erect, annual-stemmed, light blue-flowered perennial, about 6 inches high, introduced from Switzerland in 1752, and blooming from March till June; the arborescent, *V. arborescens*, a green-house, erect, evergreen, pale blue flowered undershrub, about 18 inches high, introduced from Spain in 1779, and blooming in April and May; the twiggy, *V. sarmentosa*, a hardy, evergreen, blue-flowered creeper, about 3 inches high, introduced from Caucasus in 1824, and blooming in June and July; Kroher's, *V. Kroheri*, a hardy, erect, annual-stemmed, pale red-flowered perennial, about 3 inches high, introduced from Siberia in 1820, and blooming in May and June; the streaked, *V. striata*, a hardy, erect, annual-stemmed, striped-flowered perennial, about 6 inches high, introduced from North America in 1772, and blooming in June and July; the Canadian, *V. Canadensis*, a hardy, erect, annual-stemmed, white-flowered perennial, about 6 inches high, introduced from North America in 1783, blooming in May and June, and comprising a variety with blue and white flowers; and the attenuated, *V. attenuata*, a hardy, erect, herbaceous, white-flowered evergreen, about 4 inches high, introduced from North America in 1812, and blooming from April till August.

VIOLET (Calathian). See Gentian.

VIOLET (Dame's). See Rocket.

VIOLET (Spurless), — botanically *Erpetion*. A small genus of low, evergreen, frame, trailing, ornamental plants, of the violet order. Two species, the ivy-leaved and the reniform, were introduced to Britain in 1823 from Australia; and both have a height of only one or two inches, and carry pale blue flowers from May till October, and love a mixed soil of sand and peat and loam, and are propagated by radical division.

VIOLET (Water). See Featherfoil.

VIPER. See Adder.

VIPER GRASS. See Scorzonera.

VIPER'S BUGLOSS. See Bugloss (Viper's).

VIRGAUREA. See Golden Rod.

VIRGILIA. A genus of ornamental exotic shrubs, of the sophora division of the leguminous order. The yellow-flowered species, *V. lutea*, is hardy, deciduous, and from 15 to 20 feet high, and blooms in June and July; and was introduced to Britain about 37 years ago from North America. Five greenhouse evergreen species, varying in height from 4 to 10 feet, and mostly carrying yellow flowers in summer or autumn, have been introduced from Africa. All the six species are propagated from cuttings; and most thrive best in a soil of peaty loam.

VIRGINIAN CRESS,—botanically *Lepidium Virginicum*. A hardy, annual, salad plant, of the pepperwort genus and cruciferous order. It was introduced to Britain from North America in 1713. Its stem is about a foot high; its leaves are like those of water cress, but somewhat more bitter; its flowers are white, and have a very short style, and naturally bloom in June and July; and its silicles have a sub-elliptic form, and are emarginate at the top. It is suitable to be used in winter and early spring salads; but is far less in request than some of the other cresses. Sowings of it should be made in light dry earth, either broadcast or in drills nine inches apart, in the latter half of August or the early part of September. The situation for it must be sheltered; and the beds of it should be covered, during severe winter weather, with light twigs, dry litter, or any similar substance.

VIRGINIAN HEMP. See Acnidus.

VIRGINIAN POKE-WEED. See Phytolacca.

VIRGIN'S BOWER. See Clematis.

VISCARIA. A genus of ornamental, herbaceous plants, of the carnation family. It was erected, not long ago, out of the lychnis genus, and may be popularly designated rock lychnis. Its name viscaria is formed from a word signifying bird-lime or glue, and alludes to the glutinousness of the stems. The neglected species, *V. neglecta*, is a hardy, white-flowered, summer-blooming evergreen of 8 or 9 inches in height; and thrives in any common soil, and is propagated by radical division.

VISCERA. The internal or contained organs of the animal body, particularly the saccous and tubular ones situated in the thoracic and abdominal cavities. The word viscus is the singular of viscera; and though most expressive when used in reference to such hollow organs as the stomach or the bowels, may also be applied to comparatively solid contained organs, such as the lungs, the heart, or the kidneys.

VISCUM. See Mistletoe.

VISCUS. Birdlime, glue, or any other sticky semi-fluid; also, a glutinous secretion or stickiness on the stems or leaves or other parts of plants; also, any intestinal organ of the animal frame. Viscera, in the last of these senses, seem to take their name from the mucous and somewhat glutinous secretion with which the intestinal organs are lubricated. See the article Viscera.

VISMEA. A genus of ornamental, tropical, evergreen shrubs, of the St. John's wort family. The Guiana wax-tree species and the Brazilian wax-tree species, both about 8 or 9 feet high, and carrying yellow flowers from July till October, were introduced to British collections in 1824; and the smooth species about 10 or 12

feet high, and carrying red flowers in July and August, was introduced about the same period; and upwards of a dozen other species are known.

VITEX. See Chaste-Tree.

VITIS. See Vine and Grape-Vine.

VITIS IDÆA. See Cowberry.

VITRIOL. See Sulphuric Acid.

VITRIOL (Blue). See Blue Vitriol.

VITRIOL (Green). See Copperas.

VITRIOL (Oil of). See Sulphuric Acid.

VITRIOL (White). See White Vitriol.

VIVES. A swelling of the parotid gland in horses. If the tumour be inflamed and painful, it must be fomented or poulticed; if it be hard and free from tenderness, it may be treated with some stimulating embrocation or blister; and if it suppurate, it must be treated in the manner of an abscess. See the article Abscess.

VOANDZEIA. A small genus of exotic plants, of the cæsalpinia division of the leguminous order. The underground species, *V. subterranea*—called by Linnæus *Glycine subterranea*, and popularly the subterranean pea—is a native of tropical Africa, and was introduced to Britain in 1823. It is a low, annual-rooted creeper; and carries yellow flowers from June till August; and is cultivated in its native country as an economical plant. It thrives best in rich mould.

VOCHYSIA. A genus of ornamental, tropical, calyciflorous, ligneous plants, constituting the natural order Vochysieæ or Vochysiaceæ. Its species are American shrubs and trees, with opposite or whorled, entire, feather-nerved leaves, binate stipules at the base of the leaves, and panicled or thyrsoid terminal racemes of yellow flowers. They are near akin in botanical character to the Combretaceæ, agreeing with them in having inverted seeds and convolute cotyledons; and they are not far from being closely allied also to the Onograriæ and the Rhizophoreæ. Fifteen are known; and one, the lofty, *V. excelsa*, an evergreen tree of commonly about 30 or 35 feet in height, loving a soil of sandy peat, and blooming in August and September, was introduced, about 24 years ago, from Trinidad to the botanical collections of Britain.

VOHIRIA. A small genus of ornamental tropical plants, of the gentian family. The roseate species, *V. rosea*, an herbaceous evergreen of 2 or 3 inches in height, carrying red flowers in July and August, was introduced about 27 years ago from Guiana to the hothouses of Britain. It loves a soil of peaty loam, and requires to be propagated from seed.

VOLKAMERIA. A genus of tender, ornamental, evergreen, ligneous plants, of the verbena family. It is nearly allied to the clerodendrums. Two species, the one a shrub, the other a tree, and both loving a soil of peaty loam and propagable from cuttings, have been introduced to British gardens from respectively India and Japan. The shrub was introduced in the former part of last century, and is described as follows by Miller:—"It sends out many weak shrubby stalks 12 or 14 feet high, covered with a white bark, and garnished with oval spear-shaped leaves, 3 inches long, and 1½ broad, of a lucid green colour and smooth; they are placed by pairs on short foot-stalks. The flowers are produced from the wings of the stalks in umbellated bunches, like the common sort of jasmine to which they have a great resemblance, but the segments of the petal are not so acute pointed; they are white, and have an agreeable odour; and they have each 4 stamina longer than the petal, terminated by single summits. The germen turns to a roundish capsule with 2 cells, each including one seed." The juice of the root and leaves has a bitter taste, and is prescribed by the Hindoo physicians, either alone or in conjunction with a little castor-oil, as an alterative in scrofula and similar affections.

VOMITING. The morbid or provoked regurgitation and rejection of food, drink, or other substances in the stomach of an animal. Regurgitation, in any form, from any cause, with or without rejection, cannot take place in monodactyles, particularly in the horse, in consequence of the peculiar organization of the stomach. See the article Stomach. Regurgitation, of a regular, functional, ruminantial kind, unaccompanied by rejection, and constituting part of an elaborate process of digestion, is natural and necessary in all oxen, sheep, and other ruminants. See the article Rumination. Regurgitation of a combinedly functional and forced kind, partly natural yet occasionally provoked, occurs in the canine and the feline tribes. "The dog," remarks Delabere Blaine, "swallows a large quantity of food at a time, and either by a partial deposit, or by delaying the process of digestion, he keeps it until he has found a hiding-place, when he regurgitates a portion or the whole. This must have been witnessed by most persons who have had bitches with their whelps in their possession. Vomition is certainly encouraged by the dog, who eats an emetic grass for the purpose; but the act is altogether a different one to that of (simple) regurgitation, as must be evident to any one who observes it. In (simple) regurgitation, the matters seem either not to have entered the stomach, and to have occupied only the cavity which exists around the œsophagus to favour its distention, or otherwise, by some capability in the stomach, it is received and retained at its very entrance, for its regurgitation is without effort, and the abdominal muscles are hardly called into action at all. Vomition, on the contrary, in him employs the abdominal muscles most forcibly; and it seems designed that he should have this means of relief at hand, seeing his stomach is placed so as to be immediately within the sphere of their action, which is so necessary to the act that, without their aid, attempts may be made, but are ineffectual, in procuring vomition." In other canine animals, and

in the feline ones, as in the dog, simple regurgitation is natural and functional, and vomiting is either morbid or provoked. But in man, as also in some other animals whose digestive system most nearly resembles his, vomiting is the only form of regurgitation, and proceeds only from disease or immediate provocation,—either mechanical tickling of the fauces or chemical action by means of some emetic on the organism of the stomach. The pharmaceutical use of provocatives to vomiting, therefore, is a nullity in the case of monodactyles, and comparatively limited in the case of canines and felines, and of full power only in the case of animals constituted like man.

VOMIT-NUT. See Nux Vomica.

W

WACHENDORFIA. A genus of ornamental, Cape-of-Good-Hope, evergreen, herbaceous plants, of the hæmodorum family. Eight or nine species, with either yellow, violet, or purple flowers, and varying in height from 12 to 25 inches, have been introduced to the greenhouses of Britain. All love a soil of rich mould, and are propagated by radical division. One of the longest known is described as follows by Miller, and may be taken as a good specimen of the whole:—"It has a thick tuberous reed-like root of a deep red colour, sending out many perpendicular fibres of the same colour, spreading into several offsets. The leaves which rise immediately from the root are large, spear-shaped, and channelled; they have 5 plaited veins, and resemble the folds in fans. The largest of these leaves are 2 feet long, 3 inches broad, and of a deep green colour. The flower-stalk rises from the centre of the heads between the leaves, to the height of 3 or 4 feet, and is garnished with leaves of the same form with those below, but are narrower, and ranged alternately, embracing the stalk half round with their base. The flowers, when young, are enclosed in sheaths, which, after some time, open and make way for the flowers to come out,—then they wither and dry, but remain upon the stalk like those of the yellow asphodel. The flowers are produced from the wings of the stalk, forming a loose spike at the top; there are several sustained upon one common foot-stalk, which open after each other, so that there is seldom more than one open at the same time upon the same foot-stalk. The upper flowers stand almost upright, but the lower nod downward; they are hairy and of a saffron colour on the outside, but smooth and yellow within, having generally 6 petals. Sometimes the lower one is wanting; but then the place is occupied by the pointal, which is a singular sport of nature. After the flower fades, the germen swells to an almost oval, three-cornered, blunt capsule, with 3 cells, each containing three purple hairy seeds, fixed to an oblong placenta."

WAGES. The price or hire paid to servants or labourers for their work. The wages of farm-servants and farm-labourers widely vary, not only according to the grade and qualifications and responsibilities of the parties themselves, but in different districts and situations, and to some extent in different seasons and circumstances. Some of the causes which enhance them are great demand for labour in neighbouring cities and manufactories, thinness of population in a rich and improving country, smart competition for workpeople among extensive farmers, dearth or scarcity of provisions, unusual severity of labour, and unusual length of time in the amount of daily work; and some of the causes which depress them are the want or decrease or cessation of manufactures, the comparative crowdedness of the rural population, the general unskilfulness or inaptitude or laziness of the peasantry, the lightness and shortness of the amount of labour, and either the cheapness of provisions or the low feeding habits of the people. A glance at these causes may explain that farm wages must be very high in the busiest districts of England and Scotland, and exceedingly low in most parts of Ireland and in the remote parts of the Scottish Highlands and Islands.

Farm-wages, in different districts and to different classes, are paid in three different ways,—first, chiefly in kind or in farm produce, and only in a small degree in cash,—second, chiefly in cash, and only in a small degree in kind,—and thirdly, altogether or almost altogether in cash. Persons paid in the first way and in the second never occur on the same farm, and rarely in the same district; but persons paid in the first and the third are often found together; and persons paid only in the third sometimes comprise the whole of the workers. Ploughmen, who constitute both the typal and the most important class of farm-labourers, are paid in all the three ways in different parts of Britain,—in the first, throughout most of the border counties of both England and Scotland,—in the second, throughout most

of the midland and northern counties of Scotland,—and in the third, throughout most of the southern counties of England. The portion of wages paid in kind, in both the first method and the second, varies in items, according to the custom of districts or to particular agreement, but generally comprises the most common and essential articles of household provision raised on the farm. See the articles FARM-SERVANTS, FARM-LABOURERS, BOTHY, PLOUGHMAN, SHEPHERD, and AGENT.

WAGGON. A large four-wheeled carriage, for the conveyance of heavy loads. Waggons are very various in size and structure, according to the different uses which they are intended to serve; and even agricultural waggons, or those which are employed solely or mainly by farmers, are exceedingly diversified, according to the mere custom of counties, or to the taste or caprice of individuals. Though tumbrils are employed in some districts for the carrying out of manure, and other light and rude carriages are employed in others for some other particular rural purposes, and one-horse carts are universally used in all the best parts of Scotland and in a small part of the north of England, and are also coming increasingly into favour in the central counties of England, for all the carrying purposes of the farm, yet waggons of some kind or other are sometimes used even in Scotland for general purposes of carriage, and are more or less in request in the great manufacturing cities for particular sorts of heavy and bulky conveyance, and enjoy general favour in some of the central and southern counties of England, and universal favour in others, for at least all the road carriage of agricultural produce. We may refer for the general principles of construction to the articles CART and WHEEL; and shall here make only brief notice of the peculiarities of some of the best or most favourite or otherwise most remarkable varieties.

The Sussex waggon stands 6 feet high at the back and $5\frac{1}{2}$ feet at the front, and measures nearly 14 feet in length of lade. Its bed or floor, in very many instances, is narrowed behind the fore-wheels, so as to allow the wheels to lock round in the shortest possible curve, and to give the waggon great convenience and ease in turning; but this peculiarity both diminishes the capacity of the waggon, and somewhat weakens its body; and therefore, in other instances, the bed is made straight; and contrivances are adopted to prevent the wheels from catching on the lock. The tail-board falls down for the convenience of loading, and admits of being so adjusted as to extend the length of the body; and the waggon can easily be converted, by means of hind and fore ladders, into a capacious wain for the in-carrying of hay and corn from the harvest field.

The Hampshire waggon is not very much different from the Sussex one, and contains, without heaping, about 66 bushels, and is generally compact, firm, and strong, with close-boarded or open raves; but is usually straight in the floor, and is seldom furnished with either hind or fore ladders, and is therefore less convenient and has a smaller range of adaptation than the Sussex waggon.

The Woodstock or Oxfordshire waggon has a convex curvature of the rails over the hind wheels, and has both a symmetrical appearance and a very convenient structure. The length of its top-rails is 12 feet 4 inches; the breadth of the top-rails, 1 foot; the length of the fore part of the bed, $5\frac{1}{4}$ feet; the length of the hinder part of the bed, $5\frac{3}{4}$ feet; the width of the fore part of the bed, 3 feet 8 inches; the width of the hind ladder, 4 feet 4 inches; the breadth of the contraction in the bed to allow of the locking of the wheels, 11 inches; the width of the tail-piece, 6 feet; the width of the fore-ladder, $4\frac{1}{4}$ feet; and the distance between the wheels on the ground, $5\frac{1}{4}$ feet.

The Berkshire waggon has a general resemblance to the Woodstock one, but is lower, and has shallower sides and a smaller capacity. It is well constructed and of convenient size and good appearance; and though smaller and simpler than most other varieties of English agricultural waggons, it might serve as a model for them all, and, when furnished with fore and hind ladders, carries a large load of hay or straw or unthrashed corn.

The Norfolk and Suffolk waggon is very heavily built, and possesses a cumbrous character utterly out of keeping with the flat surface and fine roads of most of the districts in which it is used; and, though a horse's draught heavier than the Berkshire waggon, it does not carry so great a load. It is 12 feet long, 4 broad, and 2 deep, and it commonly carries 10 quarters of wheat, and requires to be drawn by four horses on turnpike-roads, and by five on bye-roads. Its chief recommendation is that it locks so far under the bed as to admit of being turned round as curtly as a post-chaise.

Torr's two-horse spring waggon, invented by W. Torr, Esq. of Riby, near Grimsby, and made by Mr Crosskill at the Beverley Iron-Works, is constructed with a light broad body and solid rung sides, and carries $2\frac{1}{2}$ tons of corn in bags, and loads well with hay or corn. It is mounted on springs, and with Crosskill's patent wheels, patent iron axles and oil-boxes. The manufacturer says, "It is well adapted for speed, to trot to market with ease, at the rate of 4 or 5 miles per hour; it is intended for carrying out the system of generally working horses in pairs only, together with the various implements of the farm, as the plough, harrow, drill, &c.; and in harvest-work, it will successfully compete with one-horse carts, particularly where the distance is great." It obtained a prize at the Gainsborough meeting of the North Lincolnshire Agricultural Society in 1845.

The equirotal farm waggon, invented and manufactured by Mr. Stratton of Bristol, is constructed with a cross-lock and with four large wheels of equal diameter, and has a remarkable facility of turning in very small space. "In this waggon," says Mr. Stratton, "two horses, of average size and strength, have drawn with ease 3 tons, on ordinary roads. In addition to the advantages of equirotal wheels and the cross-lock, attention is requested to the nearness of the top of the body to the ground, by which a great lessening of the labour of loading and unloading is effected,—to the great length and breadth of the body, by which the load may be kept low, a great object in hilly districts,—and to the patent self-acting drag (the invention of Mr. Thatcher), which will be found to increase its utility. It is fitted with long portable hay ladders, before and behind, the addition of which enables it, in a hilly country especially, to carry larger loads, and with much greater safety than can be carried by an equal number of horses in carts. It is submitted for competition, as the best agricultural carriage for the general purposes of road and field." This waggon was highly approved by the judges of implements at the meetings of the Royal Agricultural Society in Bristol and Derby.

The equirotal spring waggon, also invented and manufactured by Mr. Stratton, is simply a modification of the equirotal farm-waggon, and differs from one which obtained a prize at Derby only in having the body lower so as to increase the facility of loading. "It possesses most of the advantages of the equirotal farm waggon," says Mr. Stratton, "with the addition of springs; and it is fitted with a pole for two horses to work abreast, and a portable driving-seat and footboard, and patent axles, and is recommended as being peculiarly adapted for a road-waggon, for the delivery of produce, as much time may be saved by going, when loaded, at a quicker pace than can be adopted without springs, &c."

The narrow-wheeled hoop waggon, generally used in Wiltshire, Gloucestershire, and Somersetshire, admits the use of such a high hind wheel as, when the load is proportioned to the diameter of the wheels, to obviate in some degree the disadvantages of low fore wheels. A superior variety of this waggon, manufactured by Mr. Stratton, is figured in *Plate LXI.*

The tipping waggon has 3½ inch wheels, and is constructed with double shafts to go inside when required; and besides being well adapted for the general purposes of the farm, is particularly useful in the carrying of large quantities of lime, sand, clay, coal, or similar loads, for short distances, since it occasions a saving of time and labour in unloading.

The hermaphrodite waggon is a temporary but very useful carriage, employed in Norfolk and other districts, and formed by bolting two carts together. The thill of the hind cart passes under the bed and rests on the pillars of the fore one; and the two are jointly as compact and manageable as if they really formed a single carriage. A very good harvest hermaphrodite waggon is sometimes formed by bolting a cart upon a pair of old waggon shafts and fore-wheels, the shafts of the cart resting on the bolster of the waggon-wheels, and a very long fore-ladder resting above them and upon the bolster, and projecting over the shaft-horse.—A peculiar kind of waggon used for particular purposes in some woodland districts, is noticed in the article Bavin Tug.

A controversy of similar keenness and obstinacy to that about the comparative merits of wheel-ploughs and swing-ploughs has long raged among both literate and illiterate farmers respecting the comparative advantages of waggons and one-horse carts; and, as in the case of the ploughs, it is in a good degree a sort of national dispute between the English and the Scotch, and seems, in general, to be practically determined vastly more by prejudice and custom than by argument and common sense, and, when coolly examined, may be seen to contain a large measure, and perhaps not far from an equal measure, of truth and error on both sides. The merits of it, together with good conclusions for the guidance of inexperienced farmers respecting it, are well stated as follows by Mr. Youatt:—"The advocates of light two-wheeled carts assert that a horse working alone is capable of performing more work than when forming one of a team; and that in consequence of this increased effect, there is a saving of expense nearly in the proportion of three to two, or one-third. The advocates for waggons assert, on the contrary, that it requires that each horse in a single-horse cart should be of a superior quality, and therefore more expensive than those of a team, where the average power only is considered; that the wear-and-tear, first cost, and expense of attendance of several small carts, is greater than that of a waggon carrying the same load; and that in consequence there is an economy obtained by the latter. Numbers of facts and the results of long experience are adduced on either side, all of which convey much useful information; and the substance of the whole appears to be, that with light single-horse two-wheeled carts, good horses are able to draw greater loads, and do more work in proportion than a waggon team; that these carts are easier loaded and unloaded, do less injury to the roads, and that they do not require more horses in action than are sufficient for the work to be performed. On the other hand, it is found that the horses must be stronger and better fed; that being entirely dependent on their own exertions, and doing more work, they are more fatigued and sooner knocked up; that on rough roads they are liable to be shaken and injured by the sudden movements and shocks of the cart, all of which are conveyed by the shafts directly to the

horse; that in ascending or descending hills, the whole weight being above the axle-tree, it destroys the balance, and is thrown too much upon the horse in the former case, or tends to raise him from the ground in the latter, which even if any alteration of the balance be found advantageous, is exactly the contrary of what would be necessary. That with a waggon—the average power of several horses is obtained—horses of inferior quality may therefore be used;—they are not so much fatigued, because by relieving each other they can alternately exert themselves or relax. Greater loads can be carried with less attendance of drivers, and they are less liable to accidents; they are easier withdrawn from any hole, or forced over any obstruction, because only half the load being upon each pair of wheels, the whole force of the team is applied successively to each half of the load, consequently in any bad road the power occasionally required is less, although the draught of the carriage, properly speaking, is greater than that of a two-wheeled cart. These various arguments would appear to lead to the conclusion, that upon good roads, and for short distances, with good horses, two-wheeled single-horse carts are the best; but that, with inferior roads and ordinary horses, light four-wheeled waggons, with a team of three or four horses, are the most advantageous. Two-wheeled carts with two horses are decidedly inferior to either of these: the shaft horse suffers all the inconveniences complained of in the single-horse cart, and the leader does not produce more effect than when in a waggon team. It is impossible to decide generally upon the comparative merits of the different arrangements, because the result depends entirely upon the circumstances of the case. We may, however, endeavour to unite in some degree the advantages claimed by both. The draught of a cart is less than that of a waggon for several reasons,—amongst others, because the wheels are larger and the horse produces more effect, because his force is applied immediately to the resistance. A light waggon with large front wheels would not be much inferior in point of draught to the cart, and two horses abreast in double shafts would work with equal advantage to the single horse; while an additional horse may always be applied when an excessive load or the state of the roads should require it."

WAGTAIL,—scientifically *Motacilla*. A genus of passerinous birds, of the warbler family. Their bill is more slender than even that of the fauvettes; their legs are long; their scapular feathers are extended enough to cover the top of the folded wing, and give them an affinity to the majority of the waders; and their tail is long, and is continually in upward and downward action or "wagging."

The pied wagtail or Yarrell's wagtail, *Motacilla Yarrelli*, is a British bird, and has generally been confounded with the white wagtail of Continental Europe, *M. alba*, or with the ashy wagtail of the Linnæan or old zoological nomenclature, *M. cinerea*, but possesses some quite distinct and peculiar though not very marked characteristics. It abounds in most parts of Britain, and resides throughout the year in the southern parts of England; and it is everywhere known, to even careless observers, by its pied black and white plumage, and its remarkable nimbleness and airiness and constancy of action. It lives on aquatic insects; and frequents moist pastures, the wet parts of pleasure-grounds, and the vicinity of pools and streams; and may often be seen wading in shallow water, in search of its prey. It has a very elegant form and a very graceful activity; and it is ever in motion, skipping from spot to spot, flitting and curving in short flights, chirpingly leaping on the wing, buoyantly alighting on the ground, and constantly wagging its tail with a graceful fanning motion. The male is 6½ inches long; and the female is 6. The nest is built sometimes on the ground, sometimes in a hole of a wall, and sometimes in the side of a hay rick or turf wall or peat stack, but always in the vicinity of water; and it consists of moss, dead grass, and root fibres, lined with hair and a few feathers. The eggs amount to 4 or 5, and have a white ground colour, speckled with ash, and measure 9 lines in length and 7 in width.

The grey wagtail, *Motacilla boarula*, is much less abundant in Britain than the preceding species, and generally migrates in spring from the southern countries to the northern, and in autumn from the northern to the southern. It frequents marshes and water-meadows, and is seldom seen on such comparatively dry grass lands as are partially frequented by the pied wagtail. It has a total length of 7¾ inches, nearly one half of which consists merely of the tail-feathers. The nest is built on the ground, usually in the near vicinity of the waters where the bird obtains its prey, and generally on some tufty bank or rugged surface whose inequalities afford ready concealment. The eggs amount to 5 or 6, and have a yellowish-white ground-colour, mottled with a various tint of pale brown, and measure 8½ lines in length, and 7 in width.

The common yellow wagtail, or Ray's wagtail, *Motacilla Rayi*, abounds in Britain throughout the summer, but leaves our southern shores in September, and arrives again in April. It frequents downs, pastures, fallow-lands, fields of young green corn, fields of pease and vetches, and other kinds of cultivated ground; and may generally be seen to the greatest advantage, perched on a clod or stone in a quite bare field. Its breast has a rich yellow colour, and its tail is in constant fanning motion. Its total length is 6½ inches. The nest is built on the ground, and usually consists of dried bent and root fibres, lined with hair. The eggs amount to from 4 to 6, and have a whitish ground colour, mottled

nearly all over with yellow brown and ash brown, and measure 8½ lines in length and 6½ in width.

WAHLENBERGIA. A genus of ornamental, exotic, herbaceous plants, of the bellflower family. Two annual species, one erect perennial-rooted species, and one creeping evergreen species, all hardy and blooming in the latter part of summer and early part of autumn, have been introduced to Britain; and they have either blue or whitish flowers, and are nearly allied to the true campanulas, and will generally thrive in any common garden soil.

WAIF. A strayed animal or drifted piece of goods which, for want of the owner's appearance after it has been cried and published in the neighbouring markets, is forfeited to the lord of the manor. The law of waifs, however, belonged properly to the old feudal system.

WAIN. A large, rude, or ox-drawn variety of agricultural waggon. The wain of some districts is simply any large vehicle drawn by oxen; that of others differs from a waggon principally in wanting side-rails or ladders; and that of others differs from any coarse kind of waggon in little else than the name. See the article WAGGON.

WAKE-ROBIN. See ARUM.

WALDSTEINIA. A handsome, hardy, yellow-flowered, perennial-rooted, annual-stemmed plant of the rosaceous family. It has a height of about 6 inches, and blooms in June and July, and thrives best in a soil of loamy peat. It is a native of Hungary, and was introduced to Britain about 45 years ago; and it constitutes a genus of itself, and is specifically called *geoides* or avens-like.

WALK. An artificial footpath through a garden, pleasure-ground, or park. See the article LANDSCAPE-GARDENING. A walk may be either straight, curved, or serpentine; and may be formed either of grass, or of gravel, sand, powdered brick, powdered coal, or any similar material.

Grass walks were formerly held in great esteem, and, during the prevalence of the Dutch taste, were regarded as necessary ornaments to gardens; but they eventually became unfashionable, and have long been voted untidy, disagreeable, and vulgar. "These long narrow slips of grass," it is said, "are far from being pleasing to the eye, and are for the greatest part of the year useless, being generally too damp for persons of tender constitutions to walk on; and wherever they are constantly used, they become bare in the places frequently trodden, and so are rendered more unsightly. And as the intention of walks in gardens is to have at all seasons a dry communication through them for exercise and recreation, grass walks are very improper, because every shower of rain makes them so wet as not to be fit for use for a considerable time, and the dews render them too damp to walk on either in the morning or evening; and if they are not kept constantly close mowed, they become not only unhealthful but troublesome to the feet. Besides, whenever the ground is so dry that persons may with safety walk upon grass, the lawns and other parts of verdure in gardens are most suitable for the purpose." Yet, in some situations, particularly behind lengthened screens of trees, or in some portions of gardens which do not contain any lawn, grass walks form an agreeable variety and are highly desirable. The space intended for them should be digged and levelled; the surface soil itself should be good, yet a thin layer of sand or of poor earth should be spread immediately below it, to prevent excessive luxuriance; and the grasses sown should not comprise any annual, coarse, or wiry species, and may consist of *Poa trivialis*, *Festuca ovina*, *Festuca duriuscula*, *Cynosurus cristatus*,—and, in shady situations, of *Poa nemoralis*.

Gravel is the best material for a firm or earthy walk; but is exceedingly various in quality, and may make either a prime walk or a very bad one according to its kind. Very good gravel is sometimes found on the sea-shore; but the better sorts are generally obtained from inland pits; and the most celebrated in Britain occurs at Kensington and Blackheath, and is conveyed thence in considerable quantity to remote parts of the kingdom. The space for a gravel walk—as also for one of any similar material—should be excavated to the depth of about 20 inches; and the lower half of its depth should be filled with rock rubbish, flint-stones, small boulders, or any similar substance, to prevent worm-casts and the growth of weeds, and the other half filled with successive assortments of the gravel, or with a mixture of it and loam, according to the degrees of its coarseness and cohesiveness. The common superficial convexity allowed for a gravel walk of five feet in breadth is an inch in the crown; so that if a walk or drive be twenty feet wide, it should be four inches higher in the middle than at the sides. When a gravel walk has been evenly laid, trodden down, and raked, it should be rolled well both in length and in width; and in order that it may be sufficiently firm, it should receive three or four water rollings, or rollings immediately after a heavy fall of rain, so that the gravel may bind, and become as hard as stone pavement. In summer, the walk must, from time to time, be hand-hoed and raked, to clear it from weeds and tufts of grass; and after every such operation, or even sometimes after a simple sweeping, it should be rolled with a hand roller.

Sand walks are less expensive to make and keep than gravel ones; and sand walks which go through woods and plantations are much drier and wholesomer than gravel ones; and whenever they appear mossy or weedy, if they are scuffled over with a Dutch hoe in dry weather, and raked smooth, they will appear as fresh and handsome as when first laid. The breadth of such walks and drives should be proportioned to the size of the ground; and in a large extent

may be twelve or fourteen feet wide, but in small gardens five or six. The ground for them being traced, the earth should be taken out, and laid in the quarters. The depth must be proportioned to the nature of the soil; for where the ground is dry, the walks need not be elevated above the quarters, and the earth may be taken out to the depth of four or five inches; but where the ground is wet, only two inches may be taken out, and the surface should be raised so high as to throw off the wet into the quarters. After the earth is taken out, the bottom should be laid with rock rubbish, coarse gravel or any similar material, to the thickness of five or six inches, and beaten down close; and then a layer of sand about 3 inches thick should be laid on, trodden down, raked over, and made thoroughly level and smooth. The sand should be such as will bind well and at the same time have no tendency to become mortary; for if it be too incohesive and loose, it will slide from under the feet in dry weather, and may even be drifted by strong gales of wind; and if it be too much of a loamy nature, it will stick to the feet in wet weather, and become poached and corrugated.

WALK. The slowest natural pace of a biped or a quadruped. In the first action of the walk of the horse, one of the hind legs is lifted and carried forward, both of the fore legs become inclined backward, and the diagonal fore leg is lifted and carried forward; and in the second action, the other hind leg is lifted and carried forward, both of the fore-legs again become inclined backward, and the opposite fore leg is lifted and carried forward. But the pace, though thus simple in its easiest and slowest mode, is completely altered by acceleration of speed, and may be performed laterally as well as diagonally, and may become ready to glide into either the trot or the amble according to the mode of its movement and the degree of its speed.

WALKERIA. A small genus of ornamental, tropical, evergreen, yellow-flowered, ligneous plants, of the ochna family. Two species, the serrated and the entire-leaved, have been introduced to British hothouses from respectively India and Guiana; and both have a height of about 12 or 14 feet, and love a soil of peaty loam, and are propagable from cuttings. The roots and leaves of the serrated species have a bitter taste; and a decoction of them, either in water or in milk, is used in India as a tonic, a stomachic, and an antiemetic.

WALL. The elementary structure of masonry,—whether of stone, or brick, or of other material; and it either may exist in its simple elementary character, as when it forms a plain fence, or may be combined with all the other structures of masonry, and with many of those of ornamental architecture, as when it constitutes the main fabric of houses, from the smallest and humblest to the largest and most ornate. The chief kinds and properties of it, when built of stone, are discussed in the article Masonry; the principal constructions of it, when built of brick, are discussed in the article Brickwork; the main forms and adaptations of it for the purposes of the farmery, are noticed in the article Farm-Buildings; and the most important kinds and varieties of it suitable for horticulture, are noticed in the article Garden. All that remains to be done in this place is to discuss the important practical subject of dry stone walls as a fence for fields; and this we shall do by giving an abridgment of a long and valuable paper by Mr. Stephens in the third volume of the Quarterly Journal of Agriculture.

Should materials appropriate to the purpose of building stone-walls be plentiful at a short distance—should the situation be so elevated, or exposed to such a cutting wind, as to produce baneful effects on the growth of hedges—should much of the time in summer not be always required to prosecute what may be called the extraordinary operations in summer fallowing, such as draining, carting lime and manure from a distance—by all which favourable circumstances the expense of constructing stone-walls will be much decreased—stone-walls may be preferred to hedges as a fence. There are some situations, too, in the most favoured soils for the growth of hedges, in which walls may be introduced with advantage; as in those parts of low lying fields near the margins of sluggish rivers, which are liable to inundate their banks in winter, or even during the periodical rains in summer. Hedges in such situations lose their vigour of growth, and become a prey to parasitical mosses and lichens. In hollow grounds near bogs or fresh-water lakes, over which vapours are frequently suspended during the nights in summer, and which blight the vegetation of the most vigorous hedges, stone-walls are preferable to hedges. The sides of paths leading to watering places from fields, and particularly if they are environed with plantations, are best protected by stone-walls. Around plantations on sandy or gravelly soils, where no ditch is required to carry off surface-water, or on a bleak moor, where the soil may be too scanty and poor for the successful growth of a hedge, a stone-wall may be found the most efficient fence.

Most of the stone obtained from quarries of amorphous rock, however durable it may be in its texture, forms inconvenient materials for dry built walls. Basalt, and some of the older sandstones, together with most of the rocks of the older formations, may be classed under this character. Greenstone, clinkstone, and the newest sandstones, often exhibit even cleavages which qualify them as useful materials for dry-stone walls. And yet, either from the want of care, or knowledge in the proper dressing of these latter stones by the hammer, they frequently form uncouth-looking fences. From their rugged appearance, they indeed form formidable barriers

against the attempts of cattle; but they present a very unworkman-like aspect, not unlike the rude attempts of primeval cultivation. Rolled masses of rock, of the older formations, make the very worst materials for stone-fences. Round stones present so small and smooth a surface while in contact with each other, that they cannot long retain the position in which they have been placed, without the aid of mortar. On this account also, they are unfit to be used as a coping to any wall. Their excessive hardness repels the free use of the hammer. They may be used, however, with advantage as foundation stones; and as many such masses are found near the surface of the ground, in the act of clearing away the obstructions to its cultivation, they can be got rid of in the most economical manner, by being thus usefully employed. Sandstone of a slaty structure, and slate-clay, are desirable materials for walls. The former sometimes, however, presents a smooth hard surface when split into thin layers, which property permits the sliding of one stone over another, when built in a wall, and which endangers its stability; while the latter, having an excess of alumina in its composition, which being frequently decomposed by the action of the atmospheric air, crumbles into powder. Both of these evils must be avoided as much as possible, by rejecting the improper materials which produce them. The very best material for the construction of dry-built walls as a field-fence, is supplied by those rolled masses of sandstone found in gravelly deposits. They occur in size from 1 foot to 4 feet in diameter. Containing small plates of mica in their composition, they easily split into thin layers immediately after they are extracted from the gravel in their naturally damp state. These layers harden by exposure to the atmosphere. Very often they exhibit a smooth and straight fracture across their face, and this property causes them to be easily divided into conveniently sized stones for building, which is often accomplished by merely throwing them upon each other into a heap. These layers split with parallel faces, and they have a rough granulated surface, which makes them readily adhere to one another by friction when they are built into a wall. Such material leaves no waste, and, when properly built, forms a more compact, stronger dry wall than any other kind of stone.

Much of the stability of any wall, of whatever material it may be built, will depend on the knowledge and dexterity of the builder. The best builder of a dry wall is he who practises no other kind of building than of dry materials; for any ordinary mason, particularly in building rubble-work, depends so much on the lime keeping the smaller stones safe in the inside of the wall, that he will not take the trouble to embed them firmly. The implements to be used are a wooden frame, of the shape and size of a vertical section of the wall to be erected,—a common mason's hammer, about four pounds in weight,—a line, and a pick and shovel to prepare the ground for laying the foundation. The wooden frame should be 2 feet in breadth at the bottom over the wood, 15 inches wide at the upper edge of the cross rail near the top, which latter point should be 3 feet from the bottom, and the whole height of the frame may be 3 feet 3 inches.

In choosing a line of fence for the foundation of a wall, the ground should be as hard as possible, to prevent it from sinking. A good foundation may be found either upon a natural sward, or upon removing the soil which had been disturbed by the plough. If the soil is deep in any part of the line, the arable or soft part alone may be thrown aside; or, if it is not very soft, the largest and flattest stones may be used as a foundation upon the surface of the ground. The arable soil which is thrown out of any foundation may be used as a compost or top-dressing. All sudden turns or curves in such particular line of wall should be avoided, as well as any sudden elevation or depression in a vertical direction, as these points will be found to be the weakest in a wall. The curves should be made segments of as large circles as the circumstances of the case will admit; and sharp elevations of ground should be cut down to a moderate curve, even though this work, for the sake of the wall, should cause additional trouble in removing a little of the circumjacent earth. Over a slight depression of the ground, if of considerable extent, the top of the wall should run along a line of the same apparent elevation, for the sake of its general uniform appearance.

The stones for building should be laid down immediately after the line of fence is fixed upon. If the ground is clear on both sides of the line, double horse cart-loads of stones should be laid down within two yards of each other fron centre to centre of the load, on each side of the line. If one side only of the line can be approached by the cart, they must be placed within one yard from centre to centre of the heap, that is, as close to each other as they can be emptied out of the cart. For the convenience of the builder, the large boulder-stones meant for forming the foundation of the wall, should be laid down at first on the ground previously prepared for the foundation, and the common building stones should be afterwards placed as near to the hand of the builder as is practicable, without intruding too much on the space allotted to the foundation.

Poles and stakes should be driven along the whole line in the centre of the space to be occupied by the wall, in order that it may be continued straight. The frame is then to be placed in advance on the line to be built on. It must be set in a perpendicular position by a plumb line, hanging down in a line which bisects the frame in a vertical direction, and it is kept steady in its position by a stick, having a notch cut into one end of it, or a nail driven into it, and which

notch or nail rests on the upper rail of the frame, and the other end of the stick rests upon the ground, and is there made firm by the weight of a large stone. Another frame, or small stakes, may be temporarily erected at the point which forms the commencement of the wall, till the first length of it is finished, after which the wall itself will serve the purpose of the temporary frame. A building line is then stretched on the outsides of the frame, on each side of the wall. Two builders, one on each side of the wall, will perform the work much better than one can do by himself. One man cannot carry up both faces of the wall simultaneously. He must first do the one and then the other, which prevents him building so firmly as when both are built up together. If boulder-stones are used for the foundation, they must be placed firmly on their base on the ground, by wedging them with the hardest stones. They must not yield in the least to the tramp of the feet upon them. They should be placed at a little distance from one another, one in the alternate face of the wall, in order that a firm piece of building may be erected between them. If they have a square face, the appearance of the wall is improved by presenting it to the outside, though the mere appearance of the wall is of less importance than the placing of a flat surface upwards for the support of the superincumbent building. It is highly commendable to cause these large stones, or indeed any form of stone in the foundation, to project three inches at least beyond each face, so that the wall will stand upon a base of two and one-half feet in breadth. Thus placed, these base stones are said to form a "toe" to the wall, which certainly imparts a very firm footing to it.

Most sandstones, even of the hardest kinds, absorb water very readily, and, if saturated by rain before frosty weather, the frost takes effect on them, and often splits and injures many of them. But if they are placed in an inclined position on each side of the wall, the rain will not be able to find access into its interior, and must drip down its face to the ground. This inclination should be downwards towards the outside of the wall, and it is formed by laying the exterior edge of the stone upon the same edge of the one immediately below it, and elevating its interior edge a little, and keeping it in that position with a flat stone placed under it as a wedge. After the spaces between large stones, when they are used, are built up, and brought nearly to a level, or, after the wall is built about half-way up with ordinary stones, when they alone are used, it is desirable, if the nature of the materials used admit of it, to lay large flat stones across the whole breadth of the wall, or nearly so, as binders to the building below, and upon which the upper part of the wall may be more securely placed. These stones are called 'thorough bands.' These bands are very serviceable to the wall in cases of violent concussions against it, which might drive off the coping, and the upper part of the building, but which in such cases might not affect it to the foundation. The wall is then built up, with the stones in the above inclined position, upon the band to the height of three feet, which is the ordinary height of the building for a common stone fence. Some thin stones will be necessary to be laid on the top, to make the building level for the reception of the cover, which should now be placed not only over the whole breadth of the wall, but projecting about two inches on each side of it. This cover should be made of stones selected from the rest for their flatness, strength, and apparent durability. It is not necessary that all the covers should be of the same thickness, for the coping can be formed of lower stones over the thickest covers. These covering stones secure effectually the top of the wall, and prevent much of the rain that, without them, would descend into the inside of the wall. Even if the coping should be thrown off at any time, the wall itself will be preserved if the covers remain unhurt.

The coping may be formed of all those stones which had been rejected in the building, provided they are not too small. Mere waste shivers are unfit for any part of a wall, but they may be used in draining. Strong angular stones which can stand close and firm together, form good coping. Round stones are very objectionable, as they are ever rolling off, and the small stones which it is necessary to use as wedges in keeping them steady, are easily displaced. The best coping is made of flat stones placed on edge. The edge on which they stand on the cover should not be of a round form, as with that form they will easily lose their balance. It should rather be curved upwards like an arch, so as the cope may stand on two extreme points only. It is advisable to place the broadest cope-stones over the joints of the covers, in order to obstruct the passage of the rain through them into the heart of the wall. After a number of cope-stones are placed firmly together, and perpendicularly beside each other, thin hard stones should be driven in the openest spaces between them as wedges, so as to render the whole coping one connected row of stone.

The finished wall presents a breadth in end of $2\frac{1}{2}$ feet at the base, and 15 inches immediately below the cover. The cover may be from 2 to 3 inches in thickness. The cope will stand nearly a foot in height, so that the height of the whole wall will not exceed 4 feet 3 inches. Such a wall is called a five quarter one,—its body measuring 36 inches, which are four quarters of a yard of 9 inches each; and the cover and cope, which stand 1 foot 3 inches, are considered equal in labour to the building of another quarter of 9 inches. This is the ordinary height of dry stone field fences, and it will be found to form an efficient fence for the confinement of the ordinary kinds of live stock.

A most important consideration respecting dry-stone wall fences is to render them efficient for confining mountain sheep. It is found that a five quarter wall cannot confine that kind of sheep; nor, indeed, can a much higher wall do it; for they have a clambering way of scaling, not leaping, high walls. The propensity in these creatures to leap fences, is strongest, when they are brought down at first to the low country from the hills. After they have acquired some condition by feeding, the desire to escape, in a great degree, leaves them. There is a device, however, which has been practised with some success on these walls, to keep them in at first, and that is, to erect long stones, like pavement stones, about a foot above the ordinary coping, at short distances from one another, among the coping-stones. These stones have a notch cut into their upper edge, which can support a small rail of wood, or a rope of twisted straw. This rail or rope appearing to them so frail, as not to be able to bear their weight at such a height, seems to deter them from attempting to leap the wall. Sometimes small branches of furze are stuck in between the cope-stones as objects of terror to them, but which are objectionable, in as far as when they begin to shrink in withering, they lose hold of the wall, and are blown about among the sheep by the wind; and, as they generally get entangled among their wool, they become sources of serious annoyance to the sheep, particularly in spring, as they feed on turnips, when the weather is often windy, and the ground bare.

In a line of wall, near perhaps the outside of the farm, through which there is no traffic by carts, but which may be adjacent to a common or moor, over which the sheep may sometimes be allowed to ramble, an opening in the wall will serve the purpose of egress and ingress to the sheep, better than a common gateway. Such an opening will be found a convenient outlet in any part of the farm, for the sheep at particular seasons, such as lambing-time, for the ewes and lambs to pass through a short cut to the new grass, or for sheep feeding on turnips, to pasture on an adjoining part of the lea in wet weather. This opening should never be made less in size than will easily admit a free passage to a ewe big with lamb.

It is the practice of some fence-builders to allow the thorough-band to project beyond one or both faces of the wall, to show that it is a thorough-band stone; and they even leave others projecting out of the wall, on the pretence that they would rather do that than run the risk of breaking a good stone to pieces. A dexterous hand at the hammer will never break a good stone uselessly. These projecting stones are not only temptations to wandering people, who are constantly trespassing through the country, to step over walls, to the danger of pushing off their tops at least; but the end of the horse-trees catches hold of them when the plough passes as near to the wall in ploughing as it can go. If the builder should leave a small or thin edge of a stone projecting beyond the wall in building, or the edge of a cover too far out, he should break the projecting part off by a smart blow with the hammer when the building is finished, and the pressure of the superincumbent building will greatly assist in breaking it off at the point of projection.

When a wall has two faces, it is said to be a double one; and in all cases where two fields are separated by a wall, it should be a double one. But should the wall be between a wood and a field, then the side next the wood need not be finished so finely as the one next the field, as it will not be so much seen, though it will be as strong as the other; and, therefore, in choosing from a great mass of materials, some of the coarser should be taken to the side of the fence next the wood. Any projecting pieces left next the wood will do no harm. Sunk fences should be built with a taper back towards the top, and the space between the earth and the wall should be well packed with stones for the sake of stability. Inattention to this packing sometimes causes a dry-built earth-fence to fall down by the pressure occasioned behind the wall by the swelling of the earth.

Where a wall has to cross an old-est blished footpath, it is expedient for the safety of the fence to construct easy steps in the wall at that part of it, for the sake of allowing the passengers to step over with facility; as, in every such case, the more easily the passage can be effected, the less damage will accrue to the wall. These steps can be made either of stones, or of wood built into the wall itself; or a wooden stair placed astride over the cover of the wall will serve the same purpose. They are much better than those cross turn-stiles which are sometimes used, and which cannot keep in sheep. Small ladders of the former kind are useful in saving the fences from the passage of shepherds, who may have frequent occasion to walk to the extremities of the farm, even late at night, to look after the sheep, and who cannot be expected to go always round by the gateways.

WALL-CRESS,—botanically *Arabis*. A somewhat large and diversified genus of herbaceous plants, of the cruciferous order. Six species grow wild in the British Islands; about fifty have been introduced from other countries, principally Continental Europe, North America, and North-eastern Asia; and nearly twenty more are known. A few of those in Britain are annuals, more are biennials, and the majority are evergreen perennials; some are creeping, and most are erect; about one half have a height of from 3 to 9 inches, and the rest vary in height from 9 to 30 inches; many have clasping cauline leaves, and many sessile cauline leaves; some have either sulphur-coloured, pinkish, reddish, bluish, or

purplish flowers, and almost all the rest have white flowers; about one-third have marginate seeds, and most of the others have immarginate seeds; about one-fourth or so are more or less ornamental, and all the rest are uninteresting and weedy; all are hardy, and most thrive well on rock-work, old walls, or any common soil. The indigenous species are the hairy, *A. hirsuta*, an erect weedy perennial of about a foot in height, inhabiting the rocks of both England and Scotland, and carrying white flowers from May till July; the upright, *A. erecta*, an erect handsome perennial, of about 6 inches in height, inhabiting the rocks of some parts of England, and carrying cream-coloured flowers in May; the tower mustard, *A. turrita*, an erect weedy biennial, of about 20 inches in height, inhabiting walls in some parts of England, and carrying sulphur-coloured flowers in April and May; the common or Thalius's, *A. thaliana*, a weedy annual, of about a foot in height, inhabiting walls in both England and Scotland, and carrying white flowers in April and May; the ciliated, *A. ciliata*, a handsome biennial of about 6 inches in height, inhabiting the shores of some parts of Ireland, and carrying white flowers in June and July; and the rock, *A. petræa*, a creeping ornamental perennial, of about 6 inches in height, inhabiting the rocks of Scotland, though introduced of a more normal form from Austria, carrying white flowers in May and July, and comprising a hastulate-leaved, purple-flowered variety, which inhabits rocks in both England and Scotland.

WALL-EYE. A horse's eye, with a whitish or light-coloured iris. A wall-eyed horse is generally good.

WALLFLOWER,—botanically *Cheiranthus*. A genus of ornamental, fragrant, evergreen plants, of the cruciferous order. One species grows wild in Britain; about a dozen species, besides many varieties, have been introduced from other countries, principally Southern Europe and Northern Africa; and six or seven other species are known. One of the species in Britain, *C. ochroleucus*, is a hardy, evergreen herb; and all the other species are greenhouse or frame or slightly tender evergreen undershrubs, varying in height from 6 to 40 inches; and about one half have scarcely any styles and immarginate seeds, while the rest have filiform styles, marginate seeds, and four-sided silicles.

The indigenous or small shrubby wallflower, *Cheiranthus fruticulosus*, inhabits old walls in various parts of Britain, and is also admitted to a place in flower-gardens. Its stem is erect, shrubby, determinately branched, and from 6 to 20 inches high; its branches are angular, leafy, and beset with close, bristly, silvery hairs; its leaves are stalked, crowded, lanceolate, acute, and of a deep green colour; and its flowers are corymbose, fragrant, and of a bright yellow colour, and bloom from April till July. This plant, being a native, might be thought quite hardy; but, when cultivated in cold situations, it sometimes requires a little winter protection. In its wild state on walls, it has very tough roots and firm stalks, and is seldom more than 6 or 8 inches high; and, in spite of being much exposed to winds and frosts, is far hardier than when grown any where in the garden.

The garden wallflower, *Cheiranthus cheiri*, is sometimes regarded as a variety of the indigenous species, but it really comprises at least a dozen pretty distinct varieties of its own, most of which were introduced from the South of Europe, so long ago as the year 1573,—and it always comes true and distinct from its own seeds, and cannot be obtained from those of the indigenous species. It has always a natural height of between 15 and 36 inches,—generally about 2 feet; it normally possesses in its flowers an orange or golden colour, yet commonly displays markings or stains or pervading tints of some dark colour between orange and blood, but, in this respect, has great diversity of character, and sometimes displays more yellow, and at other times more blood or bloody brown; and it sports into many subvarieties from seeds, and has produced a great number of most elegant and gorgeous double kinds, and can be fixed and perpetuated in any of its fine forms by the simple expedient of annual or biennial cuttings. Eleven of the oldest varieties of it, all kept up and propagated by means of cuttings, are the yellow double-flowered, *C. C. flore pleno*, with luscious spikes of double flowers, displaying a habit of inflorescence similar to that of the finest double stocks; the large-flowered, *C. C. grandiflorus*, with large-petalled yellow flowers; the largest, *C. C. maximus*, also with large-petalled yellow flowers; the saw-flowered, *C. C. serratus*, with serrated-petalled yellow flowers; the spreading, *C. C. patulus*, with double spreading yellow flowers; the rusty, *C. C. ferrugineus*, with brown or rust-coloured flowers; the flavescent, *C. C. flavescens*, with yellowish flowers; the various, *C. C. varius*, with variegated flowers; the thyrse-flowered, *C. C. thyrsoides*, with blood-coloured variegated flowers; the bloody, *C. C. sanguineus*, with dark or bloody brown flowers; and the double bloody-flowered, *C. C. hæmanthus*, with double blood-coloured flowers.

Some confusion of ideas prevails among cottage florists on the subject of the cultivation of the garden wallflower, occasioned by inadvertence to the distinction between it and other species, and between its own normal habit and the habit of its mere varieties. The wallflowers commonly called German, and somewhat recently come into notice, are readily produced from imported seed, and often develop themselves out of seedling state in extraordinary habit of growth and in semidouble fulness and singular colouring of flowers. They are well worth cultivating, and only require sowing in the open ground, planting out, when large enough, where they are to grow, and saving the seed for another year. Some are

very nearly double, yet differ widely from the ordinary double wallflowers, for they have the organs of reproduction and seed freely. As to common single garden wallflowers, the seed should be sown in June or July; and when they are up, they should be watered as often as required; and as soon as they are two or three inches high, they should be planted out in nursery beds, or where they are to remain for bloom. They will flower very early in the spring, and want nothing in the way of attention all through their culture, but keeping clear from weeds. The double wallflowers, whether the dark blood, the golden, or the pale yellow, are of a habit highly favourable for propagation. When the bloom is over, they require watering quite as much as when coming into flower; and it is a very good plan, when the flower is declining, to plant them out in the open ground, give them plenty of water, and pick off all the remaining flowers, as well as any that may be coming from side shoots. Soon after they have been so planted out, they will throw out shoots all over the stems. These are to be taken or stripped off as soon as they are large enough, and planted all over the space that can be covered with a hand-glass, not more than an inch apart. The soil must be rich and light, but not fresh manured; and when they are planted and well-watered, the glass must be pressed down close to exclude the air. Where this is done on a smaller scale, pots may be filled with the proper soil, loam, peat, and leaf mould, and the few cuttings placed away from the edges, so that a goblet or small bell-glass may be pressed down within the rim. In either case the cuttings will require occasional watering and shading until they have struck, when they may be potted, one in a forty-eight sized pot, and placed still in the shade, on a dry surface of ashes, or gravel, or slate, or paving of some kind, until the end of September, when they may be put into their winter quarters, which should be a common garden frame and light. But they should be covered only during the night and in hard weather; for it is impossible to give them too much air. Here they may be kept until they flower, after which, if they are to be grown another season, they must be shifted to pots of thirty-two to the cast, as soon as the bloom decays, and then all their shoots must be allowed to grow, instead of being taken off for cuttings. Plants of the second year, however, though they grow larger, bloom smaller flowers; and therefore wallflowers, like pinks and pansies and many other subjects, are annually raised from cuttings.

The other principal introduced species of wallflower are the pale-yellow, *C. ochroleucus*, about 9 inches high, carrying pale yellow flowers from April till July, thriving well in any common soil, propagable by radical division, and introduced from Switzerland in 1820; the tree, *C. arboreus*, about 3 or 3½ feet high, carrying yellow flowers from April till July, loving a soil of sandy peat, and introduced from Egypt in 1827; the firm, *C. firmus*, about a foot high, carrying yellow flowers from May till July, loving a soil of sandy peat, and introduced from Continental Europe in 1816; the alpine, *C. alpinus*, about 6 inches high, carrying yellow flowers from May till July, loving a soil of sandy peat, and introduced from Northern Europe in 1810; the fine-leaved, *C. tenuifolius*, about 2 feet high, carrying yellow flowers in May and June, loving a soil of loamy peat, and introduced from Madeira in 1777; the flax-leaved, *C. linifolius*, about 2 feet high, carrying purple flowers from March till August, loving a soil of sandy loam, and introduced from Spain in 1815; the ever-blooming, *C. semperflorens*, about 2 feet high, carrying white flowers throughout the greater part of the year, loving a soil of sandy loam, and introduced from Barbary in 1815; the changeable, *C. mutabilis*, about 3 feet high, carrying yellow and purple flowers from March till May, loving a soil of loamy peat, and introduced from Madeira in 1777; the long-leaved, *C. longifolius*, about 3 feet high, carrying white and purple flowers from September till December, thriving in any common soil, and introduced from Madeira in 1815; and the broom, *C. scoparius*, about 3 feet high, carrying white and purple flowers from May till October, but comprising also two varieties with respectively rust-coloured flowers and yellow and purple flowers, loving a soil of rich mould, and introduced from Teneriffe in 1812. Most of these require nearly the same treatment as the common garden wallflowers; only those from sub-tropical countries are comparatively tender, and need the protection of the greenhouse.

WALLNUT. See WALNUT.

WALL-PELLITORY. See PELLITORY.

WALL-PEPPER. See STONECROP.

WALLROTHIA. A small genus of hardy, exotic, tuberous-rooted, white-flowered plants, of the umbelliferous order. Two species, the tuberous about an inch or two high, and the shining about a foot high, have been introduced to Britain from respectively Hungary and the Pyrenees; and both bloom from May till July, and thrive in any common soil.

WALL RUE, — botanically *Asplenium ruta-muraria*. A curious indigenous fern, of the spleenwort genus. It grows on rocky places on the shore, and has bipinnate fronds and a height of about 4 inches, and carries a brown-coloured frutescence from June till October.

WALNUT,—botanically *Juglans*. A genus of monochlamydeous, hardy, deciduous, ornamental, fruiting timber-trees, constituting with the genus Carya the natural order Juglandeæ or Juglandaceæ. All the plants of this order are large trees, with pinnate leaves, small insignificant flowers, and esculent-kernelled nuts; and most are natives of North America. They belong to the Linnæan class *Monœcia* and order *Polyandria;* and the male flowers grow in oblong catkins,—

the female ones in sessile clusters. The botanical distinction between the true walnuts and the caryas is rather slender. See the article CARYA. Five species of true walnuts have been introduced to Britain,—one from Persia and four from North America; and all thrive well in any common soil, and are propagated from seeds.

The common or royal walnut, *Juglans regia*, is a native of Persia, and was introduced to Britain in 1562. It commonly attains a height of about 40 or 50 feet, and is capable of becoming a very large, lofty, and massive tree. Its head is globular and inelegant; its boughs are strong and spreading; its leaves comprise each from two to four pairs of leaflets, and a terminating odd one, and, when pressed between the fingers, emit a strong odour somewhat similar to that of apples; its leaflets are nearly equal in size, except that the odd one is the largest, and are entire, smooth, and shining; its foliage is thin, and of comparatively short continuance; its winter appearance is stiff, bald, and uncouth; its flowers are apetalous, and bloom in April and May; and its fruit is a smooth, coriaceous, oblong drupe, enclosing an irregularly grooved nut, with a yellow skin, an irregular knobbed surface, and a four-lobed, oily, eatable kernel. The principal varieties in cultivation are the largest-fruited, *J. r. maxima*,—the thin-shelled, *J. r. tenera*,—the late-vegetating, *J. r. serotina*,—and the cut-leaved, *J. r. laciniata;* and all these are similar in height, in time of flowering, and in general appearance to the normal plant.

The ornamental character of the common walnut is greatly marred by the lateness of the exfoliation, the thinness of the leaves, the baldness of the unleafed boughs, and the tameness of the outline of the head; yet it forms a pleasing diversity upon a pleasure-ground, and owes much to the distinctiveness of its foliage.—The timber is less beautiful for the finer kinds of cabinet work than mahogany, and more expensive, more difficult to be worked, and less clean in texture for the coarser kinds than beech; yet it takes a fine polish, and ranks next to mahogany for many purposes, and is in good esteem among cabinet-makers, turners, and gunsmiths.—The fruit is in much request, both in its green state for pickling, and in its ripe state for the esculency of its kernel.—The oil yielded by the fruit, and the marc left after pressing it out, are valuable. One bushel of nuts yields about 15 pounds of peeled kernels; and these will yield more or less oil, according as they are more or less dry,—but on the average, they yield about one half their own weight,—though the drier they are, and the less they yield, the better is the oil. The marc is excellent food for fattening hogs, and, like rape-cake or linseed-cake, it forms a powerful manure.—A good dye, of a dark yellow brown colour, is obtained by boiling the green husks without any mixture. The kernel, when rubbed on any crack or chink of a leaking vessel, stops it better than either clay, pitch, or wax. A decoction of the leaves, if sprinkled on gardens, kills earthworms, and if sprinkled on gooseberry bushes soon after they have put forth their leaves, defends them from the caterpillar.

The walnut will thrive as a timber tree or ornamental tree on any light dry soil; but will make little progress in a cold barren situation, and attains its greatest height on rich dry loam or on rich dry intermixture of vegetable mould and trap-rock debris; and it succeeds best as a fruit tree on dry calcareous soils, such as those of the chalk hills of Kent, or on light sandy loam superincumbent on either chalk or gravel. The best manure for the walnut is wood or turf ashes, spread in the beginning of winter, after the land has been well ploughed or trenched. Plants intended for timber-trees or park-trees should be raised from the seed, and removed direct to their final station. The walnut is very impatient of transplanting, and was long, though mistakingly, regarded by almost all cultivators as incapable of grafting. All the young plants of it require to be removed from the seed-bed with the utmost caution; and the knife should not touch the head of any, and should be applied but very sparingly to the roots. Trees designed to bear fruit, or otherwise planted in masses, must stand at distances from one another of at least 40 feet; and, on good soil, in an advantageous situation, may profitably stand at considerably greater distances. Plantations may be raised for the double purpose of yielding an annual crop of fruit throughout a series of years, and of then being felled for their timber. The trees want no pruning or particular care, and attain a large size in less time than the oak, and continue to bear well throughout a period of 20 years. Many subvarieties, as well as the well-defined and somewhat truer varieties, are in cultivation; but all more or less sport, or run into other subvarieties when raised from seed, and they therefore require to be propagated by budding or grafting; and, in consequence of their shyness, they need to be managed with much skill and care.

"The walnut-tree," says Mr. Knight, "appears hitherto to have effectually baffled, under all ordinary circumstances, the art of the grafter. The inserted scions wither and die, without apparently making any effort to unite themselves to the stock, or to draw nutriment from it; and consequently, the value of every superior variety has been limited by its use to the possessor of the original seedling-tree. It is true that a part of the seedling offspring of every fine variety generally inherits a portion of its good qualities; but I have found it extremely difficult to obtain from seed good varieties of sufficiently early habits to ripen well, except in very warm seasons; and I doubt much whether the value of the crop of walnuts, throughout the British Islands, be one-third so great as it would be if proper varieties were everywhere planted. The

walnut-tree may be propagated with more success by budding. I have succeeded tolerably well in some seasons, and in one season perfectly well; but in several others not a single inserted bud has been found alive in the following year, though all had been inserted with the greatest care. I therefore communicate the following mode of grafting the walnut-tree, which I found most perfectly successful under many unfavourable circumstances; and which mode, for reasons which I shall proceed to state, will, I believe, point out the means of propagating some other species of trees with facility, which have not hitherto been so propagated without difficulty and uncertainty. The fluid which the seeds of the walnut-tree contain, when that is fully prepared to germinate in the spring, and which was deposited within it for the purpose of affording nutriment to the seminal buds, or plumule, in the preceding autumn, is sweet, as in a great many other kinds of seed; but during germination this becomes, in the seed of the walnut-tree, bitter and acrid. Similar changes take place in the sap which is deposited, for analogous purposes, in the bark and wood of the walnut-tree, during the germination of its buds; and I was led by the discoveries of M. Dutrochet to infer the probability, that the sap during, and subsequent to, its chemical changes, might acquire new and more extensive vital powers, I therefore resolved to suffer the buds of my grafts, and those of the stocks, to which I proposed to apply them, to unfold, and to grow during a week or ten days; then to destroy all the young shoots and foliage, and to graft at a subsequent period. A severe frost saved me the trouble of destroying the young shoots, but it deranged my experiment by killing much of the slender annual wood, which I proposed to use for grafts; so that I found some difficulty in discovering proper grafts. The swelling of the small, and previously almost invisible, buds, within a few days enabled me to distinguish the living wood from that which had been killed by the frost, and the stocks were grafted upon the 18th day of May. My grafter had more than once been previously employed by me to graft walnut-trees in various ways, and never having in any degree succeeded, he did not seem at all pleased with the task assigned him, and very confidently foretold that every graft would die; and I subsequently found that he had insured to some extent the truth of his prophecy, by having applied grafts which were actually dead. The whole number employed was 28, and out of these 22 grew well; generally very vigorously, many producing shoots of nearly a yard long, and of very great strength; and the length of the longest shoot exceeding a yard and five inches. The grafts were attached to the young (annual) wood of stocks, which were between five and eight feet high; and in all cases they were placed to stand astride the stocks, one division being in some instances introduced between the bark and the wood, and both divisions being, in others, fitted to the wood or bark in the ordinary way. Both modes of operating were equally successful. In each of these methods of grafting, it is advantageous to pare away almost all the wood of both the divisions of the grafts; and therefore the wide dimensions of the medulla in the young shoots of the walnut-tree do not present any inconvenience to the grafter."

Green walnut fruit suitable for pickling should be gathered by hand from the tree when they are about one-half or three-fourths grown, before the outer coat and internal shell become hard; and only such as are freest from specks should be chosen. The common time of gathering them is the latter part of July and the former part of August.—Ripe fruit suitable for the esculency of the kernel should remain on the trees till the husk of some open at the valves and let out the nut, or at least till that of most or all becomes easily separable from the nut; and this commonly happens in the latter part or toward the end of September. But in Scotland, in the north of England, and even in backward situations much farther south, they seldom ripen at all; so that the planting of trees for the sake of producing them in these districts would be an absurdity. The ripe fruit, in consequence of its growing principally at the extremity of the branches, cannot easily or economically be gathered by hand; and it is commonly beaten off with long poles or rods ;—and this process breaks many of the points of the shoots, and causes the production of many cursons which afterwards bear flowers and fruits, and is therefore regarded as favourable to the prolificity of the trees, and is sometimes even practised upon a barren tree for the purpose of making it bear, but ought never to be done with any considerable violence, or with more than a gently beating action. As soon as the fruit are beaten down or otherwise gathered, they should be laid in heaps a few days to heat and sweat, so that their husks may readily separate from the shells; and after being cleared of the husks, they should be well dried a day or two beneath a well ventilated shed or in the open air and in sunshine; and then they should be stored away either on shelves in an airy room, or in a perfectly dry place beneath a twelve-inch layer of dry straw, or in jars or boxes among dry white sand; and if stored in the last of these ways, their shell will improve in colour, and their kernel be kept comparatively long and moist.

The black or Virginian walnut, *Juglans nigra*, is a native of Virginia, Carolina, Maryland, and Ohio, and was introduced to Britain in 1629. It grows to be a large tree, yet commonly attains in this country only about two-thirds the height of the common walnut. The young shoots are smooth and of a greenish brown colour; their leaves come out irregularly, and are large and fine-

ly pinnated, and comprise each from 8 to 14 pairs of leaflets and a terminating odd one; the leaflets are lanceolate, acute, and serrated, and the bottom pairs are always the smallest; the flowers are inconspicuous, and draw the attention only of botanists and the curious, and bloom in April and May; and the nuts have different shapes and sizes, but in general have a thicker shell and a rounder form than those of the common walnut, and are furrowed. Many varieties and subvarieties of the black walnut arise from seed, and may be perpetuated by grafting; and they differ from one another principally in the properties of the leaves and in the form of the fruit; and some of the more common or permanent popularly bear names descriptive of their peculiarities, such as the aromatic walnut, and the deeply furrowed fruited walnut. Specimens of the black walnut in a wild state, have been observed on the banks and islands of the Ohio river from 60 to 70 feet high and 6 or 7 feet in girth of stem. The timber of this species is much more valuable than that of the common walnut, but the fruit is inferior either for oil or for eating.

The grey or Pennsylvanian walnut, *Juglans cinerea*, is noticed in the article Butter-Nut (Grey).—The ash-leaved walnut, *Juglans fraxinifolia*, and the winged-fruited walnut, *Juglans pterocarpa*, are natives of North America, and have been introduced to Britain, and commonly attain a height intermediate between that of the common walnut and the black walnut.—Other species which popularly bear the name of walnut now belong to the genus carya.

WALNUT-TREE (Jamaica.) See Ajuapar.

WALTHERIA. A genus of tropical plants, of the byttneria family. One yellow-flowered biennial of about 2 feet in height, and four yellow-flowered shrubs, varying in height from 2 to 10 feet, have been introduced to the botanical collections of Britain; and 7 or 8 other species are known.

WAMPEE-TREE, — botanically *Cookia*. A small genus of exotic evergreen ligneous plants, of the orange-tree tribe. The dotted species, *Cookia punctata*, was introduced to Britain from China, toward the close of last century; it is a small tree of about 15 or 18 feet in height, carrying white flowers, and producing esculent fruit; and it loves a soil of light loam, and requires stove heat, and is propagable from cuttings.

WANGENHEIMIA. A curious, exotic, small, hardy, annual weedy grass of the wheat tribe. It is a native of Spain, and was introduced to Britain in 1776; it has a height of about 6 inches, and blooms in July and August, and will thrive in any common soil; and it constitutes a genus of itself, and bears the specific name of Lima.

WANG-TOOTH. A jaw tooth.

WANT. A mole.

WANTY. A broad leathern belt, used for binding a load upon a horse.

WARBLER. A large family of passerinous birds, distinguished by the straightness, slenderness, and bodkin-like form of the bill. It comprises the nightingale, the blackcap, the stonechat, the wheat-ear, the mill-clappers, the whitethroat, the fauvettes, the wrens, the wagtails, the meadow-larks, and a number of others; and many of the most common or most interesting are noticed in their respective alphabetical places in our work.

WARBLES. See Bots.

WARP. The ooze or slimy alluvial substance which constitutes the deposit left on land by the process of warping. See the article Warping of Land.

WARPING. Abortion in the cow. See the article Abortion.

WARPING OF LAND. The forming or renewing of soil by means of a sedimentary deposit from silty tidal waters. It differs from irrigation in employing marine water instead of river water, in forming a new soil instead of fertilizing an old soil, and in obtaining a deep solid deposit instead of procuring a mere filmy crust or soluble impregnation. It more nearly resembles the Italian operation called colmata than any other georgical process; but differs in employing salt water instead of fresh, and in obtaining a shallower deposit, and in a shorter time. See the article Colmata. It somewhat resembles also the enrichment of such valleys as those of the Nile and the Mississippi, which derive vast fertilization from silty fluviatile deposits, but differs from them in some of the same respects as from irrigation and colmata, and also in its being artificial, and wholly dependent for extent, frequency, and depth on the arts of the georgist. It can occur only on lands which lie lower than the level of high-water, and in the immediate vicinity of estuaries or tidal rivers whose waters are strongly charged with fine silt of composition suitable to constitute soil; and hitherto it has not been practised to any considerable extent in any part of Britain except the low districts of Lincolnshire and Yorkshire, around the tidal region of the Trent, the Ouse, the Dunn, and the other streams which form or feed the Humber.

The main portions of the warpable tracts in these districts naturally lie so low that they would be flooded by the tide of high-water but for being protected by strong embankments along the sides of the rivers. These embankments are of vast strength and size, and must have been a work of prodigious labour; yet when they were made, or by whom, no man knows. Considerable improvements were made during the reign of Charles I. by a company of Dutchmen, and a few Frenchmen, calling themselves Participants, who contracted with the Crown to drain a tract of about 75,000 acres south of Thorne, one-third of which was to become their own property, one-third to be appropriated by the Crown, and one-third distributed among the commoners of the

district; and among their numerous works, they widened the river Dunn, and turned its course into a new and artificial channel which enters the Ouse at Goole, and is now called the Dutch river. Some tracts also, which naturally lay higher than the level of high-water, have become available for warping by means of subsidence consequent on draining. Of this kind is a peat-moss of about 10,000 acres, called Thorne Waste, situated about two miles from the banks of the Ouse, with a bottom of sand, a basal stratum of prostrate forest, a general body of very spongy peat, and a maximum depth near the centre of about 18 feet. In bygone days, when the rivers were not contained within their present banks, they must have had a natural flow up to the margin of this peat-moss, which at that period must have been above the level of the tide at high water; but years and ages passing by, and drains having been cut through the cultivable land, a considerable tract of this peat-moss became in a certain way drained, and of a much lower level than it originally was, and consequently proved capable of being covered by the tide-water from the river Ouse.

The practice of warping was first tried about the year 1743, by Mr. Richard Jennings of Armin near Howden; and was not tried by any other person till about ten years after; and remained in obscurity till enquiries, consequent upon the institution of the Board of Agriculture, in the winter of 1793. It was long done on a very limited scale, the sluices or cloughs then used being merely what now would be called shuttles; and the deposit at first was very small, from want of power consequent on the smallness of the works. Gradually, however, the benefit became more generally known, and the works were made larger. In 1821, Ralph Creyke, Esq. entered into an agreement with certain proprietors of land in the townships of Goole, Swinefleet, and Reedness, for the purpose of warping their land; an act of parliament was obtained; and he commenced excavating a large main drain to convey the tide-water from the river Ouse, through the old cultivated land to the barren and uncultivated morass about to be improved. The sluice or clough was built of stone, with two openings of 16 feet each in width, and 19 feet in height from the sole to the crown of the arch, with four substantial doors, made when shut to oppose the entrance of the tide, yet with power at will to keep them open for the admission of the tide during the time of warping, by means of strong staples and iron rods fixed in the stonework. The main drain was very large, it having been proved by continued observation and calculation, that the area of a warping-drain ought to be three times that of the sluice, to prevent as much as possible any considerable resistance to the flow of the water; its dimensions were 30 feet wide at the bottom, 90 feet wide at the surface of the land, and 11½ deep; the banks were placed 9 feet from the edge of the main drain, the base of each bank was 60 feet wide, and they were 10 feet high; this main drain extended originally for near 3 miles, and cost, with the purchase of land and erection of sluice, about £18,000. This main drain and its extension have for some time been used as a canal for vessels of about 75 or 80 tons burthen, and are found very convenient for the purpose of conveying one of the chief productions of the warp-land, namely, potatoes, to the London market, where they command a high price under the name of Yo k-shire Reds.

In commencing the warping of any plot of land, it is first enclosed with banks, the size of which varies according to the extent and the level of the land. The general batten or slope of the banks is from 15 to 18 inches on each side for every 12 inches' perpendicular rise; and they are left from 2 to 3 feet wide at the top; and particular care must be taken in erecting them to procure the proper levels. The main drain being cut up to the newly-embanked compartment, the tide is suffered to flow in. At first it is very advisable only to take rather small tides in, beginning to admit the water before they are at their height, and allowing them to increase by small degrees; for the banks being generally made of very porous materials—that is, peat-moss and bad sand—they are subject to leak very much, and in some instances considerable damage has been done by a breakage of the bank. In case of a bank being rather exposed to the action of the wind, which is one of the greatest enemies that a warper can have to contend with, it is generally what is called 'puddled;' that is, a trench from 2 to 3 feet wide is cut longitudinally through the centre of the bank into the foundation, the material is chopped up and mixed with water, which being pressed down and beat by repeated treading, becomes a solid mass. The water is allowed to flow over the land during the spring-tides. The reason why the spring-tides only are generally made use of is, that the neap-tides are much smaller in body of water, and although they might in certain instances be of sufficient height to flow the land, yet as one of the greatest difficulties in warping is to keep the main drains in order by preventing the warp from being deposited in them, and as that is chiefly done by the return of the water from the compartment under the process, which in spring-tides being a larger body of water, scours out the drains, in neap-tides there would not be sufficient flow, and they would be warped up.

The water conducted by the main drain into the embanked allotment is more or less divided into smaller ones, called 'inlets' (which vary much in size), and conducted to different parts of the compartment; for wherever the current, leaving a drain, expands itself, there the greatest quantity of warp is deposited. As soon then as the plots of land next the mouth of the inlets

have a sufficient quantity of warp deposited, the inlets are extended by what are called 'call banks,' which, though much smaller than the others, still conduct the current onward to parts not acted upon by the currents before, and so on according as required. One of the greatest niceties in warping is to have the land finished as level as possible, which can only be done by the strictest attention, and by proper judgment in conducting the different currents, which must not be suffered to cross one another, or to meet, as in such a case the deposit of the warp is less, not so regular, and of an inferior quality. Care must also be taken that the currents should not be too strong, for in warp there is a considerable portion of sand which, being the most heavy of all the particles floating in the water, sinks first, the lighter particles being carried on by the violence of the current, consequently a sand-bed is formed. These sand-beds, however, if covered afterwards with warp, generally are found to crop better than warp which may be too strong. With respect to the depth of warp deposited, it depends much upon the level of the land to be warped; for, should the land be very irregular, in some places there would be a great deposit, and in others only comparatively a small one. It is generally advantageous to have the land to be warped as level as possible. A deposit may then be obtained of from 1 to 3 feet, and in some favourable instances it has been considerably more, but it cannot be generally calculated on.

The time it takes to warp a compartment cannot be very accurately defined, there being many circumstances to take into consideration. Some of the compartments are much farther from the mouth of the drain than others; in addition to which, should the lands to be warped be very low, they can only take in perhaps every second tide, and even sometimes only every fourth, on account of the difficulty of getting the water back again, for the tide continues to flow into the compartment until perhaps nearly low water in the river. The tide then returning, as it does very rapidly, prevents the water from flowing out of the drain, and would fill the compartment too full of water. The doors are consequently closed against the tide. They open themselves, however, when the water in the river is of a lower level than that in the drain. When the compartment is near the river, that does not occur, as the water has time to get off before the tide returns. The seasons also vary very much; but with a large main drain, and in a fair average season, from 350 to 450 acres might be warped in two years, or two years and a half. The immense size of the main drain which has been mentioned, and its consequent great power, facilitate very much the warping of land of a higher level than that which could be warped by a small drain; for the current being forced on by the great flow in the drain, can be made to flow over the high ground by turning a drain towards it, provided that there be sufficient land of a lower level on the other side to draw onward the water so forced over the hill. The warp so deposited is at first of an inferior quality, the current being so strong; but in a short time the peat-moss becomes pressed down by the weight of the deposit. The current is then easier, and the deposit becomes better.

It may be asked, whence comes this inexhaustible supply of mud or warp? An immense quantity of it floats about the Humber and its tributaries; and opinions widely differ as to whence it comes. Considerable ravages have been made by the sea on the coast of Holderness, extending all the way from Bridlington Quay to Spurn Point; but as the Humber is comparatively clear at the mouth, it is difficult to say whether it can come from that source. It does not come directly from land-floods, as these always deteriorate, for the time, the deposit, although considerable deposit being carried down into the Humber by land-floods, may return in the shape of warp. The greatest probability is that it arises from the action of the tide on the immense and almost hidden beds of soil which form the bottom of the Humber. It appears, however, that the warp is full of seeds of different sorts, more particularly the white clover, which it grows in great abundance, and quite naturally. The quantity of warp in the water differs considerably; there is more in the water during fine and dry weather; and the deposit is greater when there is no wind. It is highly advisable, if possible, to avoid finishing the warping of a compartment during the very fine and hot weather of June and July; for the tides are small at that period of the year, and are apt to be strongly impregnated with saline particles, which, being left in the warp, have a very injurious effect in retarding vegetation. The expense of warping cannot be laid down with any certainty, as the different compartments vary so much; when the land to be warped is very low, the banks require to be so much higher; and the internal works are very expensive, should the general surface of the land be irregular. There is a great difference between the flow and the ebb of the tide in the river Ouse and the neighbouring rivers, the flow only taking three hours, consequently running with great rapidity, and the ebb taking the remaining nine hours. The tides frequently flow as much as from 18 to 22 feet.

The general benefit to the country from warping cannot but be very apparent, it having created a steady demand for labour throughout the whole of the district where the improvements have been carried on. Between 3,000 and 4,000 acres of land have been brought into a state of cultivation; and where formerly was a morass may now be seen the finest crops of wheat, clover, and potatoes. The original rent was in many instances nothing — now a rent is received of from 35s. to 50s. per acre. The most general

course pursued in the cultivation of the newly-warped land is to grip it every 4 or 5 yards, throwing the soil taken out of the grips on to the land, amongst which, as soon as it is tolerably dry (the season, of course, permitting), oats, and red and white clover, and rye-grass, are sown. The oats are not expected to be a good crop: they are merely sown as a protection for the seeds, as what is chiefly wanted is to have a good coating of seeds. They are sometimes pastured, and would be better to remain so for two years; and they are then followed by wheat or potatoes.

These statements, however, apply principally to low marsh land within manageable distance of the great canal drain; and, indeed are abridged from a report in the Journal of the Royal Agricultural Society which has special reference to Thorne Waste. But warping, on the same principles, in a similar way, and with similar results, is equally practicable on all sorts of low lands within reach of the tidal waters of the Humber, whether peat, sand, or clay,—whether soft or hard, porous or retentive; and the soil which it forms varies both in fertility and in adaptation according to the circumstances of the locality, the composition of the warp, and the manner, season, and duration of the floodings. The best months for the operation, because the driest, are June, July, and August. Some warped land is very stiff, and some very pliable; and the two qualities sometimes occur in the same compartment, and in frequent alternation. The land nearest the drain is generally the lightest, in consequence of its receiving the first and heaviest depositions of silicious matter from the floodings; and the land farthest from the drain is generally the best. The produce of warped land is exceedingly varied, according to the original quality of the soil, the course of husbandry pursued, and the length of time since the warping; but, in a general view, it amounts to from 20 to 40 bushels of wheat per acre, from 5 to 8 quarters of oats, and from 35 to 70 bushels of beans. No warped land does well for grain or flax or potatoes till after it has been two years or so under grass seeds; but all the best or even middle-rate kinds of it, after two years of grass seeds, are capable of yielding a good crop of wheat,—and, though liable to be infested with the slug, may be freed from this foe by means of a surface strewing of salt after the wheat-seed has been sown. But warped lands of all kinds require manure, and will not carry many crops without its aid.

WARRANTY. A formal written declaration, on a stamp receipt, that a horse sold to a purchaser is, at the time of sale, perfectly sound, free from every kind of vice and blemish, of a specified age, and, if a saddle horse, quiet to ride, —if a draught horse, steady in harness, and not given to kicking, rearing, or jibbing. This declaration, accompanied with a written agreement to rescind the bargain if the warranty should prove incorrect, empowers the purchaser to return the horse and get back his money, on proving that any unsoundness, vice, or unquietness existed at or before the sale; and even the declaration itself, without the agreement, entitles him to raise an action for the price. No verbal warranty of any kind, no warranty which may be presumed or argued from highness of price or circumstances of sale, and no correct written warranty on unstamped paper have any legal force. The paper employed should be a stamp receipt for the price of the horse; and the form of expression should be "Received of —— —— the sum of —— —— for a —— —— warranted," &c.

WARRATAH. See Camellia.

WARREN. A piece of ground privileged either by prescription or by royal grant for keeping in a wild state large numbers of game, quadrupeds, game birds, or similar animals, particularly rabbits, hares, partridges, and pheasants. But the word, in modern times, is used almost exclusively in reference to a burrowing ground for rabbits. See the article Rabbit.

WART. A small spongy tumour on any part of the body of an animal. It commences on the cuticle, and afterwards becomes seated on the true skin. Warts are not uncommon on the muzzle, the eye-lids, the ears, the neck, the belly, the penis, and the prepuce of horses; and they frequently cause much annoyance, and require to be removed. A small-necked one may be nipped off with a pair of scissors, and afterwards touched with lunar caustic; a larger-necked one may be tied firmly, and more and more tightly, with a ligature of waxed silk till it die and fall off from want of nourishment from the blood; and a broad-based one may either be slowly reduced by frequent applications of caustic, or removed at once with the knife, and seared with a red-hot iron.

WART-CRESS,—botanically *Senebiera*. A genus of herbaceous plants of the cruciferous order. Two species grow wild in Britain; one white-flowered annual species, the Nilotic, has been introduced from Egypt; and five other species are known.

The common or buckhorn species, or swine's cress, *Senebiera coronopus*, called by some botanists *Coronopus Ruellii*, abounds on waste grounds and roadsides in many parts of Britain. Its root is annual and tapering; its stems are short, spreading, branched, leafy, and smooth, and lie quite flat on the ground; its leaves are deeply pinnatifid and somewhat glaucous; its flowers grow in dense corymbs, and come out opposite to the leaves, and are small and white, and bloom from June till August; and its silicles grow in dense clusters, and are much shorter than the leaves, kidney-shaped, notched, and furrowed. This plant is, in a certain sense, eatable, but has acid, fetid, and nauseous properties, and requires to be very abundantly boiled.

The lesser or pinnatifid species, *Senebiera pinnatifida*, called by Linnæus *Lepidium didymum*, and by Smith *Coronopus didyma*, grows on rubbly spots and waste grounds near the sea in the south of England. Its root is annual, small, and fibrous; its habit is similar to that of the common species; its stems are procumbent, branched, leafy, finely hairy, and a foot or more in length; its leaves are deeply pinnatifid, smooth, and flat; its flowers come out in clusters opposite the leaves, and are numerous, small, and white, and bloom in July and August; and its pouches are distinctly two-lobed and turgid.

WARTWORT. See EUPHORBIA.

WASHING OF SHEEP. The cleansing of sheep from coarse dirt upon their fleece, preparatorily to their being shorn. On some hill farms, this process is omitted; and on others, where the flocks are very large, it is performed simply by compelling the sheep to swim three or four times across a stream; but on select hill farms, and on most large farms of the mixed husbandry, it is commonly done in some such manner as the following:—The washing pool may be made in any part of a rivulet which is deep enough to take a man at least mid thigh. The bed of the rivulet must be pebbly, and not muddy; and this character it will possess if a gentle current passes through the pool. If no suitable rivulet be near, a pool must be made by damming. The sheep must be brought to one of the banks of the pool, so that, when they are removed from the water, they may have grassy ground to stand upon, in order that they may keep themselves clean. At least three and at most five men will be necessary to stand in the water, so arranged that the first who operates shall be lowest down the stream, and the last shall be the shepherd or chiefly responsible person himself; and there should be plenty of hands to keep the sheep near the edge of the water, as the ewes have a strong desire to wander away in search of their lambs, and require to be restrained; and a piece of the ground also may be netted or hurdled in, to keep all from wandering. Every thing being thus prepared, the first man at the water's edge gets a sheep brought towards him; and this he seizes and pulls into the water, and immediately turns over on its back, holding the arm of the foreleg with the left hand, and grasping a portion of the wool at the side of the head with his right. He swings the sheep in the water, turning it over on its one side, and then on its other; and at the same time he pulls it gently backwards and forwards, from and to him, at every successive turning. In this process the wool waves up and down in the direction of the length of the body, and swirls round the body first in one direction, and then in another. He then hands the sheep to the next washer, who repeats the same operation; and he to the next, till the shepherd gets it, who, after feeling the skin with his hand, and judging by the clear state of the water, of the cleanly state of the animal, dips it over the head, and turns it gently over on its feet, and assists it up the grassy bank. The sheep stands for a while dripping and wobegone; but at length, twirling its wool like a mop, and making the spray fly from it in a shower, it forgets the rough handling it has passed through, and crops the green herbage in contentment. By this operation, the body being in an inverted position, the skin and wool of the sheep are cleaned, as if they had been washed with soap and water; and, in fact, they have been so washed, for the oil or yolk of wool presents similar chemical components to soap. The surface of the water may be seen covered with greasy matter and filth, which are carried away gradually by the current. The washed sheep are put, till they are shorn, into a clean grass field, where they cannot dirty their wool under banks of earth.

A wash-dike, in many instances, is formed for the use of a whole district, and let out for a small sum per score; and either in this case, or upon a large farm, it may possess higher facilities than in the simple plan which we have noticed,—and, in particular, there may be a floodgate in the middle of the dam to regulate the accumulation and flow of water, a pen for the sheep before the washing, a fenced path to direct and confine their ascent up the bank after the washing, a channel and parapet for the process of washing, and suitable accommodation for the work-people and their clothes and implements. —The process each day ought to terminate before three o'clock in the afternoon, so that all the sheep may have time to become somewhat dry and warm before the cool of the evening. Water containing any calcareous impregnation is unsuitable on account of rendering the wool rough and brittle; and water of any kind popularly called hard will not clean so well as any kind of pure soft water.—Some good judges think that the whole process would be much more efficiently and economically done by first immersing the sheep in a tub of blood-warm water till their fleece should become softened, and then rapidly and sousingly washing them in a pool; and Bakewell, who was one of these, maintains, "that the keeping of the animal a sufficiently long time in the water endangers its health,—that fleeces of a close pile cannot be cleansed by the usual mode of washing,—and that the extra labour required to wash sheep in tubs with warm water would be amply repaid, were the first and second washings carried out and applied as manure, the quantity of rich animal soap which it contains making it one of the most fertilizing applications which can possibly be used."

WASP,—scientifically *Vespa*. A genus of insects of the diplopterous family of hymenoptera. The antennæ have thirteen distinct joints, and have an elongated, pointed termination; the mandibles are strong and dentated, hardly longer

than wide, and broadly and obliquely truncated at the extremity; the clypeus is large and nearly square,—and the middle of its anterior margin is widely truncated, and has a tooth on each side; the ligula is short or but slightly elongated; and the abdomen is ovoidal or conical. The individuals of each species live in large societies or communities, composed of males, females, and neuters; and all the females and neuters are armed with an extremely powerful and venomous sting. The nest or domicile of a community consists of a variable number of combs or amassments of cells; it is constructed by the females and the neuters with a pultaceous substance, similar to paper or pasteboard, formed out of particles of old wood or bark, detached with the mandibles, and afterwards moistened and reduced; it usually comprises horizontal ranges of combs, suspended by one or more pedicles, and has on its inferior side a range of vertical cells in the form of hexagonal and truncated pyramids; and in some cases it is exposed, but in others is surrounded by an envelope, which has a common and generally a central opening, and to the parietes of which the combs adhere, whether they be in the open air, or hid in the earth, or concealed in the hollows of trees. A few females alone are alive at the beginning of each season, and they found the communities by laying eggs, which produce neuters; and these, when matured, assist in enlarging the nest and taking care of the succeeding young ones. The larvæ are vermiform, and destitute of feet, and, as well as the pupæ, inhabit each a separate cell; and all which cannot complete their metamorphoses before the month of November are put to death and dragged from their cells by the neuters. The males and the young females make their appearance in the beginning of autumn; and all the males, all the neuters, and some of the females perish on the approach of winter, leaving only a few females to survive till spring and found new communities. The males never work. The larvæ lie with their head downward; and, when about to pass into the pupa state, they shut themselves up and spin a cocoon. The females and neuters feed principally on fruit, and nourish the larvæ with its juices.

Six species of wasp, if not more, occur in Britain; but the principal are the hornet, the common wasp, and the small wasp.—The first is noticed in the article Hornet.—The common wasp, *Vespa vulgaris*, is about eight lines long, of a predominantly black colour, with a yellow patch and black point in the middle on the front of the head, several yellow spots on the thorax, four yellow spots on the scutellum, and a yellow band with three black spots on the posterior margin of the rings of the abdomen. The males are smaller in size and sting less than the females; and the number of each in a community is nearly equal, and commonly amounts to between 200 and 300; but the number of cells in a vespiary often amounts to more than 10,000, and each cell serves for three ovule deposits or three successive larvæ in a year, so that the total number of wasps produced in one community in a single season may amount to 30,000. The nests are built in the ground, and consist of a substance so very like paper that only a keen observer could discern the difference. — The small wasp, *Vespa coarctata*, resembles the common wasp in almost every thing except the size of the body and the form and habitat of the nest, —the latter having an oval outline, and being usually suspended from the branches of trees, and coated with a kind of varnish which renders it impervious to moisture.

"Few insects," says Mr. Duncan, "are more troublesome to horticulturists than the wasp; and all their care can scarcely prevent it from annually appropriating a share of the choicest produce of their labours. Proverbially pert, irritable, and intrusive, confident in its hard coat and formidable sting, this winged pest is ever on the watch for some sweet morsel, and almost every kind of fruit is attacked with eagerness. Pears, apricots, and plums seem, however, to afford its most favourite repast, the latter especially; for, according to a local English rhyme,

> "When the plum hangs on the tree,
> Then the wasp you're sure to see."

It is even alleged, that those seasons most favourable to the growth of plums, produce the greatest number of wasps, a coincidence which may well occur, for dry and warm weather is beneficial to both. The number of these insects varies greatly in different seasons, and occasionally from causes which we cannot appreciate. Thus, in the summer of 1836, so few appeared in England, that the circumstance was remarked even by those who are least observant of such things; in 1814, on the contrary, they abounded to a most extraordinary degree in every part of Britain. It is well known that the whole inhabitants of the vespiary perish in the winter, except a few females, who continue in a torpid state during the inclement season, and revive in the spring; on these devolves the whole duty of constructing a nest and founding a new republic; it may be supposed, therefore, that an unusually severe winter, or a cold and backward spring, would either entirely destroy a portion of these few solitary matrons, or so interfere with their operations for continuing the species, as to diminish the entire brood throughout the year. It is not, however, of their paucity we have in general to complain, but of the difficulty of getting rid of those that visit us. The existence of solitary females in spring, on whom the continuance of the race entirely depends, shows what effect would attend any measure taken against them then. In the north of Scotland, where we have seen wasps so abundant as to become a very serious evil, we have known instances of

boys being employed to catch them at that season, being paid at so much per head. As there is as much amusement as profit in such a bee-hunt, they generally proved very successful; and a similar step may be safely recommended to all that suffer from this cause. When infesting the fruit-trees in numbers during the autumn, one of the best and most common means of destroying them is that described by the author of the "Splendid Shilling," in a poem, which deserves to be known to horticulturists, written in praise of "Cider:"—

"Myriads of wasps now also clustering hang,
And drain a spurious honey from thy groves,
Their winter food,* though oft repulsed, again
They rally undismayed; but fraud with ease
Ensnares the noisome swarms; let every bough
Bear frequent vials, pregnant with the dregs
Of moyle or mum, or treacle's viscous juice;
They, by the alluring odour drawn, in haste
Fly to the dulcet cates, and crowding sip
Their palatable bane; joyful thou'lt see
The clammy surface all o'erstrewn with tribes
Of greedy insects that, with fruitless toil,
Flap filmy pennons oft, to extricate
Their feet, in liquid shackles bound, till death
Bereave them of their worthless souls. Such doom
Waits luxury, and lawless love of gain."

The most attractive composition of this kind is vinegar and water, mixed with a little honey, sugar, or treacle. A bee-hive recently emptied of its contents, and still smelling strongly of honey, if exposed in a suitable place will attract a great number of wasps, and if bottles filled with some similar liquid be placed in or near it, many may be thus destroyed. But a more effectual mode of destruction than any of these is to suffocate them in their nests. A writer in the Memoirs of the Caledonian Horticultural Society affirms, that he found it easy to discover the nests, by observing, in a quiet sunny day, the course of the flight of the wasps from the garden, following them as far as he could notice them flying, then waiting till others passed the same way, which he likewise followed, and so on till he reached their habitation. Having discovered the nest, various methods may be adopted to destroy the inmates; but this should never be attempted but in the evening, when the whole colony is within, and can easily be taken by surprise. The writer just referred to introduced a match of damped gunpowder, which burnt like a squib, into the entrance-hole, then put his foot on it for a few minutes, and afterwards dug till he found the combs, when he threw a pailful of water upon them, and trod the whole together like mortar. In this way he destroyed fifty nests within 300 yards of his garden, without receiving a single sting. Rags dipped in sulphur will be found to answer the purpose perhaps better than anything else. The entrance to the vespiary should be a little widened, and the lighted rags introduced; the hole should then be partly closed with small stones, but not so as wholly to exclude the air, which is necessary to keep up the combustion. In regard to the pendulous nests, it will be sufficient to apply the sulphur-rags or matches to the lower extremity, where the entrance-hole is usually placed.

"It is of very great importance that these marauders should be excluded from hothouses, as the delicate fruits there cultivated are speedily disfigured by their attacks; but this is no easy matter to accomplish, as the means taken to admit air, so indispensable to such places, usually give free access to the insects likewise. Grapes are sometimes enclosed in paper or gauze-bags, which is both a troublesome and clumsy expedient. There seems to be no great difficulty in covering such portions of the frame-work as require to be opened, with some kind of coarse gauze or wire-cloth, for insects do not readily pass through an obstacle of that kind, even when the meshes are pretty wide. Mr. John Dick recommends for this purpose a kind of cloth which he calls scrime. This individual has likewise invented a canvass screen for covering wall-trees, which appears to be exceedingly well adapted for the purpose, as it not only proves an effectual protection from wasps and such-like insects in the autumn, but also serves to protect the blossoms from frost in the spring. A description and figure of it will be found in the 4th Volume of the Memoirs of the Caledonian Horticultural Society, from which body he received a reward for the invention.

"Wasps are deservedly objects of peculiar dislike to the cultivators of the honey-bee. In the autumn, they sometimes hover about the entrance to the hive in considerable numbers, at times killing the bees (which they do very adroitly, suddenly pouncing upon them, tumbling them on the ground, and with their serrated jaws speedily separating the abdomen, which contains the honey-bag, from the hard and sapless thorax), and frequently entering the hive in spite of all opposition, and feeding on the honey. 'We have often observed one of these marauders,' says Dr. Dunbar, one of the most skilful apiarians of the present day, 'enter a hive with fearless intrepidity, and, watching its motion through the glazed frame, have been astonished by its feats of strength and agility. In ascending the combs, it is, of course, instantly attacked by the rightful inhabitants; if one only venture to assail it, the unfortunate bee has no chance of victory, and but little of escaping with life; if five or six cluster round it, as is generally the case, and cling close to its body, endeavouring to pierce it with their stings, their efforts are set at nought by the intrepid wasp, which struggles with unwearied obstinacy, rolls along the floor of the hive so closely enveloped in a mass of bees, that but little of its body is visible; and though at last it is forced by overwhelming numbers to

* Few require to be told that the poet is here in error, wasps never laying up a store of provision for the winter.

take to flight, it flies off apparently uninjured from the conflict. These partial attacks of single wasps, however, are of little moment, farther than that they are, perhaps, exploratory; it is when they come in a body that the safety of the hive is endangered; in such cases the utmost care of the bee-master is often unavailing. The wily insects soon discover the weakness of any particular hive in point of population, and, acting on this discovery, attack it in such numbers, that nothing but its removal can save it from speedy and utter destruction.' There is perhaps no effectual means of preventing the inroads of an enemy of such superior strength, and seemingly so insensible to the only weapons of offence which bees can employ. But we have known instances in which much good has been done by diminishing the size of the entrance-hole almost to the dimensions of a bee's body, and forming a narrow covered way to some distance without it: only one wasp can thus make its approach at a time, its movements are impeded, and the defence more easily made good."

WASTE. The demolition or unlawful removal of any structure or part of a structure which has in law the character of a fixture. See the article Fixtures.

WASTE LAND. Land which is incapable of cultivation till it be reclaimed and improved. It comprises many kinds, from mountain to marsh, and from inland downs to sea-beech sands,—and many gradations from bare rock to tangled brushwood, from absolute sterility to comparative productiveness, and from the scantiest and shallowest pastoral soil to deep, easily improvable, and constitutionally rich land, of texture suitable for tillage.

According to the evidence of Mr. Cowling before the Emigration Committee in 1827, England contains 3,454,000 uncultivated acres and 3,256,000 unprofitable acres, Wales 530,000 uncultivated acres and 1,105,000 unprofitable acres, Scotland 5,950,000 uncultivated acres and 8,523,930 unprofitable acres, Ireland, 4,900,000 uncultivated acres and 2,416,664 unprofitable acres, and the small British Islands 166,000 uncultivated acres and 569,469 unprofitable acres.

A law enacted in the second year of Edward VI. says, "that all such barren heath or waste ground, which before that time had lain barren, and paid no tithe by reason of the same barrenness, and now or henceforth shall be improved and converted into arable ground or meadows, shall from henceforth, after the end and term of seven years after such improvement fully ended and determined, pay tithe for the corn and hay growing upon the same;" and this law gave rise to conflicting opinions and angry litigations, and came generally to be interpreted with a decided leaning to the ecclesiastics, but was at last, after a long-contested suit, decided by three different juries to mean that "where the first crop shall be inadequate to pay the whole cost of cultivation, lime, &c., tithes are not payable for the succeeding seven years."

Mountainous, hilly, and steep waste grounds, clothed with dwarf or stunted heath, and also all other kinds of waste grounds clothed with heath, are discussed in the article Heaths; mountainous, hilly, and steep waste grounds, possessing a thin soil, and producing a short dry herbage, in the article Pasture; mountainous, hilly, and steep waste grounds, capable of most economical improvement by planting, in the articles Plantation, Planting, Coppice, and Orchard; moorish waste lands, in the articles Moor and Heaths; boggy and morassy waste lands, in the articles Bog, Peat, Fen, Marsh, and Morass; meadowy waste lands, in the articles Meadow, Irrigation, and Grass Lands; calcareous and drifting waste lands, in the article Downs; and waste lands subject to inundation by the freshets of rivers and the tides of estuaries, in the articles Embankment, Colmata, and Warping of Land. Some of the causes and indications of the most common kinds of sterility in waste lands are noticed in the article Barren Soils; some general remarks on the reclaiming and fertilizing of waste lands occur in the article Improvement of Land; and the principal arts and practices necessary for the reclamation of waste lands are discussed in the articles Draining, Paring and Burning, Subsoil-Ploughing, Enclosure, Lime, Manure, Fallow, Stone, Rolling, Fern, Furze, Heaths, Bog, and Irrigation.

The following rules respecting the improvement of waste lands are propounded by Sir John Sinclair:—"1. Not to put in practice any scheme of improvement, without the fullest deliberation, nor without the command of an adequate capital. 2. Not to begin on too great a scale, nor until, by experience it be found, that the design is suitable to the soil, situation, and climate. 3. When the intention is to cultivate bogs, or peat mosses, not to begin cropping, till at least one season after the drains are completed, and the soil thoroughly reclaimed from superfluous moisture. In bogs abounding with fluid matter (flow mosses), a longer time is necessary. 4. To plough or delve peat-moss in autumn, that it may first be effectually exposed to the winter frost and rains, and not to the summer's heat, which would harden it, and prevent its decomposition. 5. Whatever is done, to do it effectually; not to think of laying on four acres, the manure necessary for three, nor the lime, chalk, earth, clay, sand, or gravel, upon two acres, that should be employed in covering only one. 6. To carry on the improvement of waste lands, without encroaching upon the dung necessary for the improved part of a farm, as dung ought never to be brought from a good soil, to lay upon a bad one. Unless dung therefore can be procured from a neighbouring town or village, it will be better to leave the lands in their natural state, except in cases, where the soil, by being pared,

burnt, limed, or marled, or covered with chalk, clay, earth, &c. will pay the expense of the improvement, and rendered so fertile, that it can afterwards be preserved, in a good condition, from its own resources. 7. To lay down any land, improved from waste, in high and bleak situations, as soon as possible into grass, and to retain it in that state as long as it is tolerably productive. For though grain and roots may be cultivated on waste lands, when properly improved, and favourably situated, yet grass pastured, particularly by sheep, is principally to be depended on for improving weak soils, in barren districts, and remunerating the improver."

"It has been thought," says the same distinguished writer, "that greater profit may be derived from the improvement of wastes, or of lands not hitherto completely cultivated, than of similar soils that have been long under the plough. The rent is necessarily lower, they are freer from weeds, and if once brought into good order, and properly managed afterwards, will give lucrative returns. Instances might be stated in support of the above doctrine, but unfortunately it has not in every case been sanctioned by experience. The real cause is, that a great expense must be incurred in the first instance, while the subsequent advantages are uncertain. —Among the various modes of improving wastes, that of bringing them into a state of cultivation, by establishing colonies of labourers, fishermen, tradesmen, &c. in advantageous situations, has been found beneficial to the proprietor and to the public,—to the first, because his land is improved, perhaps without any expense being incurred by him,—and to the second, because, as a distinguished character has well observed, when land is given to a cottager for a number of years, under a small reserved rent, he and his family will exert in its cultivation, a quantity of labour, which would not otherwise be called into action; and by which, many thousand acres of land may be cultivated, which would not, in any other mode, pay the expense of improvement.—Whether exertions for the improvement of wastes are beneficial or injurious to the undertaker, there can be no doubt, that they are advantageous to the public. By these means, thousands of acres have been already added to the national stock of arable land, which, in proportion to their extent, will continue to yield food for our increased population. Besides the multitudes employed in reclaiming these wastes, occupation is provided for as many persons as are requisite for their subsequent cultivation; and the surplus food, beyond what the actual cultivators may require, increases the fund of provisions for maintaining those who are employed in manufactures and commerce. In all these respects, the improvement of waste and unproductive land is an object of very high national importance, and well deserves the attention, and indeed the encouragement, of the legislature."

WATER. Water, in a perfectly pure state, consists of 88·89 per cent. of oxygen and 11·11 of hydrogen. These two elements, in their separate or gaseous state, will not combine except by electrical agency; and though confined in one vessel, they will only diffuse themselves through each other, and will not make any attempt to unite till so attacked by either a voltaic spark, a red heat, or a strong pressure as to excite electrical action. A mixture of oxygen and hydrogen in a close vessel when electrically acted on, explodes and forms water; a stream of hydrogen escaping into the air, if ignited, will combine with the oxygen of the atmosphere in a process of regular combustion, and form water; and the free hydrogen which arises from many a process of decomposition on the surface of the earth, and ascends to the higher regions of the atmosphere, combines under the action of free electricity with the oxygen of the air, and forms much of the rain which falls in torrents during thunderstorms. The amount of electrical power necessary to maintain the union of oxygen and hydrogen in every grain weight of water is equal to a heavy flash of lightning. Water is, however, decomposed by electricity in excess, and its specific electricity liberated; and this fact may account for the formation of nitrous acid gas in the air during thunderstorms. The electricity compels the union of atmospheric nitrogen with oxygen yielded by either the decomposed water in the atmosphere or by the atmosphere itself. This formation of nitrous acid is a wise provision by nature for the purification of the air we breathe; every one knows that the air is always pure and more healthy after a thunderstorm; the nitrous acid acts upon and decomposes the miasms with which it was previously impregnated.

Water is a transparent, colourless liquid, well known to all, and, therefore, requiring no further description of its form and appearance. It is a universal solvent of soluble matter, acting slowly upon some inorganic substances, and not at all upon others, unless assisted by another chemical agent. It is said by Canton to possess considerable electricity,—yielding, as he affirms, in a perceptible degree, to the pressure of air in the condensing machine. But may not this philosopher be mistaken? May not the effect of the pressure result from atmospheric air and carbonic acid contained in the water with which he experimented? Nothing appears to show that he employed distilled water; and all other waters, whether from rain, springs, or rivers, contain both of these gases. The action of some metals upon water is to decompose it rapidly, of others to decompose it slowly; and of others not to decompose it all. Thus, iron decomposes it rapidly and seizes its oxygen; copper and zinc decompose it more slowly, whilst gold does not act upon it at all. The activity of water in its action upon organic substances is moderate, pro-

ducing no violent and sudden changes. The results of its action are various and useful. This moderation is highly beneficial to the life of animals and plants, which a too great energy of action would destroy. Water is a component part of the blood, and of milk; and it is an indispensable agent in both the structures and the food of the body. In its capacity of solvent, it carries into the animal frame the salts necessary for the secretions of living animal matter. It serves as a vehicle for the exhalations of the lungs and skin; and it is mixed with all the animal excretions. It acts the same beneficial part for vegetable as for animal life, being the vehicle of vegetable excretions and products; and is also an agent in the structure of plants. By its assistance flint and potash find their way into the structure of wheaten straw; by its aid the various other salts necessary to the structure of plants are absorbed. In vegetable matter, starch exists in mechanical mixture with it, gum and sugar are held in solution by it. In grain, in the potato, in farinaceous plants, water exists in large proportions, as it does in every kind of fruit, and in every kind of wood, stalk, leaf. and flower. Water, in short, fertilises the surface of the earth; in its absence, no vegetation could occur, no living thing exist. All organised nature requires it to sustain organism and life. Inorganic nature cannot do without it. Few liquids are free from water. Most of the fixed mineral acids contain it more or less; and it is a constituent of alcohol, even of ether. Solids also contain it. There is no crystallization of salts which is not due to water; deprived of it, the crystals fall to powder. Water likewise exists in almost all our appliances in domestic life. Without it we could not manufacture soap, nor paper, nor cloth, nor linen, nor leather, nor felt, nor china, nor earthenware, nor hardware, nor a variety of other matters of indispensable utility. Without it we should have neither wine, nor beer, nor ale, nor cider; for when not used artificially, it exists naturally in the fruits employed to produce these beverages. Without it, we should often be suffocated; for it absorbs noxious gases, and many molecules of matter that would strangely affect the lungs of breathing creatures.

Water at ordinary temperatures remains a liquid; at 32° Fahrenheit it hardens into ice; at 212° Fahrenheit it is converted into steam or vapour, quite invisible when not condensed by a colder medium, but generally visible in ordinary domestic boilings, because condensed by the colder air into which it emerges from the pot or tea-kettle. Although the temperature of water from ice just melted be precisely the same as that of the ice itself, namely, 32°, an amount of 140° more of insensible or specific heat, not indicated by the thermometer, must have been absorbed by the water to maintain its liquid condition. If this heat could not be absorbed from the surrounding media, if the temperature of the air remained at 32°, no thaw could take place. Thus, a lump of ice at 22°, being 10° below the freezing point, placed in a room at the temperature of 50°, would require, to melt it, just fourteen times the number of minutes or hours that would raise it from 22° to 32°. If, for instance, ten minutes were occupied in bringing the lump of ice from 22° to 32°, two hours and twenty minutes would be required to melt it into water at 32°. Thus, 10° of heat having entered the ice in ten minutes, fourteen times that amount was necessary to liquify it without raising the temperature, and $14 \times 10 = 140$. Dr Black suspended, side by side, two glass globes, of the same dimensions and capacity, the one filled with water at 33°, the other with ice at 32°. In half an hour, the temperature of the water had increased to 40°; but ten hours and a half elapsed before the ice was melted and the temperature of the water resulting from it raised to 40°. Hence, if, in half an hour, the water was heated to 40°, and it required twenty one half-hours to heat the ice to the same temperature, the corollary deducible is that 7° of heat entered into the globes every half-hour. Thus, $7 \times 21 = 147$, from which we must subtract the 7° which the water reached above 33° Therefore, $7 \times 21 = 147 - 7 = 140°$. Again, if a pound of ice pounded, at 32°, be mixed with a pound of water at 172°, the ice is immediately melted, and the result is two pounds of water at only 32°. Therefore, 140° have disappeared during the melting, being the exact quantity absorbed by the melted ice at the expense of the heated water. If this absorption of heat had not taken place, the result would have been two pounds of water at a mean temperature of 102°. These facts explain the cause of the slowness with which the ice and snow melt when a thaw succeeds an intense frost. Days and even weeks sometimes intervene before the whole is liquified. The same facts also account for the chilliness of the air during a thaw; the specific heat absorbed by the water from the melting ice is taken from the atmosphere at the expense of its *sensible* temperature, to become latent or specific; and therefore the air feels more cold and raw than before the thaw commenced.

If water, in the process of cooling and solidifying, followed the ordinary laws of heat and expansion of liquids, its surface would contract, and become heavy in proportion to its contraction, and sink beneath the other layers; and these would successively replace it, so that the whole body would become gradually cooled to the freezing point, the lower stratum being always the coldest, and therefore the first to solidify or freeze. But, were this really the case, the bottom or under surface of the fluid would freeze first, which is contrary to fact; also, every river would become so full of ice, each of its banks, as well as every sea-coast in our latitudes, would become so ice-bound, that the strongest heat of summer

would not suffice to thaw them; and perpetual snow and ice, as upon Alpine summits, would cover and render uninhabitable those beautiful countries in which organic matter flourishes, in which vegetation spreads its luxuriant fruitfulness, in which living creatures not only breathe and exist, but enjoy the manifold blessings of physical comfort which God's Providence has specially created for their benefit. But the Creator has beautifully contrived to obviate this. Everybody knows that water always freezes at that part nearest to the atmosphere, that is to say, at the top or upper surface, and not at the bottom or under surface. This, however, appears to be contradictory to the general laws of heat and expansion; and so it is;—for the Maker of all things has ordained an especial exception to these laws in regard to water, so useful to his organic world, so necessary to the comforts, nay, the very existence of animal life. In our temperate latitudes we are not ice-bound; our rivers never possess more ice than will thaw in a week or ten days under the temperature of spring. Water does not contract by the loss of heat, after it has reached a certain temperature; on the contrary, it expands. Water contracts until it reaches 39½°, being 7½° above the freezing point; it then begins to expand in proportion as its temperature descends to that point. The colder water consequently rises to the surface. Thus, when the liquid has reached 32°, the warmest layer of the fluid is at the bottom, the coldest at the surface. Here, then, the freezing begins, and the ice increases in thickness as the upper ice becomes colder. But it never descends to the bottom of rivers; otherwise the population of our waters, so useful to us as food, and for many other purposes, would be wholly destroyed. There is another fact: water, in the act of solidifying, expands still further; and so powerful is this expansion, that it will cleave the hardest and most tenacious rocks. No metal can resist its power, as may be exemplified by filling the barrel of a gun with water, sealing it hermetically, and placing it in a situation for the water to freeze. The expansion will burst the barrel; so it would a cannon under similar circumstances. See the articles Freezing and Frost.

Under ordinary atmospheric pressure computed from the level of the sea, pure water boils at 212°; though waters containing matters in solution, as all our domestic waters do, require a higher temperature to boil. Every 500 feet of elevation diminishes the pressure so much, that water will boil at one degree less; so that on the Peak of Teneriffe, it boils at 192°, and on the highest part of the Himalaya range where human creatures can breathe, at 170°. In a vacuum, water will boil at a much lower temperature than this; nay, it will actually boil on the application of cold, as the following pretty experiment will show. Let a clean Florence oil-flask be half filled with water; place it over a lamp until the water boils; remove the flask from the fire and cork it while still full of steam. The water has now ceased to boil; but if the flask be plunged into a pail of cold water, the boiling will recommence. The reason is obvious. The steam generated by the boiling alone occupies the space in the flask above the water, the atmospheric air being expelled by the heat; and the flask being corked, the steam remains where it was; but on plunging the flask into cold water, the steam is condensed by the cold, and falls in the form of water into the liquid beneath it, leaving a vacuum above, when the boiling immediately recommences.—When a vessel containing water is placed over a fire, a hissing sound is soon heard as the fluid increases in temperature. This is caused by the vibrations arising from the vaporisation of the particles of liquid in contact with the bottom of the vessel, which being nearest to the fire is, of course, the first part heated. These particles vaporise and again become condensed as they rise, until sufficient heat is imparted to the mass of the liquid. As this heats, the sound becomes louder, until ebullition begins and steam is rapidly evolved. The temperature is now stationary; it never rises above the boiling point, nor does the steam formed acquire a higher temperature. It may be remarked, however, that under considerable pressure water may be heated to a red heat, that is to say, to a heat which cannot exist without light, about 800° Fahrenheit; but the moment the pressure is removed and the liquid open to the air, the temperature suddenly jumps down to 212°, and steam violently escapes. When water is thus heated, the vessel containing it becomes red-hot, the water itself being so; and this state of things no doubt sometimes exists, when not suspected, in steam-engine boilers, and in the hot-water apparatus for warming churches, dwelling-houses, and manufactories, and may there give rise to very serious accidents. See the article Boiling.

Though steam is generated from water at a temperature of 212°, yet this vapour requires a thousand degrees more of heat to assume the gaseous condition. This fact is shown by the following experiment, which we take from Professor Donovan's Elements of Chemistry:—"If a pound of steam at 212° be received into 5·56 pounds of water at 32°, the former will be condensed into water; and the whole, amounting to 6·56 pounds of water, will have the temperature of 212°. The temperature of the steam, now water, has not been reduced, yet 5·56 pounds of water have been raised from 32° to 212°, that is 180° for each pound, or 1000° (180° + 5·56) in all. Had a pound of water at 212°, instead of a pound of steam at 212°, been mixed with the 5·56 pounds of water at 32°, the resulting temperature would only have been 64° instead of 212°. Hence the number of degrees of heat which steam at 212° contains in a latent state, and which does not elevate its temperature, is

one thousand." Steam, of late years, has been employed not only in the principal mechanical arts, but in the wonderful appliances of steam navigation aad railway travelling; in many kinds of manufacture, its substitution for boiling water has produced a perfection of process quite unattainable without its aid; and even in the culinary department, it has been employed during more than half a century with very great advantage in schools and public institutions, where it obviates a considerable expenditure of fuel which would arise from water-cooking. A range of tin vessels, each containing its separate articles to be cooked, are made to communicate with each other, and the last with a boiler containing water; and as soon as the water commences ebullition, the steam enters the first vessel, then the second, and so on to the last, which has just as good a share of heat as the first. Proper precautions are taken for the escape of the steam, which, if confined, might cause an explosion. In preparing food upon an extensive scale for cattle, and hogs, and for the dog-kennel, steam is most valuable, being a much more perfect as well as a more economical agent. See the articles STEAM and STEAMING-APPARATUS. — In heating apartments, especially in large manufactories, steam is superior to every other agent, as regards both economy and the production of an equable and permanent temperature, attended by comfort, cleanliness, and safety. We are told by Dr. Ure, that a single cubic foot of boiler will heat 2,000 cubic feet of space in a cotton-mill, having an average temperature of from 70 to 80 degrees. Again, one square foot surface of steam-pipe is sufficient to warm 200 cubic feet of space. Thus, a pipe containing little more than 27 square feet of surface would warm a drawing-room 24 feet by 20, and 12 feet high. But as the heat from the pipe is communicated principally by radiation, the surface of the latter should be kept black.—Drying operations in calico manufactories have for many years been effected by steam; and the same agent is employed in the drying of gunpowder. In the rooms where steam-drying takes place, the workpeople remain particularly healthy, which is far from being the case where stoves are used for the drying process. The heating of baths by steam is also very advantageous, especially in public establishments. One gallon of steam will heat 18 gallons of water to 100 degrees,—the steam being driven into the water through a pipe; and this heating is almost instantaneous. In private families, a steam-pipe, with a stop-cock, might communicate from the boiler of the kitchen-range to the bathing room.

Besides the vapour thus generated by the temperature of boiling water, there is another kind of vapour of water in constant progress of vaporisation, which, however, is slow and imperceptible, but upon which depends the very life of the organic world. This is called evaporation. It takes place at all temperatures, from the burning heat of the torrid zone to the temperature of a Siberian winter. The atmosphere has an insatiable thirst for moisture; and takes it from all sources. Evaporation into it is therefore always going on from the surface of the ocean, from that of lakes and rivers, from that of every body of water, however minute, and from the surface of the earth, from the surface of plants, and even from the bodies of living animals. Though more powerful in a warm temperature, it is still in activity, greater or less, at all seasons and in all climates; and if condensed vapour be seen rising from the surface of a pond during the evening in autumn, the same kind of vapour, though in less quantity, will arise when the weather is very cold—nay, even should the surface of the pond be frozen. Within the tropics, the amount of evaporation is enormous; and even the waters of the Mediterranean are supposed, every hot summer's day, to diminish by evaporation to the amount of five hundred millions of tons; and they make good this loss partly by the tribute of rivers, and partly by influx from the Atlantic. The leaves, stems, and fruits of plants—nay, their very seeds—the respiration, perspiration, and excretion of animal life, all supply water to the air; and so does even the humus or vegetable soil of the earth. This universal evaporation accounts for the drying of anything that is wet; and it dries sooner before a fire than at ordinary temperatures, because the higher the temperature, the more rapid the evaporation. If no evaporation took place, we should be unable to dry anything; our clothes, our houses, our articles of manufacture or raw materials, once wetted, would ever remain so till the end of time. Evaporation at equal temperatures is much more rapid during wind than when the air is calm,—a fact exemplified by every washerwoman, who will certify that a strong breeze greatly hastens the drying of her clothes. If the evaporation from the ocean be prodigious, that from the surface of the land is not less so. Bishop Watson, in his Chemical Essays, states that, during a summer's day in Great Britain, the evaporation from an acre of mown meadow-land, after the removal of the hay, amounts to 1,600 gallons,—a conclusion to which he came as the result of a series of experiments carefully conducted by himself.—But what is the use of this enormous evaporation, of this unquenchable thirst of the air surrounding our globe? It is another beautiful provision of the Almighty Creator for the wants of organic nature; it is the life-spring of the animated creation. We have explained the absorption of specific heat by steam as it is generated from boiling water. A similar absorption of specific heat takes place during evaporation, otherwise there would be no evaporation at all, and the water at present evaporated would retain its liquid condition. This absorption of specific heat, being made at the expense of the surrounding media, causes a sensible diminution of tem-

perature. Thus, the heated air is cooled by evaporation from the earth, without which all tropical regions would be uninhabitable by man, and even our temperate latitudes so hot in summer as to cause death. When the body is overheated, nature has provided a flow of aqueous perspiration, which appears upon the skin, and by its evaporation keeps the body at a proper temperature. Anything impeding this perspiration causes disease and death. All our supplies of fresh water also come from the atmosphere as a result of this general evaporation, which is a modifier of heat, and the source of the freshness and fertility that make the surface of the earth so beautiful to look upon, when teeming with luxuriant verdure, and with grain and fruit for the use of living creatures. When the air becomes surcharged with moisture, or when a change of temperature or a change of electrical action takes place, the vapour is condensed and falls to the earth in refreshing showers, or in the form of snow or hail. Snow is the vapour frozen ere it has had time to condense into rain-drops; hail is formed by the freezing of the drops themselves; and all three have their several uses in the economy of nature. The water which thus falls, charged with some matters contained in the atmosphere, has several functions to perform. The greater portion of it sinks into the earth, forming springs, sources of rivers, or remaining hidden in great reservoirs till called forth by the energy of man; another portion is immediately evaporated back again into the atmosphere; and a third portion is decomposed by the plants upon which it falls, and which, assimilating its hydrogen for their nourishment, give out the oxygen to the air,—and this last explains why the proximity of vegetation is so refreshing immediately after a heavy shower, the portion of oxygen being increased without having yet had time to be diffused. See the articles Evaporation, Atmosphere, Cloud, and Rain.

Rain water, though freer from foreign substances than any water which has flowed in contact with the solid earth, contains atmospheric air, carbonic acid, ammonia, and sometimes other gases; all of which it absorbed during its formation in the clouds or during its descent thence to the earth; and all the ammonia—but very particularly in the first rain which falls after a drought—is distinctly charged with the offensive odour of animal perspiration, excrements, and putrefaction. See the article Ammonia. Though in London rain-water is seldom applied to domestic purposes, as the Thames supplies the wants of the laundress, and no contrivances are generally used for its preservation, yet in many provincial cities and towns, and in the rural districts, it is carefully preserved for the purposes of the wash-house; and where no other soft water is to be obtained, rain-water forms a very important article of domestic use and consumption. But it is unfit to drink; though in some countries, where none other is to be had, it is preserved in tanks, and applied to the purposes for which hard water is preferable. Rain-water, however carefully filtered, is mawkish and unpleasant to the taste, and, if not actually unwholesome, is very inferior, as a solvent in the stomach and for the supply of the human frame, to water from springs and fountains, or even to that from rivers and lakes. Filtering does not divest it of any matter held in chemical solution; and those who drink rain-water must take it with the unpleasant accompaniments which are combined with its ammonia.

Water derived from rivers and lakes is sometimes as soft as rain-water, and sometimes as strongly impregnated with lime and other compounds as water from hard springs, or from those termed 'mineral springs.' What it carries with it depends entirely upon the soil through which it runs. But it requires a number of years before the water from heaven can, by contact with the soil, extract an alkaline salt from it. This is the reason why rivers and lakes, especially when fed by heavy rains, or periodical meltings of snow and ice, have their waters soft; and these waters are sometimes freed from the ammonia derived from the atmosphere, sometimes strongly impregnated with it. When at hand, they serve for the same domestic purposes as rain, and are used besides as a beverage for men and cattle. But such waters, especially in rich valleys, are frequently charged with matters which render them unwholesome unless carefully filtered. They carry with them, in mechanical mixture, not only the alluvium which renders them turbid, but much putrid animal and vegetable matter. In addition to this, in large cities, especially in those where manufactures exist, and through or near which a river flows, this latter receives, in addition, various very unwholesome compounds, besides the worst filth and soil of the place, from which no filtering will free the water. No attention is ever paid to keep such rivers from pollution, and the inhabitants are not unfrequently compelled to draw water for their tea and other purposes from a river into which run the drains and sewers of the town. The soft water of rivers, springs, and brooks, not far from the sea, generally holds in solution a minute quantity of common salt. Unless it run over a rocky bed, the water of rivers requires filtering before it is fit for human drinking. Many of the mountain torrents in Switzerland are said to be impregnated with salts which, when the water holding them in solution is applied to domestic use, produce that deformity in the throat known by the name of goîtres,—a complaint common in mountainous districts, even in England. The soft water of rivers, lakes, ponds, or fountains is generally preferred for the preparation of vegetable infusions and decoctions, and of vegetable extracts. It is stated to be preferable likewise for the brewing of ale, porter, and beer; though

we do not quite assent to this proposition. Many of the beverages derive the peculiar qualities for which they are celebrated, from the salts held in solution by the waters employed in their preparation. The famous Burton ale receives a distinguishing flavour from the liquid used in brewing it, which liquid in its natural condition, that is to say, in the state in which it is drawn by the brewers from its natural reservoir, is said to hold in solution small quantities of the sulphates of iron and lime, and of nitrate of potash. It has been affirmed, and was once generally believed, that the soft water taken from muddy ditches and stagnant pools, teeming with both animal and vegetable matter, was preferable for the purposes of brewing, to the harder waters of rivers, wells, or fountains; and many infatuated individuals, misled, doubtless, by their blind confidence in the asseverations of ignorant men who hire themselves to brew in families, are persuaded, even now, that the decomposed matter, mixed with this water, is actually advantageous to the vinous fermentation of the ale. For our own part, we believe that both hard water from wells and soft water from rivers, provided neither contains any matters in mechanical mixture which will putrefy, will dissolve all the fermentable matter of the malt, when the mashing is properly done; and this is all that is required. It has long been a vulgar error, especially in the provinces, that no good porter can be produced anywhere out of London; and that the reason of this is the peculiar property of the Thames water, with which alone good porter can be brewed,—no other water being capable of yielding that beverage in perfection. The cause assigned is that the Thames is charged with much fermentable matter, which hastens the action of the brewers' yeast; but they have overlooked the fact that this matter is a strong putrefactive ferment. Without having recourse to theory or hypothesis to ascertain why the water of the Thames should alone be possessed of the property of producing good porter, we must first inquire whether such be really the fact; and this question will be answered negatively, for not one of the public brewers of porter in London ever uses the Thames water in his brewery,—each has, on his premises, a well from which he draws all the water that enters into the composition of his porter. The water of the Thames is certainly the best in the world for the use of ships sailing on long voyages. When pure, it is of a rather soft taste, being not greatly charged with soluble matters. But it holds in mechanical mixture substances which impart to it a very singular property. After it has been at sea two or three days, it commences a very active putrid fermentation, during which much carbonic acid and some carburetted hydrogen are given out, together with a most offensive odour. By the time a week has expired, this fermentation begins to subside; all foreign matter contained in the liquid falls gradually to the bottom of the cask or tank, where it becomes a tenacious mass; whilst pure water, beautifully limpid and free from taint, lies above it. This water will keep more than a year; and when passed either through a filter or a common dripstone, is the finest and purest water that can be obtained for human drinking; it is brisk and gratifying to the palate, which shows that it is well charged with atmospheric air and carbonic acid. We have already observed, that soft water is the preferable for vegetable infusions. That of tea, so much used in this country, is often defective; and the grocer is unjustly accused of having sold a bad article, from the mere fact that the water employed is very hard. Moderately hard water will make tolerably good tea; but in water with excess of hardness, the leaf will not infuse, unless an alkali be employed to diminish this hardness by precipitating a portion of the salt that constitutes it. This is the reason why, where very hard water prevails, a small quantity of soda is often put into the teapot.

Generally speaking, calcareous waters moderately charged with carbonate of lime, are the most wholesome for drinking. It is a vulgar error to suppose, because a deposit of a hard concrete salt takes place round the inner surface and over the bottom of the teakettle, that it is much more wholesome to drink water previously boiled and cooled. Such water is decidedly unwholesome; the boiling temperature deprives it of both its atmospheric air and its carbonic acid, and the water so treated requires long exposure to the atmosphere ere it absorb sufficient of these matters to be again drinkable. It is the heat which, by depriving the water of its carbonic acid, makes the lime precipitate in the form of carbonate of lime. This compound is insoluble; for everybody knows that neither chalk nor marble, nor any kind of limestone, will dissolve in water. Yet water, in passing through or over beds of chalk or other carbonate of lime, generally carries away with it a small portion of that substance; and this it is enabled to do by means of the free carbonic acid which it contains, and which, uniting with the insoluble carbonate, forms a soluble super-carbonate. But the proportion of this salt, as also that of other saline substances, is exceedingly variable in different kinds and specimens of drinkable water. For example 100,000 parts of the water of the Seine above Paris contain 11·3 of carbonate of lime, 0·4 of carbonate of magnesia, 0·5 of silica, 3·6 of gypsum, 0·6 of Epsom salt, 1·0 of chloride of calcium, 0·8 of chloride of magnesium, and traces of nitrates and of organic matter; 100,000 parts of the water of the Marne contain 10·5 of carbonate of lime, 0·9 of carbonate of magnesia, 0·6 of silica, 3·1 of gypsum, 1·2 of Epsom salt, 1·7 of chloride of magnesium, and traces of organic matter; 100,000 parts of the

water of the Ourcq at St. Denis contain 17·5 of carbonate of lime, 2·0 of carbonate of magnesia, 2·0 of silica, 15·3 of gypsum, 7·0 of Epsom salt, 4·0 of chloride of magnesium, and traces of common salt and of organic matter; 100,000 parts of the water of the Yonne at Avallon contain 4·3 of carbonate of lime, 1·9 of silica, traces of gypsum, 1·5 of chloride of calcium, and traces of common salt and organic matter; 100,000 parts of the water of the Benvronne contain 25·7 per cent. of carbonate of lime, 20·3 of gypsum, and 8·5 of chloride of calcium; 100,000 parts of the water of the Thérouenne contain 26·2 of carbonate of lime, 2·0 of gypsum, and 3·6 of chloride of calcium; 100,000 parts of the water of the Gergogne contain 18·0 of carbonate of lime, 1·5 of gypsum, 1·5 of chloride of calcium, and 0·9 of common salt; 100,000 parts of the water of the Bièvre near Paris contain 13·6 of carbonate of lime, 25·1 of gypsum, 10·9 of chloride of calcium, and 1·2 of common salt; 100,000 parts of the water of the Arcueil contain 16·9 of carbonate of lime, 16·9 of gypsum, 11·0 of chloride of calcium, and 1·9 of common salt; 100,000 parts of the water of the spring of Roye at Lyons, contain 23·8 of carbonate of lime, traces of silica, 1·4 of gypsum, 1·2 of common salt, and traces of nitrates and organic matter; 100,000 parts of the water of the Fountain Spring at Lyons contain 23·4 of carbonate of lime, traces of silica, 1·7 of gypsum, 1·3 of chloride of calcium, traces of chloride of magnesium, 0·2 of common salt, and traces of organic matter; 100,000 parts of the water of the Rhone at Lyons, in July, contain 10·0 of carbonate of lime, traces of silica, 0·6 of gypsum, and traces of Epsom salt, of chloride of calcium, of chloride of magnesium, of common salt, and of organic matter; 100,000 parts of the water of the Rhone at Lyons, in February, contain 15·0 of carbonate of lime, 2·0 of gypsum, 0·7 of Epsom salt, 0·7 of chloride of calcium, and traces of nitrate of lime, and of organic matter; 100,000 parts of the water of the spring of the Garden of Plants at Lyons contain 27·0 of carbonate of lime, 25·2 of gypsum, 16·8 of carbonate of calcium, 1·6 of chloride of magnesium, 12·6 of common salt, 7·6 of nitrates, and traces of organic matter; 100,000 parts of the water of the Lake of Geneva contain 7·2 of carbonate of lime, 0·7 of carbonate of magnesia, 0·1 of silica, 2·6 of gypsum, 3·1 of Epsom salt, 0·9 of chloride of magnesium, and 0·6 of organic matter; 100,000 parts of the water of the Arve, in August, contain 5·2 of carbonate of lime, 0·4 of carbonate of magnesia, 0·1 of silica, 3·2 of gypsum, 2·9 of Epsom salt, 0·7 of chloride of magnesium, and 0·3 of organic matter; 100,000 parts of the water of the Arve, in February, contain 8·3 of carbonate of lime, 1·2 of carbonate of magnesia, 0·2 of silica, 6·5 of gypsum, 6·2 of Epsom salt, 1·5 of chloride of magnesium, and 0·4 of organic matter; 100,000 parts of the water of the Loire near Orleans contain 1·7 of carbonate of lime, 5·1 of chloride of calcium, and traces of common salt; 100,000 parts of the water of the Loiret contain 11·9 of carbonate of lime, 3·8 of gypsum, 10·2 of chloride of calcium, and 2·5 of common salt; and 100,000 parts of the water of the Artesian Well at Grenelle, near Paris, contain 6·8 of carbonate of lime, 1·42 of carbonate of magnesia, 2·90 of bicarbonate of potash, 1·2 of sulphate of potash, 1·09 of chloride of potassium, 0·57 of silica, and 0·24 of nitrogenous organic matter. All these are drinkable waters, and were analysed by some of the most distinguished chemists of Continental Europe,—Bouchardat, Boussingault, Dupasquier, Tingry, Guindant, and Payen; and, of course, the drinkable waters of the streams and wells of Britain differ as widely as they in both the kinds and the proportions of their saline impregnations.

Water which is quite or even grossly unsuitable to be drunk by human beings may be statedly drunk without any injury, or even with very salubrious effects, by horses and cattle. See the articles Horse and Pond. Even water so highly impregnated with saline matter as to contain upwards of one ounce of it in every four gallons may be constantly drunk by horses with perfect safety. A specimen not long ago analysed by Professor Johnston contained in every gallon 78·42 grains of common salt with a little chloride of potassium, 4·18 of chloride of calcium, 3·53 of chloride of magnesium, 25·71 of gypsum, 15·44 of carbonate of lime, 12·88 of carbonate of magnesia, 0·48 of carbonate of iron, and 1·0 of silicate of soda; and some horses who had statedly drunk this water unexpectedly died, and were conjectured to have been injured by it, but proved on enquiry to have fallen victims, quite independently of it, to an epizootic pleuro-pneumonia. In all ordinary watering of horses and cattle, however, some streams and ponds and springs may soon be observed by careful, keen-eyed practical men to comport better with health than others; and unless they exist under circumstances which would involve the constant use of them in too much cost or trouble, such ought, of course, to be always preferred. Yet saline ingredients which are neither useful nor hurtful to cattle, but which constitute direct and valuable food of cultivated plants, or excessive quantities of such as are useful to cattle and at the same time constitute food of plants, exist so largely in some waters as to render them highly preferable in the watering of cattle for sake of the ulterior enrichment of the farm-yard manure. "The waters which serve as drink to the cattle of a farm," remarks Boussingault, "introduce into the dung-heap all the matters which are dissolved or held in suspension. At Bechelbronn, for example, I find that more than 2 cwts. of alkaline salts get into the dung in this way every year. When a farmer has the choice of several waters for giving his cattle or irrigating his meadows, he will do well to select that which is richest in alkaline salts, and

still good to drink. In the steppes of America, it is astonishing with what discernment the cattle choose waters for allaying their thirst, containing minute quantities of sulphate of soda or common salt."

Waters suitable for irrigation are vastly more variable in the kinds, combinations, and amount of their impregnations, than waters suitable for drinking; and though they have already been discussed in the article IRRIGATION, the following notes upon them, in a recent report of the Scottish Agricultural Association drawn up by Professor Johnston, may here be introduced as valuable:—"Our present knowledge of the composition and wants of the growing plant, forbids us to ascribe to its lime alone the whole of the chemical influence which a water may exercise when employed for irrigation. Plants require common salt, and all natural waters contain it; they require sulphur, and in nearly all natural waters it is present; they require also magnesia and phosphorus and iron, and animal or vegetable matter, and nearly all waters contain these, though often in quantities too minute to be readily detected. Each of these substances, therefore, when present in water, may have its influence in producing the results which are brought about by its use in irrigation. The precise degree of merit to be ascribed to each, will depend upon the proportion in which it exists in the water and in the soil, and upon the kind of plant or herbage cultivated. As a general rule, it may be stated that the value of water for the purposes of the irrigator, depends first upon the quantity, and second upon the quality, of the solid matter it contains. That which contains most solid matter, other things being equal, should be the most valuable. To this, however, there are exceptions, as in the case of waters which, like those of the sea, or of salt springs, contain so much saline matter as in weather of ordinary drought to injure and sometimes actually destroy the herbage; or of spring waters which contain so much lime as to form a deposit or incrustation on the leaves of plants. It will also be understood, that, generally speaking, though a water contain a larger proportion of solid matter, yet if this solid matter consist almost entirely of one substance, it may be less valuable than a water which contains a smaller quantity of solid matter on the whole, but in which a number of important ingredients occur in proportions more nearly resembling those in which they are required by plants. It is in especial reference to such points as these that a careful analysis of waters which have been successfully employed for irrigation upon our soils and in our climate, is both practically and theoretically important. The four following analyses exhibit the composition of waters which are sufficiently abundant to be used for irrigation, but which are not, so far as I know, any where in their course employed for this purpose.

	River Ale.	River Eye.	Biglaw burn.	River Wear.
Organic matter	1·75	1·64	2·58	0·92
Potash in the state of sulphate	1·68	0·80	0·72	1·50
Soda and chlorides		0·44	1·94	
Gypsum (sulphate of lime)	0·64	1·46	2·94	0·88
Carbonate of lime	5·28	3·48	7·32	7·92
Carbonate of magnesia	1·00	1·24	3·64	2·04
Chloride of magnesium	1·82	0·80	1·25	—
Oxide of iron	0·56	0·48	0·60	0·56
Sulphuric acid	1·44	0·98	1·80	0·96
Chlorine	0·36	0·70	1·65	1·10
Silica	0·24	0·08	0·32	1·20
	14·77	12·10	24·76	17·08

These waters are so far fitted for irrigation, that they all contain nearly every thing which the plant requires. That from Biglaw burn, however, both by the quantity and quality of the ingredients it holds in solution, is most likely to administer to the growth of plants, and to supply the natural or acquired deficiencies of any soil over which it may be made to flow."

Some of the chief uses of water to vegetation, irrespective of the nourishment which it contributes in the form of the salts and the gases held in solution by it, are noticed in the articles GERMINATION, ABSORPTION IN PLANTS, DEW, AGRICULTURAL CHEMISTRY, and LIQUID MANURE; and some of the many chemical actions of water upon the constituents and the temperature of the soil, in their connexion with vegetation, are noticed in the article DRAINING. Water not only brings to plants the constituents of their food which it gathers and absorbs during its descent through the atmosphere, and during its progress on the surface and through the strata of the earth, but also acts as the solvent and the vehicle of all the constituents of their food obtained from manure and from the solid ingredients of the soil; and it constitutes by far the bulkier portion, not only of the sap which ascends within them from the roots to the leaves, but also of the cambium which descends after the processes of evaporation and elaboration to form all their secretions and excretions,—and even constitutes a main portion of their secreted juices, and a very considerable portion of their cellular and vascular substance or of their somewhat solid matter. See the articles SOIL, MANURE, SAP, CAMBIUM, and ORGANIC CHEMISTRY. The chemical actions of water, in their joint simplicity and power, are probably nowhere more remarkable than within the organisms of plants; and they no doubt play both a conspicuous and a manifold part in the multitudes of decompositions and recombinations which characterise vegetable organic chemistry, and particularly in those which deal with gases, and which reduce the elements of aeriform substances into liquid and solid secretions. Water, when deprived of all its air by ebullition, has the power of absorbing in every 100 cubic inches of its bulk, under the mean temperature and pressure of the atmosphere, about 100 cubic inches of sulphuretted hydrogen, about 100 of carbonic acid, about 76 or upward of nitrous oxide, about 12½ of olefiant gas, about 3·7 of oxygen, and

about 1·56 of respectively carbonic oxide, nitrogen, and hydrogen; so that, in all the approaches of water to plants, whether through the air or along the surface of the earth, or through the interior of the soil, it acts as a mighty, greedy, and general forager on their behalf, and constantly comes laden to them with a variety of the most enriching spoils. In its capacity of general menstruum, general solvent, and grand constituent of juices, also, it is a mighty and essential modifier of all other natural agencies upon plants, lubricating all the organic energies, sustaining all the absorptive, inhalent, and exhalent functions, assisting every internal act and process of chemical transmutation, attempering the outward play of light and heat and weather, and resisting all mischievous effect from excess of calorific, absorbing, or caustic agencies. The reasons, therefore, are strong and many why field plants are injured or destroyed by droughts, and why garden ones are benefitted by artificial waterings. Yet the diffusion of water as vapour through the atmosphere when it loses its liquidity and rises out of the soil,—the accumulation and abundance of it in the former state proportionately to the decrease and scarcity of it in the latter,—and the adaptation of it as a vapour, together with all the gases which it has absorbed, to be bibulously inhaled through the stomata of plants,—are to the full as wonderful as any of its other properties, and beautifully supplement the amazing powers with which the Creator has endowed it for supporting vegetable existence. "The quantity of water which exists in air as vapour," remarks Sir Humphrey Davy, "varies with the temperature; in proportion as the weather is hotter, the quantity is greater. The leaves of living plants appear to act upon the vapour in its elastic form and to absorb it. Some vegetables increase in weight from this cause, when suspended in the atmosphere and unconnected with the soil; such are the house-leek, and different species of the aloe. In very intense heats, and when the soil is dry, the life of plants seems to be preserved by the absorbent power of their leaves; and it is a beautiful circumstance in the economy of nature, that aqueous vapour is most abundant in the atmosphere when it is most needed for the purposes of life, and that when other sources of its supply are cut off, this is most copious."

The command of a sufficient supply of water for all the uses of the farmery and of live stock, is essential to agriculture, and was formerly a great desideratum throughout some extensive districts in Britain. In the low tracts of Lincolnshire, water free from brackishness and perfectly fit for drinking is so scarce that carts are sent for it to the distance of several miles,—sometimes even to the distance of 16 or 17 miles; in the wolds of Yorkshire, previous to the invention of the improved mode of making artificial ponds, instances were frequent of numbers of animals perishing from thirst; and in Hampshire, from the long continuance of dry weather during the autumnal months, the wells became so exhausted, that great labour and expense were incurred in supplying the family and stock, by means of water-carts. To avoid the risk of such serious misfortunes, it was anciently the practice, for the conveniency of having water, to erect farm-buildings in low grounds, near brooks or rivers; but on this plan the house became damp, the grain, from the moisture of the atmosphere, was frequently injured, and, from the vicinity of the water, accidents of various descriptions frequently occurred. When the advantages, therefore, of having a house and offices in the centre of the farm, and rather on an elevated situation, came to be generally understood and admitted, methods were adopted for obtaining supplies of water from the roofs of the farm-buildings, from natural springs, and from wells, artificial ponds, and artificial rills. The buildings and yards of a farm are supposed to receive rain sufficient, if duly collected, to supply both the family and the cattle of the place for a considerable part of the year; and ponds, where necessary, may be made in any situation, at a very small expense, for the remainder. See the article Tank. Where natural springs occur, they will generally furnish a sufficient supply for family use; but they are seldom adequate to the necessities of a great farming establishment. See the article Spring. In Middlesex and Surrey, the farmers have dug to the depth of from 100 to upwards of 560 feet, before they could procure water; in Essex they have been obliged to go as deep as 500 feet to obtain water of a good quality; and, in Hampshire, they have likewise dug from 300 to 400 feet in depth, through dry, cracked, or fissured chalk rock. See the articles Well and Artesian Well. In several parts of England, as in Hampshire, in Lincolnshire, and in Norfolk, artificial ponds were long ago formed with varied skill and success. In Gloucestershire, they were made either of a square or of a circular shape, and generally so situated as to furnish a supply to four fields. Three layers of clay, free from the smallest stone or gravel, were so worked in as to form an impenetrable cement; and the whole was afterwards covered with sand and finished with pavement. In Derbyshire, artificial 'meers,' or cattle ponds, are made in dry rocky pastures, with great success. Having selected a low situation for the purpose, they deepen it ten or twenty yards across, and spread over the whole excavation a layer, about five inches thick, of refuse slaked lime and coal cinders; they then spread, trample, and ram down, a stratum of well-tempered clay, about four inches thick; and upon this they place a second bed of clay, in a similar manner, of the same thickness; the whole of the bottom and edges of the meer is then paved with rubble stones; and small rubble stones, several inches thick, are spread upon

the pavement. Other and newer methods are noticed in the article Pond. In the North Riding of Yorkshire, there is a tract, extending for many miles, entirely destitute of water, except what flows along the bottoms of the deep valleys by which it is intersected, and little relief could consequently be afforded by streams thus distantly and inconveniently situated to the inhabitants of the uplands and their cattle. About the year 1770, a person of the name of Ford devised a method of watering this district, by means of rills brought from the springs that break out at the foot of the still loftier moorland hills that run parallel to and northward of this tract, in some instances at the distance of about ten miles. These springs he collected into one channel, which he carried in a winding direction about the intervening tract, according to its level, and along the sides of the valleys, until he gained the summit of the arid country which he wished to supply with water; and when this was accomplished, the water was easily conveyed to the places desired, and also to the ponds in all the fields, over a considerable tract of ground. The plan of thus watering a dry upland country has much merit. It is not expensive, the original charge rarely exceeding £100 per rill, while it affords a most important accommodation to the occupier, and greatly enhances the value of the property. Though not generally applicable, this plan might certainly be adopted, with great advantage, in some other situations. A supply of water is also an object of great importance in every field where pasturage is intended. With that view, if there happens to be a small rivulet in the neighbourhood of the lands, it may often be distributed in branches, so as to water many fields. Springs, or the collected discharges from drains, may also be applied to the same purpose. All land used for grazing requires to be constantly well supplied with water. In conducting water through fields, it is of material importance to take care that the slopes be gentle, and not more than sufficient for easy transmission; as, when water is conveyed down fence ditches, or open conduits of considerable declivity, it is too apt to do injury in its progress by washing away the sides of its channels. Sometimes water is collected in a field, not only for the use of the animals pastured there, but also to be afterwards diverted for other uses, as for threshing and other mills, for irrigation, for ponds, for bleaching, and similar purposes. To accomplish these objects, and at the same time to prevent injury from this element, the drains, conduits, sluices, bridges, gates, and fence-ditches, require to be designed with skill, and constructed with scientific attention.

WATER CALTROPS. See Caltrops (Water).

WATER CART. See Cart and Liquid Manure Cart.

WATER CHICKWEED. See Montia.

WATER COWBANE. See Cowbane.

WATER CRESS,—botanically *Nasturtium Officinale*. An indigenous, culinary, aquatic plant, of the cruciferous order. It inhabits rills and ditches in most parts of Britain. The roots are perennial, and comprise a great many long fibres, and attach themselves to the mud at the bottom of the water; several stems arise from each root or set of roots, and have a height of about 18 inches, and are hollow, channelled, and leafy, and divide at the top each into two or three branches; the leaves are pinnate, and have each 5 or 6 pairs of leaflets and a terminating odd one; the leaflets are roundish or almost heart-shaped, and stand almost alternately along the midrib; the flowers come out in loose spikes at the ends of the branches, and are small and white, and bloom from May till July; and the pods have a tapering form, and are full of small brown seeds. This plant came into pretty high favour about a century ago as a spring salad; and it soon obtained preference to all other spring salads on account of its agreeable warm bitter taste, and for sake of its purifying, antiscorbutic and diuretic properties; and was greeedily gathered in all its natural habitats within some miles of London for the supply of the London market; and eventually came to be an object of regular, peculiar, and somewhat extensive cultivation. The places most suitable for growing it are gently flowing rills, with a gravelly or chalky bottom, and with from 1½ inch to 4 or 5 inches depth of water; and if only muddy bottomed rills are available, the mud should be removed from them and gravel substituted. The plants are propagated by division of the root; and require to be cleaned, lifted, and replanted twice a-year. The plantings and removals should be done in successions during May and June for affording supplies of salad in August, and during September, October, and November for affording supplies in spring. The plants should be set in rows, commencing as near as possible to the sources of the stream; and the rows should be about 18 inches asunder in shallow rills, and from 18 inches to 7 feet in deeper ones. In every process of cleaning and renewal, all weeds, mud, and rubbish should be cleared away; and in the accompanying process of replanting, all the youngest and best-rooted cresses should be selected for use, and each returned into the stream and retained in its proper place with a stone; and during winter, crops in even the shallowest streams should be so managed in the cutting as to impede the current to a sufficient degree to maintain it at a depth of 4 or 5 inches. Gatherings from the plants should be done always by cutting, and never by breaking; and, in a favourable situation, with a good set of plants, may be made so often as once a-week. The cuttings should be very close in summer; and after the plants have been cut about three times, they

begin to stock, and may thenceforth be cut freely and often.

WATER DOCK. See Dock.

WATER DROPWORT. See Dropwort (Water).

WATER ELDER. See Guelder Rose.

WATER FARCY. A dropsical disease in the horse,—excited by catarrh, fever, or inflammatory action, and sometimes tending toward true farcy or glanders. Blaine calls it "that protean complaint beyond definition;" and adds, "Gibson is not very wide of the mark when he describes it as of two kinds,—one resulting from febrile attack, the other partaking of the nature of dropsy. A limb in these cases is often suddenly seen to be gorged, and often so much so as to press out the diseased accumulations, which are seen around it like dew-drops. Mr. Percivall considers it as of an inflammatory character, as did also Professor Coleman. One singularity of it, which is noticed by Mr. Percivall, and must have been also observed by others, is, that it often confines its attack to one limb only. It will sometimes break out in a state of grease; and sometimes it will extend itself to the opposite limb also. The treatment of water farcy should be prompt, or true farcy may follow. Mr. Percivall recommends to take two gallons of blood from the horse, and to follow that up by a mercurial and aloetic purge: bleed again in two or three days, and continue a ball daily of a mild kind, composed of aloes, calomel, digitalis and Venice turpentine; and follow this treatment with tonics, as blue vitriol, gentian, &c." See the articles Farcy and Dropsy.

WATER FURROW. See Draining and Ploughing.

WATER GLADIOLE. See Butomus.

WATER GERMANDER. See Germander.

WATER HEMLOCK,—botanically *Phellandrium*. An indigenous biennial plant, of the umbelliferous order. It constitutes a genus of itself, and is specifically called the aquatic. It inhabits ditches, rivulets, and ponds in most parts of Britain; and though somewhat scarce in most districts of the country, is abundant in muddy ditches and pools in the vicinity of both London and Edinburgh. It has a height of about 3 feet, and carries white flowers in June and July; and it sufficiently resembles some of the cultivated umbelliferous plants to be readily mistaken for them by ignorant or superficial observers. It is a narcotic poison, of considerable violence, yet has been used medicinally in cases of pulmonary consumption and some other diseases. It takes its botanical name phellandrium, which signifies "to deceive a man," from its liability to be mistaken for some of the innoxious umbellifers.

WATER-HEN,—scientifically *Gallinula chloropus*. A large British bird belonging to the long-toed family of grallæ. It has a near resemblance to the water-rail, particularly in the bill; but may be readily distinguished from it by its greater size, by the shield on its forehead, and by its very long toes furnished with a very narrow border. It has congeners in almost every part of the globe; and though not in the ordinary or large sense a migratory bird, it makes partial flittings from one district to another, and is found in summer on cold mountainous tracts, and during winter in lower and warmer situations. It abounds in many parts of Britain; and frequents the weedy, willowy, and tangled banks of ponds and streams, perching on the boughs of low bushes, concealing itself during the day among thick and impenetrable recesses, and running and skulking in the evening among the roots of bushes and long loose herbage by the margin of the waters in quest of its food. It lives on worms, water-insects, aquatic plants, and seeds; and it likewise picks up corn from the neighbouring stubbles. It is at all times very good eating; but from September till December, its flesh is extremely delicious. The female forms her nest with a large quantity of withered reeds and rushes closely interwoven, in a retired spot, close by the brink of the waters, and frequently places it upon some low tree or stump by the water side. She lays seven eggs, each nearly two inches long, of a yellowish white colour, marked with irregular reddish brown spots; and is said never to leave the nest during incubation, without covering the eggs with the leaves of the surrounding herbage. She has two and sometimes three hatchings in a summer. The young brood remain but a short time in the nest, under the fostering care of the mother; and as soon as they are able to crawl out, they take to the water and shift for themselves. In the spring, the water-hen has a shrill call; it strikes with its bill like the common hen; its flight is slow and awkward, with the legs hanging down, and to no great distance at a time; and in running, which it does pretty fast, the tail is so flirted up as to show the under white feathers. The total length of the bird is about 14 inches; the breadth 22; the weight from 12 to 15 ounces. The bill is red, with a greenish yellow tip, and upwards of an inch long. At the base of the bill a singular kind of red membranous substance shields the forehead as far as the eyes; and this in the breeding season has the colour of sealing-wax, and at other times varies or fades into a whitish colour. The head is small and black, except a white spot under each eye; the irides are red; the plumage of the upper part of the body has a sooty black colour, tinged with shining olive green; the outer edge of the wing, the outside feathers of the tail, and the under tail coverts, are white; the vent feathers are black, those on the belly and thighs tipped with dirty white; the long loose feathers on the sides hanging over the upper parts of the thighs are black, streaked with white; above the knee, at the commencement of the bare part, is a circle of red; from the knees to the toes the col-

ours are of different shades, from pale yellow to dark green; the toes are very long, the middle one measuring to the end of the nail nearly 3 inches; the under sides of the toes are broad, being furnished over their whole length on each side with membranous edgings, which enable the bird to swim, and readily to run over the surface of slimy mud; the legs are placed far behind. The body is long, and compressed at the sides, contrary to those of the duck kind, which are broad, flat, and depressed; and the feathers are thickly set, and bedded upon down.

WATER HOREHOUND. See HOREHOUND (WATER).

WATERING POOLS. See POND and WATER.

WATER-IN-THE-CHEST. See HYDROTHORAX.

WATER-IN-THE-HEAD,—*Hydrocephalus.* A dropsy of the head of animals, or diseased collection of serous liquid within the head's circumscribed cavities. It sometimes occurs in individuals of each of the three chief species of farm live stock,—horse, ox, and sheep.

Hydrocephalus in the horse is occasionally congenital, occasionally though rarely idiopathic, and oftener though still rarely the result of irritation of the brain or its membranes from some other disease. It sometimes or perhaps generally commences in a similar way to phrenitis or mad staggers, but more slowly and with much less violence of symptom; but its commencement can seldom be detected, and even in its progress, or the degree in which it has become established, cannot easily be determined. Some bold cure for it perhaps may at some future time be invented by mechanical abstraction of the liquid; but as yet no better practice is known than to attempt absorption by means of vesicants, mercurial unguents, nauseants, purgatives, diuretics, and repeated small bleedings.

Hydrocephalus in fœtal oxen is sometimes so great as to render parturition difficult or impossible; and in every such case the fœtus may be unhesitatingly and promptly destroyed in order to save the cow. The disease also developes itself in some weak and sickly calves; and as soon as it is ascertained to exist, they may be destroyed, as they will never come to any good. A dropsy, not in the ventricles of the brain, but between the membranes, and therefore not indicating itself by any change in the size or form of the cranium, sometimes occurs in adult cattle; but it can seldom if ever be distinguished from apoplexy or flow of blood to the head, except in being milder and slower,—and it may be treated in a similar way, by bleeding and purging.

Hydrocephalus, both of the ventricles and of the enveloping membranes, is not uncommon in both fœtal and young lambs; and, in the former case, is a warrant for promptly destroying them, —and even in the latter, does not admit of cure, unless in rare cases by the natural supply of abundant milk from the mother or from a foster-mother, with the administration of aperient and tonic medicine. Its symptoms in young lambs are dulness, want of appetite, distension of the skull, languor and projection of the eye; and stupid appearance and staggering gait; and it is sometimes mistaken for turnsick or goggles, but may readily be distinguished from that disease by the total absence of gyrating and circular motion in the gait. See the article HYDATID. It seems to be hereditary; and is most commonly caused by general debility in the ewe. If many instances of it occur on a farm, the ram formerly employed should not be employed again; and in every one instance, the ewe should be dismissed from among the breeders.

WATER LEAF. See HYDROPHYLLUM.

WATER LILY,—botanically *Nymphœa.* A genus of ornamental, floating, aquatic plants, constituting the type of the natural order Nymphæaceæ. The botanical structure of this order has been a subject of great dispute among the most eminent botanists,—some contending that it is exogenous, and others that it is endogenous. Its true place seems most probably to be among the many-carpelled thalamiflorous exogens, not far from the barberry and the moonseed families, or even from the magnolia family. All are floating plants of great interest and beauty; and many have flowers of most elegant forms and very pleasing or brilliant hues. Three adorn the waters of our own wilds with liliaceous magnificence; and all the rest perform a similar office—some with vastly more splendour—in other countries. About 20 hothouse species, and upwards of a dozen hardy ones occur in British gardens; and are distributed among the genera nymphæa, nuphar, euryale, and nelumbium. See the articles LOTUS, NELUMBIUM, and NUPHAR.

No fewer than eighteen of the species of Nymphæaceæ in Britain belong to the genus nymphæa; and seventeen of these are exotic. Seven, including the indigenous one, have cordate leaves and white flowers, and, with one exception, are hardy; seven have peltate and for the most part toothed leaves and either white or red flowers, and are all tender; and four have peltate and for the most part entire leaves and blue or bluish flowers, and are all tender. The hardy species may be grown in ponds, canals, and similar collections of water; the stove species require to be grown in tubs of water, placed in a warm part of the house, with some rich loamy soil at the bottom; and all are propagated either from seeds or by dividing the roots, or by separating the tubers.

The indigenous species, or common water lily, *Nymphœa alba,* inhabits the clear ponds and slow clear rivers of many parts of Britain; and is one of the most superb of our native flowering plants. Its root is tuberous and horizontal, and sends down many long stout radicles, with fibrous extremities; its leaves are oval heart-shaped and about four inches wide, and have nearly parallel or close lobes at the base, and are entire and

smooth, and float on the surface of the water; and its flowers are four or five inches wide, and have a calyx with white upper surface, often tinged with pale red, and have white petals and yellow stamens and pistil, and bloom in June and July. The whole plant is slightly vascular, and exhales rapidly, and becomes very soon dry; the leaves have innumerable absorbing pores on the under surface, and innumerable exhaling ones on the upper surface; the flowers emit a faint sweet smell, and expand only in sunshine in the middle of the day, and either recline on the water or sink into it when they close toward evening; and the whole plant, after ripening its seeds in autumn, sinks to the bottom to enjoy there its winter repose. Hogs eat this plant; goats dislike it; and cows and horses totally reject it. The root was eaten in a boiled state by the ancient Egyptians, and is sometimes used as a substitute for corn by the modern Swedes,—but requires, for all esculent purposes, to be well divested of its bitter taste by frequent washings; and it is used in Ireland and the Hebrides for dyeing a brown colour, and might be used also for tanning and currying leather; and is said to have been found serviceable for the cure of leprosy. The stems are better than oak-galls for dyeing grey; and the seeds were used by the ancient Egyptians as a bread-stuff. Young plants appear in the following spring from ripe seed-vessels thrown, immediately after their becoming ripe, into still ponds or large ditches; and an old plant may be removed by carefully digging up the root with a large ball of mud from beneath the water, placing it in an old fish basket, and sinking the whole in the place where it is intended to remain,—leaving the plant to make slow and firm anchorage for itself during the decay of the basket.

WATER LILY (Yellow). See Nuphar.

WATER MEADOW. See Irrigation.

WATER MELON. See Cucumber.

WATER MILFOIL, — botanically *Myriophyllum*. A small genus of aquatic plants, of the haloragis family. The whorled species, *M. verticillatum*, inhabits ponds in some parts of England, and carries herbaceous-coloured flowers in July; and the spiked species, *M. spicatum*, inhabits ditches in both England and Scotland, and carries red flowers from June till August; and both have perennial roots, stems about a foot long, floating foliage, and a weedy appearance. Some tropical species are known.

WATER MILL. See Mill.

WATER PARSNIP, — botanically *Sium*. A genus of herbaceous plants, of the umbelliferous order. Four species grow wild in Britain; nearly a dozen have been introduced from other countries; and upwards of another dozen are known. Several are poisonous, and most of the others are more or less acrid and dangerous; yet one which was long ago introduced from China is culinary, and will be found described in the article Skirret. All the species in British collections are perennial-rooted; some are tuberous, some creeping, and some erect and annual-stemmed; two are yellow-flowered and the rest are white-flowered; all are more or less aquatic, and none possess any attractions for the florist.

The broad-leaved water parsnip, *Sium latifolium*, inhabits fens, ditches, and rivulets in many parts of Britain. The root is fleshy and creeping, and has numerous long fibres; the stems are annual, erect, angular, deeply furrowed, hollow, smooth, leafy, very little branched, and from 2 to 6 feet high; the leaves are pinnate and from 6 to 12 inches long; the leaflets are oblong, lanceolate, and equally serrated; the flowers come out in both axillary and terminal umbels, and are small, numerous, and of a snow-white colour, and bloom in July and August; the fruit is small and of an elliptic-ovate form; and the seeds have an aromatic flavour. The whole plant is poisonous; and the roots and herbage of it more so than the seeds. Hogs and horses eat it, but sheep abhor it.

The narrow-leaved water parsnip, *Sium angustifolium*, also inhabits the ditches and rivulets of many parts of Britain. It is only about half the size of the broad-leaved species. The root is extensively creeping; the stem is erect, annual, cylindrical, striated, and much branched; the leaves are simply pinnate; the leaflets are unequally lobed and serrated; the umbels are stalked opposite to the leaves; the flowers are white, and bloom in July and August; and the fruit is roundish-ovate, and has three dorsal ribs and two lateral ones on each side.

The procumbent or knot-flowered water parsnip, *Sium nodiflorum*, also inhabits the rivulets of Britain. It is an evergreen creeper, and has seldom a height of more than 6 or 8 inches. The stems are cylindrical, hollow, striated, branched, of variable length, procumbent or floating, and in many instances creeping; the leaflets are ovate and equally serrated; the umbels are nearly sessile, and grow opposite to the leaves; the flowers are small, and have a greenish white colour, and bloom in July and August; and the fruit resembles that of the narrow-leaved species, but is more acute in the ribs. The juice of this plant has been recommended, very injudiciously and dangerously, for cutaneous affections.

The creeping water parsnip, *Sium repens*, inhabits boggy meadows, watery commons, and other moist grounds in various parts of Britain. It is smaller than even the procumbent species; but resembles it in being a creeping evergreen. The stems are slender, quite prostrate, and decidedly creeping; the leaflets are roundish and deeply toothed; and the flowers are white and bloom in June.

WATER PEPPER. Two hardy, floating, aquatic, annual plants, of respectively the carnation and the polygonum families. The common water pepper, *Elatine hydropiper*, has a curious ap-

pearance, and a height of about two inches, and carries white flowers in August, and was introduced to Britain long ago from the south of Europe. The mild water pepper, *Polygonum mite*, has an ornamental appearance, and a height of about a foot, and carries red flowers from June till August, and was introduced to Britain in 1800 from North America.

WATER PLANTAIN. See ALISMA.

WATER PURSLANE,—botanically *Peplis*. A small genus of curious small plants of the salicaria family. The common species, *Peplis portula*, is an annual indigen of watery places with sandy, gravelly, or moorish soil in many parts of Britain. The root is fibrous; the stems are quadrangular, smooth, leafy, 3 or 4 inches long, prostrate, floating, and in many instances creeping; the leaves are opposite, stalked, obovate, entire, smooth, and scarcely an inch long; and the flowers are axillary, solitary, almost sessile, small, and reddish, and have the petals so concealed by the calyx as to be scarcely visible, and bloom from July till September.

WATER-RAIL, — scientifically *Rallus Aquaticus*. A shy and solitary yet abundant bird constituting the type of the rail family of grallæ. It is distinguished, in common with all its family, by the comparatively great length of its toes; and in most other respects, it somewhat closely resembles the majority of them, particularly the corn-crake, but has a longer bill than any. Its total length is 12 inches, its breadth 16 inches, and its weight 4½ ounces. The bill is slightly curved, 1¾ inch long, and of a dusky black colour, but reddish at the base; the irides are red; the top of the head, the hinder part of the neck, the back, the scapulars, and the coverts of the wings and tail, are black edged with dingy brown; the under parts of the body, from the chin to the middle of the belly, are ash colour, but in some individuals, supposed to be young ones, are margined with white; the side feathers are beautifully crossed with black and white, and slightly tipped with reddish brown; the inner side of the thighs, the belly, and the vent, are pale brown, sometimes speckled with bluish ash-colour; the under tail coverts are white; the quills are dusky; the tail consists of twelve short black feathers, edged and tipped with dusky red, —some of those on the under side barred with black and white; the legs are placed far behind, and have a dusky red colour; and the toes are long, and have not any connecting membrane. The flesh has a delicious flavour. The eggs are more than 1½ inch long, and have a pale yellowish colour, marked all over with dusky brown spots. This bird abounds in the marshes of Sweden, Norway, Russia, and the southern and central parts of England, but is seen in the northern districts of Britain only during winter. It loves most such low, moist banks of ponds and streams as are overgrown with reeds, sedges, and other coarse aquatic herbage; it runs expertly and furtively athwart its haunts, occasionally flirting up its tail, and practising great adroitness in diving out of the view of any possible observer; it greatly resembles the corn-crake both in agility of ground motion, and in aversion to take flight; it generally tantalizes and disappoints the sportsman, and often exhausts his patience and distracts his dog, seldom rising till it has crossed every pool and skulked through every avenue within the sphere of its retreats, and sometimes even taking to the water, swimming the open parts tolerably well, and flitting with great speed over parts which are overgrown with aquatic vegetation; but when once it becomes flushed, it fags in running, takes to the wing, flies very indifferently, with its legs hanging down, and is easily shot.

WATER REED. See ARUNDO.

WATER SICKNESS. See DROPSY.

WATER SOLDIER,—botanically *Stratiotes*. A small genus of aquatic plants, of the hydrocharis family. The aloe-like species, or water-aloe, *Stratiotes aloides*, inhabits deep ditches and pools in some parts of England; and is an object of much beauty and elegance, yet sometimes fills its habitats, and even places where it is artificially planted, with such a phalanx of sword-like-leaves as to become almost a troublesome weed. It is a stoloniferous perennial; and has numerous smooth radical leaves, and a solitary central flower-stack, but no proper stem. It floats on the surface of the water during summer, sinks to the bottom after blooming, and sends out long simple runners on the mud; and each runner terminates in a bud or young plant, which first forms several long radical fibres, and effects an anchorage in the mud, and then in summer rises to the surface of the water, there to go through the processes of flowering; and after having bloomed, it sinks in the water, matures its seeds, sends out runners, and dies. The leaves have an acute form and a highly vascular structure, and are fringed with very sharp saw-like teeth, and measure 4 inches or upwards in length; the flower-stalk is firm, strong, two edged, and much shorter than the leaves; and the flowers are white, large, and beautiful, and bloom in June and July.

WATER STARWORT. See CALLITRICHE.

WATER VIOLET. See FEATHERFOIL.

WATERWORT,—botanically *Elatine*. A small genus of curious floating aquatic plants, of the carnation family. The three-petaled or small waterwort, *Elatine tripetala*, grows wild on the margins of ditches and ponds in sandy tracts, in many parts of Britain. Its roots are annual and comprise many long fibres; its leaves are opposite, and have a roughness of surface occasioned by numerous minute points; and its flowers have a pale flesh or reddish colour, and are for the most part three-cleft, and bloom in August. An introduced exotic species is noticed in the article WATER PEPPER.

WATSONIA. A genus of ornamental, bulbous-rooted, Cape-of-Good-Hope plants, of the iris order. Nearly twenty species have been introduced to the greenhouses of Britain. They vary in height from 5 or 6 inches to about 4 feet; they display great diversity in the colour of their flowers, composing white, carmine, lake, pink, crimson, scarlet, purple, and variegations; and some bloom in spring, others in summer, and others in autumn. All love a mixed soil of sand, peat, and loam, and are propagated from offsets.

WATTLE. A kind of hurdle formed of split wood, and used either in the same way as hurdles or for any similar purpose. See the article HURDLE.

WAX. A substance of medium character between a fat and a resin. The best known kind of it is a peculiar and abundant secretion or product of the honey bee. See the article BEE. On straightening the lower part of the body of the insect, and raising the segments into which it is divided, eight little bags will be discovered, four on each side; these are the wax bags, and belong to an organ the secretions of which contribute to form the wax,—and this is elaborated from the same substances which are collected for the honey. It is certain that bees confined and fed upon sugar only, form wax; and it is equally certain, from long and careful experiment, that they could produce no wax if they had neither sugar nor honey to make it from, when debarred from flowers. It is therefore a reasonable inference that the substance sucked in by the bee from the nectaries of flowers forms both wax and honey, the difference consisting only in the mode of its elaboration, and in the peculiar secretions of the stomach, and the organ to which the wax-bags belong. Hüber found that from sugar bees produced much more wax than from honey. The natural colour of wax is the purest white; in which state, and quite odourless, the new cells of the honeycomb remain, until filled with the luscious deposit they are formed to contain. The yellow colour which the wax assumes, is therefore due to the honey, —a portion of which always remains in the wax until bleached; and indeed one of the strong characteristics of bees' wax, with reference to any other wax, is the odour of honey which it retains in its unbleached condition. The wax of bees has the same precise elements as that found in vegeble matter; and, though an animal product, it contains no nitrogen. Dr. Ure makes it to consist of thirteen atoms of carbon, eleven of hydrogen, and one of oxygen; which would thus make eleven atoms of olefiant gas or bicarburetted hydrogen, one atom of oxide of carbon, and one atom of surplus carbon,—because olefiant gas is formed of an atom of carbon and an atom of hydrogen, whilst oxide of carbon consists of one of carbon and one of oxygen—the hydrogen and carbon in the former being bulk to bulk, the carbon in the latter being double the bulk of the oxygen. The odd atom of carbon seems so singular that there was perhaps an error in the analysis, so that there may really exist twelve atoms of hydrogen instead of eleven; in which case the constituents of wax would be twelve atoms of olefiant gas and one of oxide of carbon. It is this richness in olefiant gas which renders wax so valuable a combustible material for affording light; and if it were plentiful enough to be converted into gas, the light from it would be probably much more brilliant than that from even oil gas.

Two separate principles are found in wax, which of themselves constitute two different wax-like substances having distinct properties. If pure wax be treated with boiling alcohol, a considerable portion of it is dissolved. The solution, when cool, deposits the substance called *cerin.* If the portion of the wax undissolved be again treated with boiling alcohol, an additional quantity of cerin is obtained, and so on until no more of the residuum will dissolve. This residuum is *myricin,*—a substance much denser than wax, insoluble in boiling alcohol, and of the same specific gravity as water. The average proportions, in bees' wax, of cerin and myricin are about 75 parts of the former, and 25 of the latter. Cerin is perfectly white, strongly resembling bleached-wax; it is decomposed by distillation, and is fusible at a temperature more than 20° lower than this latter; and if treated with caustic alkaline ley, it is converted into margaric acid, and a substance termed *cerain.* Myricin is greyish white; and it does not decompose in distillation, but may be vaporised with scarcely any change Though cerin, when separated from wax, will form margaric acid, which is a product of saponified fat, wax itself will not saponify with the alkalies, a fact that distinguishes it from fats, oils, and resins. Wax therefore contains neither elain nor stearin, the two principles of fat and oil, resins containing both in a very concrete form.

For making candles, for the use of the surgeon the perfumer, and the confectioner, for modelling, doll-making, and for many other purposes, yellow wax must be rendered white. It is usually bleached by the following process:—Being melted by either hot water or steam in a vessel of wood or copper tinned, the clear liquid is poured off from the sediment into an oblong trough with a line of holes in its bottom, through which the melted wax runs upon wooden revolving cylinders set horizontally, the lower half of their diameter as they revolve being immersed in cold water. By these means the cylinders become covered with thin layers or ribbons of wax, which are stripped from them, and set to blanch in the sun, during which process they are kept constantly wet. The blanching takes place in an open field, the wax being laid upon long webs of canvass, stretched horizontally two or three feet above the surface of the soil, and then

covered with nets to prevent the wind from blowing it away. Being watered continually, it soon becomes white. If the blanching does not go on well, the wax is remelted and again run upon the cylinders. The sunbeams are so indispensable to blanching wax, that it will not keep its colour if blanched under rain, which also makes it lose a portion of its weight. On the Continent, either alum or bitartrate of potash is incorporated with the wax in the first melting. At Le Mans, where the best wax candles are made in France, great attention is paid to the process of blanching. When the ribbons are completely white, the wax is melted, strained through silk sieves, and run into their circular discs. White wax purified, when in thin plates, besides its delicate whiteness, is translucent, but not so much so as spermaceti. Candles made of the latter are called in France bougie diaphane, or *diaphanous candle*, whilst the wax light is termed simply bougie, to distinguish it from chandelle, which signifies a candle made of tallow. In Paris, and many other towns in France, all the wax candles sold are termed bougies du Mans, from the circumstance of Le Mans being celebrated for its wax lights; though the real bougie du Mans brings a higher price than any other, on account of the brilliancy of its light, which never requires the aid of snuffers. Attempts have been made to bleach wax with chlorine, also with the chlorinated alkalies, soda, potash, and lime; but such attempts have been unattended with success, because all those bleaching preparations render the wax brittle, and impair its property of yielding light. The average specific gravity of pure white wax is 0·962, taking water at 1·000. It melts at 155° Fahreinheit; but it becomes soft and plastic for the purposes of the arts at 86°. At the freezing point, 32° Fahrenheit, it is hard, and as brittle as black resin.

Vegetable wax exists ready formed in several trees, in the juice of some plants, in the pollen of many flowers, in the skin of plums and other fruits, and is a constituent of the green fecula of several plants, especially the cabbage. It also forms a varnish upon the upper surface of the leaves of many trees; it may be found in the juice of the cow-tree, and upon the stem of the violet variety of the sugar-cane; and it abounds in the bark of the *Ceroxylon andicola*, and in the berries of the *Myrica cerifera*, the *Myrica carolinensis*, the *Myrica latifolia*, and the *Myrica angustifolia*. There is also a tree common on the Malabar coast, and scarcely known in England, which yields immense quantities of a beautiful light green wax, easily blanched, and producing a splendid light; and, under proper cultivation, this wax might form a lucrative branch of trade, and very much improve our candle manufactories, now greatly dependent upon the north of Europe for their supply of tallow.

Vegetable wax is composed of the same principles as the wax of bees, but is generally of greater specific gravity, from possessing a larger portion of myricin; and this is perhaps the reason why nature makes the insect elaborate and not collect it,—the wax for the honeycomb no doubt requiring an excess of cerin, whilst that for vegetable purposes is more effective with a larger proportion of myricin. All the chief kinds of vegetable wax, however, differ somewhat widely from one another, both in some of their outward properties and in the processes by which they are separated from the plants and converted into use. The wax of the *Ceroxylon andicola*, or cera de palma, abounds most on the central cordillera of New Grenada, and is separated in its crudest state from the tree by scraping the bark. The scrapings are boiled in water; the wax swims in a softened though unmelted state on the top; the impurities fall to the bottom; and the purified wax is formed into balls and set to dry in the sun. It is with this substance, to which however a small quantity of fat is often added to render it less brittle, that the loaves of wax and the candles of the country are formed. After it has been melted, the cera de palma is of a deep yellow colour, slightly translucid, as brittle as resin, and presenting a waxy fracture well characterised. Its melting point is a little above that of boiling water. Boiling alcohol dissolves it readily, and in cooling the solution sets into a gelatinous mass. Ether dissolves it, as do also the alkalies. The wax of the *Myrica cerifera*, is procured by boiling the fruit in water. The tree is extremely common in Louisiana and the temperate regions of the Andes. The fruit yields as much as 25 per cent. of wax; and a single shrub will yield from 24 lbs. to 30 lbs. of berries per annum. The crude wax is green and brittle; and, in order to be made into candles, requires the addition of a certain quantity of grease. The wax of the sugar cane is gathered from a powder or bloom of a waxy nature, which melts at the temperature of 180° Fahr. This wax is so hard that it can be pulverized; and it may be made into candles, which for the brilliancy of their light are not inferior to those of spermaceti. M. Avequin, who directed attention to this subject, found by his experiments that a hectare, nearly 2½ English acres, of the violet cane would furnish nearly 200 lbs. of wax. The wax of the *Myrica carolinensis*, is noticed in the article Wax Tree.

There is also a mineral wax called ozocerite, found at the foot of the Carpathian Mountains, and lately, but in very small quantities, in the north of England, near the coal mines. This substance has less tenacity than wax; it easily crumbles, and can be beaten to powder in a mortar. Its specific gravity is also less than wax, being about 0·926. Its colour is different shades of brown; but it will bear bleaching. In even its natural unpurified state it is translucent. Its melting temperature is the same as bees' wax; its plastic temperature 100° Fahrenheit. In

Moldavia, the ozocerite is used for candles, which, however, do not give so good a light as those made of bees' wax.

A great deal of wax is imported into this country, in addition to that which we obtain from our native hives; for it is used in many of the arts, both common and fine. Besides the manufacture of wax candles, many thousands of individuals gain their living by making wax dolls, to say nothing of the forming of wax-work portraits, and the modelling of objects of still life and fruits,—in both which frequently much talent and considerable ingenuity and knowledge are displayed. To the engraver, wax is an indispensable object, as well as to the artist-painter, the architect, and the sculptor. In numerous useful crafts, as in many of the more scientific manufactures, wax is an article of peculiar utility; and it forms the base of the salves, ointments, and cerates of the surgeon, and occupies a similar place in the sweet-swelling pomatums and unguents and cold creams of the perfumer. It is also a valuable aid to medicine. Its demulcent properties render it very efficacious in diarrhœa and dysentery and in other cases where it is required to assist in protecting the mucous membrane of the stomach from the effect of any acrid or poisonous substance. It is generally administered first melted with olive oil, and then triturated with yolk of egg, adding, by degrees, a solution of gum-arabic, or some other mucilaginous liquid.

WAX MOTH,—scientifically *Galleria Cereana.* A bee-infesting moth, of the tinea family. The male measures about an inch from tip to tip of the expanded wings; and the female is considerably larger. The upper wings of the male are short and obtuse, and have a dusky grey colour, considerably varied in the tint, with a brown-spotted whitish band from the base to the middle; the under wings have an ash or brownish grey colour, with brown fringes and white extremity; the body is yellowish brown; and the legs are yellowish grey with spots of a lighter colour. The upper wings of the female are longer and straighter, and have the white band very faint; the under wings are white, with dark grey border and veins; and the head and the back are dark rusty brown. The female lays her eggs in bee-hives, and usually accomplishes her object in the night, when the bees are at rest. "She commonly places them in some crevice about the lower parts of the hive; but she even ventures at times to enter the hive, and lay them among the combs. Whenever the caterpillar first sees the light, its instinct immediately leads it to the combs, among which it penetrates, forming winding galleries, which are lined with strong silk, so thick that the stings of the bees cannot take effect through it. There is a difference of opinion among apiarians as to what portion of the contents of the hive this intruder chiefly employs for food. Some allege that it confines itself to the wax; others, among whom is Feburier, whose opinion is entitled to consideration, assert that it devours neither the honey nor the wax, but the exuviæ of bee-nymphs, and, very probably, the nymphs themselves. But, however this may be, the devastation caused by these caterpillars, when at all numerous, (and 300 have been found in a hive,) is speedily destructive to the prosperity of the hive; the bees gradually give way to them, and ultimately are often compelled to quit the field altogether. When full-grown, the caterpillar is about an inch long, of a dull white colour, with a brown head, and covered with small brownish tubercles, from the centre of which springs a slender hair. They attain their full size in three or four weeks after being hatched, when they prepare for becoming pupæ, by weaving a very strong web, either in some of the tubes they had formerly excavated, or in some secure corner of the hive. On the Continent there are two broods in the year; but it does not appear whether this be likewise the case in this country. Here the moth is not nearly so plentiful as in many other parts of Europe. A nearly related species, *Galleria alvearia*, likewise occurs in Britain, but it is even scarcer than that just described.—There is but one sure method of clearing the bee-hives of the wax moth; and this consists in looking for and destroying the larvæ and pupæ. If the hives are examined only once a week for this purpose, any traces of covered passages will easily be perceived, and must be immediately removed and destroyed with the caterpillars in them. The corners of the hive must also be closely examined in case of cocoons being there, which must also be destroyed. A lighted candle has been also recommended to be held before the hole of the bee-hive, that the moth, flying out to the light, may be burned. But this is labour in vain, for the female does not leave the hive till she has laid her eggs; and it is only supernumerary males that perish in the flame."

WAX TREE. Any tree or shrub which yields vegetable wax. See the article Wax. But the name is emphatically and even distinctively given in some English works to the *Myrica Carolinensis*,—an ornamental, economical, hardy, evergreen, amentaceous shrub, which was introduced to Britain from North America in 1730. Dr. Hamilton, writing in 1826, and recommending this plant for extensive cultivation in waste tracts of the South of England, says, "It is perfectly acclimated in France, where it flourishes luxuriantly in a sandy and blackish turf, rising from the height of four to six or even seven feet, producing in general an abundant crop of berries every year, and requiring little care in its culture. It is readily propagated, either by sowing the seeds in spring, and afterwards transplanting, or, which is the most expeditious method and equally successful, by taking off the young shoots, which rise in profusion at the base of the larger shrubs,

and planting these out at the distance of about three feet from each other. The *Myrica Carolinensis* succeeds wherever the soil is light and rather moist; and has been long known to flourish even in the dry sands of Prussia. In this latter kingdom, as we learn from an interesting memoir of Charles Louis Cader, inserted in the Annales de Chimie, it was successfully cultivated by the late Mr. Sulzer in a garden on the banks of the Spree, half a league from the city of Berlin, in latitude 52° 53′, which is nearly a degree and a half further north than London, and where the mean annual temperature is only 2° 9′ higher than that of London. Here the wax tree attracted the peculiar notice of every visitor by the delicious odour of its leaves, which they preserved a long time, and the fragrance of its berries. The wax obtained from these berries was also so highly odoriferous, that a single candle formed from it not only perfumed the room in which it was lighted during the period of its burning, but also for a very considerable time after it was extinguished. From what has been said we may, I think, fairly conclude that this valuable plant is capable of being successfully cultivated in the light sandy soils of a considerable part of Hampshire, in the Isle of Wight, in the vicinity of Plymouth, and in many parts of the open, and, at present, neglected tract in the neighbourhood of the Lizard, where acres, now not worth 2s. 6d. an acre for their produce above ground, might be made almost to rival on their surface the wealth which they conceal in their bowels. In America, a very fertile shrub will yield nearly 7 lbs. of berries, 4 lbs. of which yield 1 lb. of wax. This, when melted, is of a greenish yellow colour, and of a firmer consistence than bees' wax. Candles made of it give a white flame and good light without smoke, and do not gutter like tallow candles. When quite fresh they afford a balsamic odour, which the inhabitants of Louisiana esteem highly salubrious. The following is the simple process by which the wax is separated from the berries. Having collected a sufficient quantity, they are thrown into a kettle and covered with water to the depth of about six inches; the whole is then boiled, stirring the grains about, and rubbing the berries against the sides of the vessel to facilitate the separation of the wax, which rises to the surface of the water like fat, and is skimmed off with a spoon, after which it is strained through a coarse cloth to free it from impurities. When no more wax rises, the berries are removed with a skimmer, and a fresh supply put into the same water, taking care to add boiling water to supply the place of that evaporated during the process, and changing the water entirely after the second time. When a considerable quantity of wax has been thus obtained, it is laid upon a cloth to drain off the water still adhering to it; after which it is dried and melted a second time to purify it, and is then formed into cakes for use." See the articles Wax and Candleberry Myrtle.

WAX (Vegetable). See Wax and Wax Tree.

WAY BENNET. See Barley.

WAY-BREAD. See Plaintain.

WAYFARING TREE. See Viburnum.

WEANING. The means employed to induce a young mammalian animal to cease sucking, and to habituate itself to the use of common food. See the articles Foal, Calf, and Sheep.

WEASEL,—scientifically *Mustela Vulgaris*. A digitigrade, carnivorous mammal, constituting the type of a somewhat numerous family, comprising the polecats, the ferrets, the stoat, the skunk, the martens, the otters, and some foreign weasels. It differs remarkably from most other quadrupeds, except those of its own family, in the small proportion which its height bears to its length. Its height is not above 2½ inches; its length from the nose to the tail is about six or seven inches; its tail is only 2½ inches long, and so ends in a point as to add considerably to the apparent length of the body. The back, the sides, and the legs have a prevailingly pale tawny brown colour, resembling that of cinnamon; the throat and the belly are white; each jaw, beneath the corner of the mouth, has a spot of brown; the eyes are small, round, and black; the ears are broad and large, and, in consequence of a fold at the lower part, have the appearance of being double; the cheeks are whiskered like those of a cat; and the teeth amount to thirty-two, and are eminently adapted to the tearing and chewing of the food. The female brings forth in spring, and bestows great care on the comfort of her young, and prepares for them a bed of straw, hay, leaves, and moss. From three to five young ones form a litter, and are born blind, but soon acquire both sight and strength to follow their dam in her excursions. The weasel moves by unequal bounds or leaps; and, in climbing a tree, it gains a height of some feet from the ground by a single spring; and even runs so facilely and nimbly up the sides of a wall as to be able to make good its entrance into a hole or retreat at any altitude and in any sort of situation. It leaps upon its prey at a single bound, and sometimes at one long leap and from a concealed point of observation; and it possesses such flexibility of body and such agility of action as easily to evade the attacks of much stronger animals than itself. It always preys in silence, and never utters a cry of any kind or at any time except a sort of rough squeaking when it is angry or pained. It frequents barns, granaries, outhouses, and farm-yards, and is both a friend and a foe to the farmer, sometimes doing more good than harm, and sometimes more harm than good; and in summer, it ventures to a distance from its usual haunts, and goes in quest of colonies or swarms of rats, and may often be found by the side of water in the vicinity of corn-mills. It serves

the farmer in winter by clearing his premises of rats and mice,—doing far more execution upon them than can be possibly done by the cat; but it sweeps the pigeon-house of both eggs and young birds, and makes fearful havoc in the poultry-yard and upon the hen-roost. It sleeps in its hole during the greater part of the day, and comes forth in the evening to commence its depredations, and may then be seen stealing cautiously from its retreat, and creeping furtively in search of eggs, chickens, pigeons, game, and rabbits. It does not devour on the spot what it kills, but drags it off to be eaten at its leisure; and if it find old hens or cocks abroad from the poultry-yard, it does not scruple to attack them. It has an insatiable and coarse appetite, and loves its food best when reduced to a state of incipient putrefaction, and always emits a very strong and offensive odour. It cannot without extreme difficulty be domesticated; yet it might perhaps be so far tamed as to be rendered serviceable for clearing out rats from ships, close old buildings, and similar places. When it becomes wastefully or insuperably mischievous upon a farm, it may be caught by the hutch or box trap, baited with an egg or a small bird, or destroyed by a mixture of sal ammoniac, white of egg, wheat flour, and honey, laid in small doses near the places which it frequents.

WEASEL-SNOUT. The yellow dead nettle. See the article DEAD NETTLE.

WEATHER. The agencies, phenomena, and departments of weather are fully discussed in the articles METEOROLOGY, ATMOSPHERE, CLOUDS, CALENDAR, WIND, ELECTRICITY, DEW, RAIN, SNOW, FROST, HOAR-FROST, ACCIDENTS, BLIGHT, BAROMETER, ANEMOMETER, and many others whose titles either occur in the chief of these articles, or will readily suggest themselves to all persons desirous of information. Only the subject of weather-prognostics remains to be discussed here; and even this has elsewhere been so fully disposed of as to its principles, that it requires to be discussed here with reference only to facts and appearances.

"The study of the changing phenomena of the atmosphere," remarks our contemporary, W. Cuthbert Johnson, Esq., "has from the earliest periods occupied a greater or less share of attention from the tiller of the soil, the gardener, and those engaged in the pasturage of animals. To no individual (the mariner, perhaps, excepted) is a foreknowledge of the probable future state of the weather of more consequence and importance than the agriculturist; for on this must mainly depend the progress and success of his field operations, his seed-time and his harvest, and the greater or less return afforded by his crops. It may not comport with the dignity of the man of science, or the elevated learning of the erudite philosopher, to have his eyes and ears open to the plain and simple rules and guides which nature lays out before him. Perhaps he has little of leisure to note the everyday phenomena which the atmosphere and all animate and inanimate nature hold up to observation, as in a glass, where all who use their eyes may read as they run. The companions of his study are the more costly and elaborately prepared philosophical instruments; how much, however, might their value be enhanced by a careful and comparative observation of the 'skyey influences,' as the poet terms them? But to these closet companions the husbandman, the shepherd, the traveller, the fisherman, and the mariner have rarely access, while engaged in the busy out-of-door occupations of their several avocations. Those who till the land, or who go down to the sea in ships, of all others, are they who become, by habits of observation and reflection, most conversant with the signs and changes of the heavens. The sun, the moon, and the stars are to them monitors and instructors, whose warning voices meet a prompt and ready response. The ripple of the wave, the curl of the smoke, the passing shadow of the cloud, the budding of the tree, the arrival and departure of the migratory birds, the frolicsome gambols of animals, every leaf that quivers in the sunbeam, every plant that drinks the dew of heaven, the myriads of insects, and creeping things innumerable, that inhabit each leaf and opening flower, are all fraught with instruction and information to the experienced and watchful observer. Around, above, beneath, all animate and inanimate creation, animals, vegetables, the elements, a thousand objects in a thousand directions, in every recurring season, furnish their quota of information towards our stock of meteoric knowledge, and foretell the approaching variations of atmospheric phenomena. The experienced fisherman and the watchful and wary mariner will predict the coming storm, by the tiny cloud and other unerring criteria which frequent and attentive observance of the sky has rendered familiar, long before its approach is visible to the ken of the ordinary and inattentive observer. It has been well remarked, that 'the shepherd, whose sole business it is to observe what has a reference to the flock under his care, who spends all his days and many of his nights in the open air, under the wide-spread canopy of heaven, is obliged to take particular notice of the alterations of the weather; and when he cares to take a pleasure in making such observations, it is amazing how much progress he makes in them, and to how great a certainty he arrives at last, by mere dint of comparing signs and events, and connecting one observation with another. Every thing in time becomes to him a weather-gauge; the sun, the moon, the stars, the clouds, the winds, the mists, the trees, the flowers, the herbs, and almost every insect, animal, and reptile with which he is acquainted—all these become, to such a person, instruments of real knowledge.' To the farmer, a careful

study of the weather, and of the inferences to be drawn from precedent and from natural and artificial data, comes fraught with numerous and important considerations. Like the angler, the husbandman 'must observe the wind, sun, and clouds by day; the moon, stars, and waves of the air by night.' Few are so entirely dependent on the caprice of the weather, for the commonest routine operations of the farm, as the agriculturist."

Many of the most common weather-prognostics have been observed in all ages from very ancient times till the present day, and in all sorts of countries of similar climates and latitudes from the most barbarous to the most civilized, and by all classes of the population interested in them from the most boorish peasant to the most intelligent land-owner. A very eminent writer on them was Aratus, a Greek poet, who lived so long ago as about 270 years before the Christian era. In fact, "it is their being familiar to almost every age and country," as Mr. Foster remarks, "which affords the strongest confirmation of their correctness to those who have not had constant experience of them." Some popular prognostics, indeed, are founded on mistake, or on very limited and peculiar observation, and therefore possess no value, or oftener mislead than direct; and even all, or almost all, are denounced by certain theoretic writers as matters of mere superstition, empiricism, and quackery; but the great majority of the best known or most generally diffused are more or less true, and have been founded on extensive and scrutinous observation, and can easily be vindicated or explained by an appeal to heat, light, electricity, atmospheric pressure, and the other physical agencies which control the chemistry of the air and of organic bodies; and even some of the more obscure or seemingly outré ones, which cannot readily or at all be accounted for in the present state of science, rest on such sure observation as to be well worth the attention, not only of farmers for assisting their prescience of the weather, but of meteorologists for prompting and guiding their inquiries into the unexplored or unknown departments of the vast natural agency of our world.

We shall omit all reference here to prognostics by the barometer and by other artificial means, and shall present our readers with a somewhat large collection of natural prognostics, comprising most of the best and many of the middle-rate, but excluding all the inferior or most doubtful; and we shall arrange these in a sort of classified order under the heads of prognostics by plants, prognostics by animals, prognostics by air and sky, prognostics by the heavenly bodies, prognostics peculiar to certain seasons, and prognostics peculiar to upland districts. But we must say to our readers, as Henry Stephens, Esq., the author of the Book of the Farm, says to his, "You must not suppose that all the prognostics of the weather enumerated here will invariably hold true, and that you will be as certain of recognising every phenomenon here described, as if you had contemplated it before you in a picture; or that a great number of them can be observed at one time. Such certainty cannot as yet be attained in predicting and describing the changes of the atmosphere, which are generally presented to us again with such modifying circumstances, as, though the character of the kind may be distinctly preserved, the species or variety of the phenomenon may differ considerably. Still by acquiring at first the leading features of these phenomena, you will afterwards be able, by attentive observation, to recognise most of the particulars which go to make up their distinctive characters. A long-continued state of any kind of weather strongly influences the character of that which is to follow. Thus the barometer sometimes sinks, and even all the clouds present every appearance of rain, and yet no rain follows, and the symptoms subside, and clear weather returns, provided the weather had been long dry before. And, on the other hand, symptoms of drought will fail after a long continuance of wet. Nevertheless, these are only exceptions to the general rule. Be assured that every authenticated symptom is correct, and may be regarded as the forerunner of its effects; and you should be prepared to provide against these, if the symptoms are injurious, although it may happen that the forebodings have not been realized."

Prognostics by Plants.—Plants comprise such an infinity of ducts and cells and air-vessels, holding constant communication with the humidity and gases and heat of the atmosphere, that they may be regarded as delicate and complex hygrometers and thermometers, which, if attentively observed or accurately known, cannot but indicate comparatively minute changes in the state of the air, and therefore foretell vicissitudes in the weather. All wood, even the hardest and most solid, but particularly such as is light and dry, so readily absorbs vapour as to swell in moist weather; insomuch that pieces of sallow dried in an oven, and inserted into drilled holes in the rock of quarries, have been used in damp weather for the same purposes as blasting, —the pieces of wood absorbing humidity from the atmosphere, swelling out like wedges, and rending the rock into fragments. The flowers of many plants open and shut, less under the stimulus of light, than under the action of humidity, and therefore foretell changes from dryness to rain and from rain to dryness; and those of some composite plants, especially, display a sufficient variety of phenomena under the complicated influence of the various atmospheric agencies as to indicate coming changes quite as nicely and curiously as the barometer,—and in consequence are popularly called the poor man's weather-glasses.

The stem of many herbaceous plants, but par-

ticularly that of the common convolvulus and some of the clovers and trefoils, becomes more than usually swollen and upright on the approach of rain. The purple sandwort, *Arenaria rubra*, expands its beautiful pink flowers only during sunshine, and closes them either before rain or at the approach of evening. The dark and beautiful gentianella opens its blue eyes to the mid-day sun, but shuts them on the approach of a shower. The common nipplewort, *Lapsana communis*, the white water-lily, *Nymphœa alba*, and several diadelphous plants expand their leaves during the day in calm mild weather, and contract them during the night. The germander speedwell, *Veronica chamœdrys*, closes its handsome blue flowers at the approach of rain, and reopens them when it ceases. The common wood-sorrel, *Oxalis acetosella*, folds up its beautiful trifoliate leaves, and hangs its flowers toward the ground, on the approach of night or of a storm, and re-expands and redisplays them under the rays of the morning sun. The red campion, *Lychnis diurna*, opens its flowers in the morning; and the white campion, *Lychnis vespertina*, opens its flowers in the evening. The corn-field pimpernel, *Anagallis arvensis*, widely expands its brilliant, small, red flowers on the morning of a fine day, and closes them on the approach of rain. The meadow goat's beard, *Tragopogon pratensis*, will not open its flowers in cloudy weather, and has so regular a habit of closing them at noon that many of the common people call it 'go-to-bed-at-noon,' and the farm-boys of some districts regulate their dinner-time by the closing of its flowers. The winter-green, *Trientalis europœa*, and the alpine whitlow grass, *Draba alpina*, hang down their flowers during the night, particularly in moist states of the atmosphere. The common chickweed, *Stellaria media*, always closes its small, white, upright flowers on the approach of rain, and expands them freely from nine in the morning till noon during dry weather, and holds them pendent during a day or two after rain ceases, or till dry weather has decidedly set in. The Siberian sow-thistle, *Sonchus alpinus*, shuts its flowers in a night preceding a fine day, and keeps them open in a night preceding a rainy or cloudy day. The African marigold, *Tagetes erecta*, keeps its flowers closed after seven o'clock on the approach of rain. Most of the hawkweeds or hieraciums open their flowers early in the morning, and close them in the afternoon. The succory, *Cichorium intybus*, opens its flowers towards the commencement of day-light. The common daisy, *Bellis perennis*, opens its flowers at sunrise, and closes them at sunset. The great white ox-eye, *Chrysanthemum leucanthemum*, closes its flowers on the approach of a storm. The common convolvulus and the broad-leaved red clover contract their leaves on the approach of thunder or of heavy rain.

Prognostics by Animals.—Many animals are strongly affected by electric changes in the atmosphere, and afford, by their sensations or movements, decided indications of the approach, not only of thunderstorms, but of all the more violent forms of weather which powerful electric action causes or controls. Many human beings experience uneasiness, languor, or sense of oppression, and a peculiar kind of headach on the approach of a thunderstorm, even before or long before any symptom of it is discernible in the sky; and many also experience toothach, rheumatism, and peculiar pains in corns, in weak limbs, and in old bruises and fractures, on the approach of heavy rains or high winds, particularly such as are largely controlled by the electric fluid. All animals who are covered with hair or feathers, in consequence of these organised substances being susceptible of very high electrical excitement, must experience strong sensations from great electrical changes,—especially when their bodies happen to be in an opposite electrical condition to that of the inanimate objects around them; and they at the same time possess all or most of the susceptibilities to electrical influence which are possessed by man; and as they are creatures of impulse, and very readily fling their sensations and emotions into action, they may be expected to indicate by many external signs, according to their several organizations and habits, the influence of every considerable atmospheric electrical change upon them, and consequently the approach of a corresponding change of weather. Many of the larger animals, too, must feel uneasiness, and express it, under transitions from dryness to humidity in the atmosphere, or from humidity to dryness; and multitudes of the smaller ones, comprising birds, fresh-water fishes, insects, arachnidæ, molluscs, and annelidæ, are not only affected but guided or impelled in the principal habits of their nature, such as those of feeding, reposing, locomotion, and migration, by the very same vicissitudes in air, heat, electricity, humidity, and aggregate meteorological agency which cause the phenomena of weather,—so that every considerable change or move in their behaviour indicates a contemporary change in the condition of the atmosphere. The recorded prognostics of weather by animals are both numerous and valuable; and multitudes more might no doubt be added by careful, extensive, and minute observation.

When rain is approaching, horses and cattle snuff the air and congregate in corners of fields with their heads to leeward, or seek shelter in sheds,—oxen lick their forefeet,—sheep reluctantly leave their pastures,—goats seek sheltered spots,—asses frequently bray and shake their ears,—dogs are apt to become very sleepy and dull, and to lie all day before the fire, showing a reluctance to all kinds of food except grass,—cats turn their backs to the fire, and wash their faces,—pigs cover themselves more than usually in litter,—rats and mice are more than usual-

ly restless, and forsake the fields and ditches, —cocks crow at unusual hours, and often flap their wings,—hens chuckle,—ducks and geese are unusually clamorous, and fly backwards and forwards, and frequently plunge into water,—pigeons wash themselves, and return slowly to their houses,—peacocks squall loudly from trees, —the guinea fowl makes a constant grating clamour,—sparrows chirp loudly and clamorously, and assemble in crowds on the ground or in the hedge,—swallows fly low, and skim their wings in water,—the carrion crow croaks solitarily, and is late in roosting, — water wild-fowl oftener than usual dip and wash,—moles are busier than usual in throwing up their hills,—frogs croak more than usual, and toads issue from their retreats in great numbers,—bats begin to squeak and enter houses,—the singing birds take shelter,—the robin approaches very near the dwellings of man,—tame swans fly against the wind, —bees cautiously leave their hives, and fly but short distances,—ants are busily engaged in carrying their eggs,—flies severely sting, and become troublesome,—numerous earthworms crawl about on the surface of the ground,—the larger sort of snails appear,—and all sorts of insects are more than usually stirring.

When fair or fine weather is approaching, or may be expected to continue, cattle lie in the open field or in the courts instead of the sheds, —sheep lie on the brow of a knoll during the night,—pigs lie down for the night on the top of their litter,—peacocks roost on the tops of houses,—the raven sails round and round high up in the air,—singing birds carol till late in the evening,—the corn-crake utters his peculiar cry among corn or grass,—the partridge calls in the evening to his mate,—kites hover high in the air,—larks rise high, and sing long,—redbreasts sing loud in the open air,—small flies flock together in great numbers about the beams of the sun a little before it sets,—snipes boom in the air during the evening,—gnats form a vortex in the shape of a column,—spiders' webs are on the ground, or float in the air,—bats fly more numerously than usual, and early in the evening,—and glow-worms appear in unusual numbers.

When high winds are approaching, cattle frisk and jump and toss their heads,—sheep frisk and leap and box one another in sport,—hogs squeal, and carry straw in their mouth,—cats scratch trees or posts,—geese expand or flap their wings, and seem as if trying to fly,—pigeons, in flying, smartly clap their wings behind their back,—crows make somersets in the air, and at the same time are unusually noisy,—magpies assemble in small flocks, and utter a chattering noise,—and swallows fly on the leeward side of trees. And when a storm or tempest is approaching, porpoises come in great numbers near the shore,—sea-gulls come in flocks on the land, and make a noise upon the sea-board,—and the merle-thrush, popularly called the storm-cock, sings loud and long.

Several single species of animals, such as sheep, spiders, ants, and leeches, indicate very delicately and in very various ways great and different approaching changes of weather. In the mountainous district of Derbyshire around the Peak, when sheep wind up the hills in the morning to their pasture and feed near the tops, the weather, though at the time cloudy and drizzling, will clear away by degrees and pass into a fine day; but when they feed in the bottoms, the cloudiness and drizzling will increase into rain, and the wetness of the weather will continue. And in other districts, whether lowland or upland, many actions and habits of all sheep, but specially those of the most distinctive breeds, may be so studied by an intelligent shepherd as to serve nearly all the purposes of a true and nice barometer.—The webs of garden spiders are broken off and destroyed on the approach of rain or of showery weather; and the light spider webs called gossamer fly in autumn with a south wind on the approach of east winds or of fine weather. "If the weather is likely to become rainy or windy," we are told, "spiders fix the terminating filaments on which the whole web is suspended unusually short. If the terminating filaments, on the contrary, are very long, the weather will be serene, and continue so for fourteen days. If spiders be totally indolent, rain generally ensues; though their activity during rain is a certain proof of its short duration, and that it will be followed by fine and settled weather. Spiders usually make some alteration in their webs every twenty-four hours. If this take place between the hours of 6 and 7 P. M., it foretells a clear and serene night."—As to ants, a celebrated naturalist relates that he one day observed these little creatures, after having brought out their corn at eleven in the forenoon, removing the same, contrary to their usual custom, before one in the afternoon. The sun being very hot, and the sky remarkably clear, he could perceive no reason for it; but half an hour after, his surprise ceased,—the sky began to be overcast, and there fell a shower of rain, which caused all this bustle, no doubt, among these active little creatures. They evidently foresaw rain, and provided accordingly. And were we minutely to examine into the economy and management of these wonderful artificers, many other similar and equally curious facts might be gleaned relative to the weather.—As to the leech, "in fair and frosty weather, it remains motionless and rolled up in a spiral form at the bottom of the vessel. Previous, however, to rain or snow, it will creep to the top, where, should the rain be heavy, or of long continuance, it will remain for a considerable time,—if transient, it will descend. Should the rain or snow be accompanied with wind, it will dart about with great velocity, and seldom cease its evolutions until it blows hard. If a

storm of thunder or lightning be approaching, it will be exceedingly agitated, and express its feelings in violent convulsive starts at the top of the glass. It is remarkable, that however fine and serene the weather may be, and to our senses no indication of a coming change, either from the sky, the barometer, or any other cause, yet, if the leech shifts its position, or moves about sluggishly, the coincident results will undoubtedly occur within twenty-six hours."

Prognostics by Air and Sky.—A whirlwind indicates settled fair weather. A wind blowing from the north-east during three days without rain, indicates a continuance of fair weather during eight or nine days. A wind veering hastily about to several points of the compass, indicates the rapid approach of rain; yet such a wind is regarded by some observers as indicating foul weather only when it veers in a course contrary to the sun, that is from west to east, and as indicating fine weather, when it veers in a course from east to west. Any wind which makes a whistling or howling noise is as sure a prognostic of rain as wind can afford. A south wind generally brings rain; but a brisk south wind is usually dry. The rising of a wind is prognosticated by the divergence of the clouds as they come forward on the horizon; and it may be expected either from the point where the divergence takes place, or from the point opposite to that. A southerly wind during a week of fair weather, indicates a continuance of drought; an easterly wind during the former part of summer, indicates a dry summer; and a westerly wind during the latter part of summer, indicates a dry autumn. Winds from the points between the north-west and the north-east, are generally accompanied by fair weather; and winds from points between the south-east and the south-west are generally accompanied by rain. But the characters of winds, in their relations to drought and heat or to raininess and coldness, are much controlled by localities of climate, and differ very widely in different districts of the kingdom, particularly in the eastern coasts and the western, and in the highland districts and the lowland. But, in a general view, north winds are dry, east winds are cold, south winds are wet, west winds are warm, and winds between any two of the cardinal points partake most of the character of that point to which they are nearest. Hence the old doggerel rhymes:—

> "When the wind's in the west,
> The weather's at the best;
> When the wind's in the east,
> It's neither gude for man nor beast;
> When the wind's in the south,
> Of rain there will be fouth;
> When the wind's still,
> No weather's ill."

When clouds fly in two different currents, especially if the lower fly faster than the upper, and more especially if they appear in hot weather in summer, they portend the gathering of a thunder-storm. When small scattered clouds appear in clear weather, or when thin, whitish clouds fly swiftly in a lower stratum than thicker and darker ones above them, they indicate the approach of rain. When a general cloudiness obscures all the upper part of the sky, and when small black clouds drift in the under part in fragments and patches like smoke, rain is not far off, and will probably be of long continuance. When black clouds suddenly arise in the west, or when they appear in that quarter about sunset, they indicate the approach of rain. Clouds which form like fleeces, dense towards the centre, and very white at the extremities, with a bright blue sky about them, are of a frosty coldness, and will soon fall in either snow, hail, or hasty showers of rain. When every one of a series of clouds rises larger than the preceding, and all appear to be in an increasing state, they portend heavy rain, and in some cases a thunder-storm. When vapours have been copiously elevated, and large clouds suspended high in the sky and assume the peculiar appearances indicative of great electricity, and when small pieces of flying clouds augment and congregate, they are certain forerunners of rain, perhaps of very heavy rain and thunder-bursts, if they collect and spread till they cover the sky, but are equally sure symptoms of fair weather if they decrease and resolve themselves into air. Clouds with white summits and livid bases foretell thunder; and two such clouds rising in opposite quarters, or over against each other, foretell a sudden tempest. Clouds streaming within the canopy, small clouds enlarging themselves, large clouds shaped like rocks or towers, waterish clouds on the tops of mountains, and small rugged, livid clouds near the sun, especially at its setting, all prognosticate rain. Clouds which form at a great height, in thin white trains like locks of wool, indicate the approach of wind, and sometimes the approach of both wind and rain. Small, white, high, light clouds, like dapplings in the upper regions of the sky, at a time when all the lower sky and the tops of the loftiest mountains are clear, indicate a continuance of fine weather. When cirrous clouds appear in a clear settled sky, they indicate a change in the weather; when they unite in a somewhat stratous manner, at a comparatively low elevation, they indicate rain; when they appear in a deep blue sky, through a broken cloud, after rain, they indicate that the rain will continue; and when they extend on both sides of the zenith, they foretell a long continuance of high wind. When cumulous clouds are compact, round, and well-defined, they indicate settledness of weather; when they are broken and ragged on the edges, they indicate the approach of rain; when they are curled and thrown outward at the edges, they foretell wind; when they are curled inward at the edges, they foretell a storm; when they remain and aug-

ment during the evening, they indicate the approach of rain; and when they form in the morning and disappear at night, they indicate steadiness of weather. When a great bank or stratum of low cloud dissipates under the influence of the morning sun, it foretells a fine day; when it moves slowly up the mountains, and lingers on their acclivities and round their tops, it foretells rain in the after part of the day; and when it moves slowly down the mountains toward the valleys at their skirts, it affords a certain indication of rain.

When dew is heavy, it indicates fair weather; when it vanishes early or suddenly, it foretells rain; when it abounds on the grass after a fine day, it foretells that the next day also will be fine; and when it is very scanty or totally awanting after a fine day, it indicates that rain is approaching. Either a strong dew or a fog is common between a red evening and a grey morning; and a total or almost total absence of dew is common between a red evening and a red morning. A fog in the morning, in a descending direction, foretells a hot day; a fog in the morning in an ascending direction over a low or level or champaign country, foretells rain; a fog in the morning, in an ascending direction from low lands toward hills and up to hill tops in their vicinity, does not indicate rain; a fog in the morning, resting upon hills and dragging along woods, and not overspreading the low grounds, foretells rain; a fog in the morning descending from hills, and settling in the adjacent valleys, foretells fair weather.

> "When mist takes to the hill,
> Then gude weather it doth spill,
> When the mist takes to the sea,
> Then gude weather it will be."

When a fog is general before sunrise, near the full moon, it prognosticates fine weather. When a white fog, in the evening or at night, is spread over a meadow through which a river passes, it will be dissipated by the morning sun, and the day will be fine and bright. Vapours in the form of exhalations in hot weather, or possessing a medium character between fog and invisible air, when precipitated during the night, are followed by a clear morning sky, but when not precipitated, are forerunners of rain.

When the air feels light and pleasant to a person walking, fine weather will continue; when it feels oppressive to walk in, rain is not far distant; and when it is so very clear as to make distant objects appear unusually distinct and near, it indicates rain. A sky of great height, and pretty clear, foretells fair weather; a sky of small elevation foretells rain; a sky of a deep blue ground colour, foretells fair weather; a sky of a pale blue colour, foretells rain; a morning sky of an orange colour, foretells rain; a sky of crystalline transparency after rain, foretells more rain; a sky which has for some time been thick and dark, without either rain or sunshine, will change to a fair clear sky before rain come. When a lowering redness spreads far upward from the horizon, either in the evening or in the morning, it is succeeded by wind or rain or both; when a fiery redness, with ragged clouds, extends in the evening toward the zenith, it is followed by a high wind from the west or the southwest, accompanied with rain; when a sea-green colour tinges the sky near the horizon, instead of the blue which usually prevails there, it indicates a continuance and increase of rain; and when a dead blue or dark indigo colour prevails over this part, it shows the presence of loads of vapour, and foretells that the weather will be showery. An apothegm exists in most European languages, that "the evening red and the morning grey, are sure signs of a fair day." When, in the morning, some parts of the sky appear green between the clouds, while the canopy above is blue, stormy weather is quickly approaching.

A rainbow in the morning indicates rain; a rainbow in the evening foretells fine weather; a rainbow of a predominantly green or blue colour foretells rain; a rainbow of a predominantly red colour foretells wind; and a rainbow in the north in boisterous weather indicates the approach of fine weather. Lightning without thunder, after a clear day, indicates that the fair weather will continue; but much lightning through the night, either with or without clouds, especially if it be of a pale colour, foretells unsettled weather. Falling stars and fiery meteors generally indicate the approach of high winds, and always indicate a change to some kind of stormy weather; and when the falling stars are numerous, they foretell a storm at day-break. The aurora borealis appears most frequently at a change of weather, either from good to bad or from bad to good. When smoke rises vertically from chimneys in calm weather, it indicates that the fine weather will probably continue; but when it descends and rolls along the ground, it foretells rain. When distant sounds, such as those of bells, waterfalls, and the roaring of beasts, are distinctly heard through the air in a calm day,—or when nearer sounds, such as those of the purling of brooks and the talking of people, seem unusually loud,—they show that the air is loaded with vapour, and indicate that rain may be expected. When the noise of the sea passes southward of the mouth of a river or estuary, it indicates that rain is not far off; and when it passes to the north, it foretells fair weather. Extraordinary or disagreeable scents arising from fenny or meadowy grounds, indicate the approach of rain; and the long continuance of the smell of burnt tobacco, or of the smoke from a tobacco-pipe, or of any similar flavour, also indicates rain. The unusual sinking of rivers presages rain; and a white frost is generally followed by rain within three days. The speedy drying of the surface of the earth, indicates a northerly wind and fair

weather; and a low state of evaporation, indicates a southerly wind and rainy weather.

Prognostics by the Heavenly Bodies.—The sun rising of an orange colour portends rain; his rising of a red and fiery colour, portends rain and wind; his rising unclouded, and emitting a scorching heat from his rays, portends speedy cloudiness and perhaps rain; his rising with a few grey clouds, which decrease and dissipate, portends a fine day and fair weather; and his rising with a dim and hazy disc, portends drizzly weather. When the sun's light is dim, or when it gradually loses its brightness till his disc becomes whitish and ill defined, rain may certainly be expected; and when his light, after rain, though it be sufficiently clear and luminous, is of a watery transparent hue, rain will soon again fall. When sunshine has a scorching and enervating effect on man, during the greater part of the day, the next day will be cloudy and perhaps rainy. When the sun wades through clouds of any kind, rain may or may not follow; when he wades through clouds which of themselves indicate rain, rain will more certainly follow than if the clouds were the only indication of its approach; and when, at the time of his wading, he is surrounded with a coloured corona, rain will most certainly follow. A halo round the disc of the sun almost always portends rain. The sun setting of a dull blackish colour, or of a blue colour, or with the accompaniments which are popularly called foul, portends rain; his setting of a white colour, or going down into a dusky bank of clouds, portends the approach and continuance of bad weather; his setting of a dusky colour, streaked with red, portends a storm; and his setting of a purple colour, or with a bright disc, or with a red and brilliant appearance, or his going down red and blazing amongst brilliant clouds, portends fine weather.

A dimness in the light of the stars, and the visibility of very few stars at one time when there is no frost, are indications of rain. A dimness in the light of the moon, a halo or circle round her disc, and haziness in the air during moonlight, are indications of rain; a redness in the colour of the moon, portends wind; and a clear silvery aspect of the moon, with a silveriness in her light, foretells fair weather. When the new moon appears so early as to be like "the paring of a nail," rain will follow; when the new moon is faintly subtended by the whole disc of the old, or appears "with the old one in her arms," stormy weather may be expected; when the new moon does not appear till the fourth day, the whole month will be more or less rainy; when the new moon is bright, and has sharp horns, she foretells fair weather; when the new moon has blunt horns, she foretells rain; when her lower horn is sullied, foul weather will occur before the full; when her middle is sullied, storms will occur about the full; and when her upper horn is sullied, foul weather will occur about the wane.

"In the wane of the moon,
A cloudy morning bodes a fair afternoon."

"New moon's mist
Never dies of thirst."

"But four nights old (for that's the surest sign),
With sharpened horns, if glorious then she shine,
Next day, not only that, but all the moon,
'Till her revolving race be wholly run,
Are void of tempests."

When rain falls during the greater part of the course of a moon, the weather will clear up at the ensuing change, and rain will probably fall in a few days after, and continue; and when fair weather prevails throughout the course of a moon, and is followed by rain at the change, fine weather will probably be restored about the fourth or fifth day of the new moon, and be of some duration. The following table shows the probabilities of a change of weather at or after each of the moon's situations throughout an entire revolution in her orbit.

The moon's situation.	Nature of the moon's situation.	Chances that the weather will change.
New moon,	When she exerts her influence in conjunction with the sun,	6 to 1
First quarter,	When she is 90° distant from the sun,	5 to 2
Full moon,	When she exerts her influence in opposition to the sun,	5 to 2
Third quarter,	When she is in the middle point of her orbit, being equi-distant from the points of conjunction and opposition,	5 to 4
Perigee,	When she is at the least distance from the earth,	7 to 1
Apogee,	When she is at the greatest distance from the earth,	4 to 1
The ascending equinox,	When she is crossing the equator towards the north,	13 to 4
The descending equinox,	When she is crossing the equator towards the south,	11 to 4
The northern or boreal lunistice,	When she approaches nearest to our zenith during the period that intervenes between one new moon and another,	11 to 4
The southern or austral lunistice,	When she is at the greatest distance from our zenith,	3 to 1

The following table professes to show the kind of weather which will follow every new moon and every quarter of the moon, according to the hour at which the change takes place; but though it is a fair approximation to correctness, and possesses considerable value, and is inserted in almost every almanac, and has been commonly though erroneously ascribed to the greatest astronomer of the last generation, Sir William Herschell, yet it is often falsified in its predictions by the many disturbing and antagonist influences which control the influence of the moon's attraction. When the moon changes, or becomes full, or enters her first or third quarter

between the hours mentioned in the first column, the resulting weather will be as mentioned in the second column in summer, and as mentioned in the third column in winter.

Hours of change.	Resulting weather in summer.	Resulting weather in winter.
Between 12 and 2 afternoon,	Very rainy,	Snow and rain.
Between 2 and 4 afternoon,	Changeable,	Fair and mild.
Between 4 and 6 evening,	Fair,	Fair.
Between 6 and 8 evening,	Fair, if the wind be at north-west; rainy if the wind be at south or south-west,	Fair and frosty, if the wind be at north or north-east; rain or snow, if the wind be at south or south-west.
Between 8 and 10 evening,	Fair, if the wind be at north-west; rainy, if the wind be at south or south-west,	Fair and frosty, if the wind be at north or north-east; rain or snow, if the wind be at south or south-west.
Between 10 and 12 night,	Fair,	Fair and frosty.
Between 12 and 2 morning,	Fair,	Hard frost, unless the wind be at south or south-west.
Between 2 and 4 morning,	Cold, with frequent showers,	Snow and stormy.
Between 4 and 6 morning,	Rain,	Snow and stormy.
Between 6 and 8 morning,	Wind and rain,	Stormy weather.
Between 8 and 10 morning,	Changeable,	Cold rain, if the wind be at west; snow, if the wind be at east.
Between 10 and 12 noon,	Frequent showers,	Cold with high wind.

Prognostics belonging to particular Seasons.—A serene autumn, denotes a windy winter; a windy winter, denotes a rainy spring; a rainy spring, denotes a fine summer; and a fine summer, denotes a windy autumn. But it very rarely happens that the seasons succeed one another in the same tenor for two successive years. If at the beginning of the winter, the south wind blow, and then the north, cold may be expected; but if the north wind blow first and then the south, the winter will be mild. A hot and dry September, portends a cold spring; and a moist and cool summer, portends a hard winter. Dryness at the commencement of winter on walls which are usually damp, shows the air to be dry, or indicates the condition favourable to frost, and therefore portends a hard winter. The early arrival of wood-cocks, field-fares, and other similar birds of passage, indicates that the succeeding winter will be cold. The early arrival of the cuckoo in spring, indicates that the following summer will be hot. An abundance of blossoms on the broom and almond tree, foretells an abundant harvest; and an abundance of haws and acorns, foretells a long and severe winter.

"Mark well the flow'ring almonds in the wood,
If od'rous blooms the bearing branches load;
The glebe will answer to the sylvan reign,
Great heats will follow, and large crops of grain."

An old Scotch proverb says, "A green Yule makes a fat kirk-yard;" and alludes to the sickliness of a mild Christmas to both man and beast. Among other old proverbs, characterising the prognostics of the seasons, and worthy of attention, are the following:—"Hail brings frost in the tail." "A snow year, a rich year." "Under water dearth, under snow bread."

"A January spring
Is worth nothing."

"If Janiveer's calends be summerly gay,
'Twill be winterly weather till the calends of May."

Prognostics most prominent in Upland Districts.—"When there is a copious deposit of dew, and it remains long on the grass,"—says the Rev. James Russell of Yarrow, in reference to a part of Selkirkshire which may be taken as a fair specimen of the inland upland districts of Britain,—"when the fog in the valleys is slowly dissipated by the sun's heat, and lingers on the hills,—when the clouds apparently take a higher station,—and especially when a few cirro-strati appear loose or slightly connected, lying at rest or gently floating along, serene weather may be confidently expected. A change of this settled state is presaged by the wind suddenly rising, by close continuous cirro-strati gathering into an unbroken gloom, and by that variety of cirrus known as the goat's hair or grey mare's tale. Sometimes a few fleecy clouds skim rapidly between the superincumbent vapour and the earth's surface, and are the forerunners of snow or rain. Should the cirri not pass away with the immediate fall, but extend toward the horizon, and present their troubled edges towards the zenith, there will be stormy weather for some time. When a modification of the cirro-stratus is formed to leeward, thick in the middle, and wasting at both ends, with its side to the wind like a ship lying to, it indicates continued wind. After a clear frost, we sometimes see long whitish-coloured streaks of cirrus, whose two extremities seemingly approach each other as they recede from the zenith. This appearance is vulgarly called Noah's ark; and if it point from south-west to north-east, we expect a thaw from the south-west. Small blackish boat-shaped clouds rising in the west, and moving sideways, indicate a thaw, with little or no rain. A short glare of red in the east, about sun-rising, portends a rainy and windy day. When the sky shines from the watery exhalations around the midday sun, rain or snow will soon follow; when it has a green appearance to the east or north-east, frost and snow. A crimson red in the west, after sunset, indicates fair weather; a purple red indicates sleet. Atmospheric changes are more likely to happen a few days after new and full moon than in the quarters. The point when

she changes seems to have little influence; if in the north-west or north-west by west, it is often succeeded by boisterous weather. When her horns are sharp and well defined, we look for frost; when she is whitish and not very clear, for rain or snow. If the new moon seems to embrace the old, very stormy weather is likely to follow. When the wind shifts to the west, after rain from the south or south-west, it generally fairs up, or there are but a few showers. Frost and snow from the south-west are forerunners of bad weather. If the wind turn suddenly from the south-west or south to the north-north-east, while this is accompanied with a smell resembling that of coal smoke, a severe storm will follow.—The lower animals, but such especially as are in a state of nature, or exposed to the open fields, are very susceptible of atmospheric changes. Sheep eat greedily before a storm, and sparingly before a thaw; when they leave the high parts of their range,—when they bleat much in the evening or during the night, we may expect severe weather. Goats seek a place of shelter, while swine carry litter and cover themselves better than ordinary, before a storm. Wind is foretold by the cat scratching a post or wall; and a thaw, when she washes her face, or when frogs come from their winter concealment. The gathering of grouse into large flocks, the diving of sparrows in dry dust, the fluttering of wild-ducks as they flap their wings, the dismal lengthened howl of sea-gulls in an inland place or around lakes, the mournful note of the curlew, the shrill whew of the plover, the *whet-whet-whet* of the chaffinch perched upon a tree, the crowing of the cock at unusual times,—all prognosticate rain or snow. When the field-fare, redwing, starling, swan, snowfleck, and other birds of passage, arrive soon from the north, it indicates an early and severe winter. When gnats bite keenly, when flies keep near the ground (shown by swallows, who feed upon the wing, flying low), we look for wind and rain. But the most wonderful instance of atmospherical changes is upon those creatures that burrow in the ground. The earth-worm appearing in abundance indicates rain. In like manner, the mole seems to feel its approach, as, a day or two before, he raises more hillocks than usual; and when, after a long severe frost, he begins again to work, it will soon become fresh."

"When the wind turns to the north-east and it continues two days without rain, and does not turn south the third day, nor rains the third day," says Shepherd of Banbury, "it is likely to continue north-east for 8 or 9 days all fair, and then to come to the south again. If it turn again out of the south to the north-east with rain, and continues in the north-east two days without rain, and neither turns south nor rains the third day, it is likely to continue north-east for two or three months. The wind will finish these turns in three weeks. After a north wind, for the most part two months or more, and then coming south, there are usually three or four fair days at first, and then, on the fourth or fifth day, comes rain, or else the wind turns north again, and continues dry. If it return to the south in a day or two without rain, and turn north with rain, and return to the south in one or two days as before, two or three turns together after this sort, then it is like to be in the south or south-west two or three months together, as it was in the north before. The wind will finish these turns in a fortnight. Fair weather for a week, with a south wind, is likely to produce a great drought, if there has been much rain out of the south before. The wind usually turns from north to south, with a quiet wind without rain, but returns to the north with a strong wind and rain. The strongest winds are when it turns from south to north by west. When the north wind first clears the air (which is usually once a-week), be sure of a fair day or two."

WEATHER-VANE. An instrument for showing the direction of the wind. See the article Anemoscope. One should be mounted on a conspicuous part of every farmery; and, if of a simple form, it cannot have a neater or more efficient indicator than an arrow, whose dart most readily pierces the wind, and whose butt most facilely and powerfully streams before the wind, and compels the dart to point to the wind's eye. A good contrivance would be four bells of different tones at the four cardinal points of the compass, and a hammer suspended from the dart by a supple spring to strike them; so that a person within any neighbouring house might be apprised by the bell-strokes of every wide veering of wind, and of its direction. The director of almost all the vanes of former ages was a figure of a cock,—an emblem of clerical vigilance; and this has occasioned all sorts of weather-vanes and anemoscopes down to the present day to be popularly called weather-cocks.

WEBERA. A small genus of ornamental, tropical, evergreen, ligneous plants, of the madder family. The corymbose species, *W. corymbosa*, is a native of the upland districts of India, and was introduced to the hothouses of Britain in 1759. It has a height of about 6 or 8 feet, and carries white flowers, and small, black esculent berries. —The tetrandrous species, *W. tetrandra*, is another shrub of the waste lands of India, and, besides producing esculent foliage and esculent fruit, possesses considerable medicinal reputation. Its root is supposed to be anthelmintic; and both its young shoots and its leaves are used as a remedy for bowel complaints.

WECHT. A hand implement for lifting grain. If well made, with a broad slip of ash, and capacious enough to hold at least half a bushel, it is much lighter and handier than any basket; and it may be regarded as an indispensable piece of furniture in all good and extensive barn management. See the article Barn Management.

WEDELIA. A genus of exotic, yellow-flowered plants, of the sunflower division of the composite order. Seven or eight species, varying in height from 6 inches to 4 or 5 feet, varying in adaptation from the open border to the stove, and variously annual and perennial, creeping and tuberous, herbaceous and ligneous, have been introduced to Britain, principally from America; and all thrive in any common soil. The most interesting is the golden, *W. aurea*, a tuberous-rooted frame plant of about 2 feet in height, carrying golden-coloured flowers in August and September, and introduced from Mexico in 1829.

WEED. Any plant which grows spontaneously on cultivated ground. It may be either useless or useful, suitable for cultivation or unsuitable for it, a denizen of the poorest soils or a denizen of the richest ones, a greedy consumer of saline substances or a feeder principally upon air, an indigen of the region which it infests or an introduced hardy exotic,—it may, in short, be a plant of any kind whatever; for it owes its proper character of a weed, not in the slightest to anything in itself, but entirely to its intrusive presence among plants of another kind which are growing or holding possession in the capacity of a crop. Cultivated plants themselves, therefore, are weeds whenever they intrude on one another, or rise on any spot where they are not wanted. Very few weeds are exotics; not many even are imported from very different soils or from considerably distant situations; and the great majority are simple, natural, and perhaps stubborn and persistent inhabitants of the ground where they appear, having been occupants of the very spot itself or of spots in its vicinity before cultivation began, and continuing still to maintain the occupancy as far as cultivation will possibly admit. Yet very many of the most common weeds can be classified into groups according to the soils and situations which they severally love, and are more or less distinct indicators of the constitution or condition of the land on which they grow; and some of these evanish or migrate or supplant one another according to the changes which are made on land by georgy and cultivation. See the article Barren Soils, and the section "The Peculiar Vegetations of Soils" in the article Soil.

Classification of weeds might be made on many principles and in many ways. But one of the most practically useful, having reference to the best systematic methods of keeping them down or extirpating them, is to distribute them into annuals, biennials, and perennials, according to the duration of their roots and to the predominant mode of their self-propagation; another very useful classification, having reference to the degree in which they should be dreaded and the vigour with which they should be kept down, is to arrange them in a list of precedency according to the amount of injury which they do on a farm or of trouble which they give to a farmer; a third very useful classification, which is that adopted in "Holdich's Weeds of Agriculture," and having reference to the manner in which they severally injure crops and trouble cultivators, is to distribute them into such as infest samples of corn, such as cannot be extirpated or long kept down without the aid of fallowing, such as impoverish the soil and encumber crops, such as never rise in the crop or come into the sickle, and such as infest pasture lands; and a fourth very useful classification, or rather selection, having reference to the comparative barrenness or unproductiveness of land, to the indication of the character and condition of soils, and to the suggestion of needful processes of reclamation and georgical improvement, is to distribute them into plants which are liable and ready to overrun so much of the surface of the ground as to render the produce of farm crops of little value, plants which spring up spontaneously among the herbage of sterile or exhausted pastures and meadows, and gramineous plants of harsh, innutritious, or noxious nature which take possession of pastures, downs, moors, bogs, and wastes to the extensive or total exclusion of good grasses. We shall name the principal agricultural weeds of Britain according to each of these four classifications; but of course, we shall do no more than name them, all being described in their respective alphabetical places throughout our work,—and we must neither avoid repetitions under the different classifications, nor attempt a complete list in any part of even one classification.

The principal annual and biennial weeds are wild mustard, *Sinapis arvensis*,—black mustard, *Sinapis nigra*,—wild radish, *Raphanus raphanistrum*,—corn poppy, *Papaver rhœas*,—corn blue bottle, *Centaurea cyanus*,—corn marigold, *Chrysanthemum segetum*,—corn feverfew, *Pyrethrum inodorum*,—sow thistle, *Sonchus oleraceus*,—spear plume thistle, *Cnicus lanceolatus*,—burdock, *Arctium lappa*,—corn cockle, *Agrostemma githago*,—common chickweed, *Stellaria media*,—corn spurrey, *Spergula arvensis*,—goose grass, *Galium aparine*,—small nettle, *Urtica urens*,—red dead nettle, *Lamium purpureum*,—common hemp nettle, *Galeopsis tetrahit*,—sun spurge, *Euphorbia helioscopia*,—climbing buckwheat, *Polygonum convolvulus*,—knotgrass, *Polygonum aviculare*,—hairy tare, *Ervum hirsutum*,—bearded darnel, *Lolium temulentum*,—bearded wild oat, *Avena fatua*,—soft brome grass, *Bromus mollis*,—goose grass, *Bromus secalinus*,—cow parsnip, *Heracleum spondylium*,—viper grass, *Echium vulgare*,—bugloss, *Lycopsis arvensis*,—gromwell, *Lithospermum officinale*—corn woundwort, *Stachys arvensis*,—yellow rattle, *Rhinanthus crista-galli*,—nipplewort, *Lapsana communis*,—goosefoot, *Chenopodium album*,—groundsel, *Senecio vulgaris*,—shepherd's purse, *Thlaspi bursa-pastoris*,—annual grass, *Poa annua*,—and fumitory, *Fumaria officinalis*.—The principal perennial weeds are upright meadow

crowfoot, *Ranunculus acris*,—creeping crowfoot, *Ranunculus repens*,—common buttercup, *Ranunculus bulbosus*,—common ragwort, *Senecio jacobea*,—coltsfoot, *Tussilago farfara*,—daisy, *Bellis perennis*,—great white ox-eye, *Chrysanthemum leucanthemum*,—corn or way thistle,—*Cnicus arvensis*,—black knapweed, *Centaurea nigra* — corn sow thistle, *Sonchus arvensis*,—white dead nettle, *Lamium album*,—broad-leaved dock, *Rumex obtusifolius*,—amphibious persicaria, *Polygonum amphibium*,—great-nettle, *Urtica dioica*,—marsh bent grass, *Agrostis alba*,—common oat-like grass, *Arrhenatherum avenaceum*,—creeping soft grass, *Holcus mollis*,—common wheat grass or couch grass, *Triticum repens*,—mugwort, *Artemisia vulgaris*,—silverweed, *Potentilla anserina*, —bindweed, *Convolvulus arvensis*,—corn mint, *Mentha arvensis*,—horsetail, *Equisetum arvense*,—red eyebright, *Bartsia odontites*,—dandelion, *Taraxacum officinale*,—butterbur, *Tussilago petasites*,—goatweed, *Ægopodium podagraria*,—furze, *Ulex europæus*,—broom, *Spartium serparium*,—restharrow, *Ononis arvensis*,—bramble, *Rubus fruticosus*,—the villous briar, *Rosa villosa*,—the dog rose, *Rosa canina*,—the spiniest briar, *Rosa spinosissima*,—the brake, *Pteris aquilina*,—milfoil, *Achillea millefolium*,—sneezewort, *Achillea ptarmica*,—and various rushes, sedges, ferns, heaths, and mosses.

A list of principal weeds, arranged in the order of the amount of injury which they do on a farm or of trouble which they give to a farmer, would considerably vary in different districts of Britain, in different situations in any one district, and in differently managed farms of similar or even identical character; but the following, corrected from a list in Aiton's Agricultural Report of Ayrshire, and applicable in a general way to the whole of that great, rich, and diversified county, may be taken as a fair average specimen:—The corn thistle, *Cnicus arvensis*, —the spear plume thistle, *Cnicus lanceolatus*,—the marsh thistle, *Cirsium palustre*,—the corn sow thistle, *Sonchus arvensis*,—the annual sow thistle, *Sonchus oleraceus*,—common wheat grass or common couch, *Triticum repens*,—marsh bent grass, *Agrostis alba*,—creeping soft grass, *Holcus mollis*,—stoloniferous bent grass,—*Agrostis stolonifera*,—tall oat grass, *Avena elatior*,—restharrow, *Ononis arvensis*,—sharp-leaved dock, *Rumex acutus*,—broad-leaved dock, *Rumex obtusifolius*,—curled dock, *Rumex crispus*,—common field sorrel,—*Rumex acetosa*,—sheep's sorrel, *Rumex acetosella*,—common ragwort, *Senecio jacobea*,—groundsel, *Senecio vulgaris*,—corn marigold, *Chrysanthemum segetum*,—great white ox-eye, *Chrysanthemum leucanthemum*,—corn feverfew, *Pyrethrum inodorum*,—mugwort, *Artemisia vulgaris*, —coltsfoot, *Tussilago farfara*,—butterbur, *Tussilago petasites*,—sneezewort, *Achillea ptarmica*, —speedwell, *Veronica agrestis*,—field speedwell, *Veronica arvensis*,—corn spurrey,—*Spergula arvensis*,—wild radish, *Raphanus raphanistrum*,—black mustard, *Sinapis nigra*,—charlock or wild mustard, *Sinapis arvensis*,—common chickweed, *Stellaria media*,—silverweed, *Potentilla anserina*, —red dead nettle, *Lamium purpureum*,—stem-clasping henbit, *Lamium amplexicaule*,—common hemp nettle, *Galeopsis tetrahit*,—clown's all-heal, *Stachys palustris*,—corn hedge nettle, *Stachys arvensis*,—horsetail, *Equisetum arvense*,—amphibious persecaria, *Polygonum amphibium*,—common persicaria, *Polygonum persicaria*,—water-pepper, *Polygonum hydropiper*,—climbing buckwheat, *Polygonum convolvulus*,—common fumitory, *Fumaria officinalis*,—field mint, *Mentha arvensis*,—petty spurge or devil's milk, *Euphorbia peplus*,—sun spurge, *Euphorbia helioscopia*,—goosefoot, *Chenopodium album*,—corn poppy, *Papaver rhœas*,—long-headed poppy, *Papaver dubium*,—creeping crowfoot, *Ranunculus repens*, —upright meadow crowfoot, *Ranunculus acris*, —nipplewort, *Lapsana communis*,—earthnut, *Bunium bulbocastanum*,—goose grass, *Galium aparine*,—black knapweed, *Centaurea nigra*,—and great nettle, *Urtica dioica*.

The classification of principal weeds into such as infest samples of corn, such as cannot be extirpated without the aid of fallowing, such as impoverish the soil and encumber crops, such as never rise in the crop or come into the sickle, and such as infest pasture lands, we shall take from Holdich's Weeds of Agriculture, with simply some modernizement of the nomenclature. The principal weeds which infest samples of corn, are darnel, *Lolium temulentum*,—smooth brome grass, *Bromus secalinus*,—corn cockle, *Agrostemma githago*,—four-seeded tare, *Ervum tetraspermum*,—common melilot, *Melilotus officinale*,—wild oats, *Avena fatua*,—goose grass, *Galium aparine*, —shepherd's needle, *Scandix pecten-veneris*,—climbing buckwheat, *Polygonum convolvulus*,—snakeweed, *Polygonum lapathifolium*,—wild mustard, *Sinapis arvensis*,—wild radish, *Raphanus raphanistrum*,—and rape charlock, *Brassica napus*. About one half or so of these chiefly infest wheat, and the rest chiefly infest oats or barley; but they vary much on different kinds of soil, and very seldom do more than two of them occur in one sample of corn. They abound most on light loams and deep loose soils; and sometimes give little trouble on cold clay soils and on the arable lands of fen districts; and often are scarcely known or but very slightly troublesome on light, dry, well-cultivated turnip soils.—The chief weeds which cannot be extirpated without the aid of fallowing, are common couch grass, *Triticum repens*,—creeping bent, *Agrostis repens*, —creeping soft grass, *Holcus mollis*,—smooth-stalked meadow-grass, *Poa pratensis*,—restharrow, *Ononis arvensis*,—corn thistle, *Cnicus arvensis*,—curled dock, *Rumex crispus*,—tall oat-like soft grass, *Holcus avenaceus*,—coltsfoot, *Tussilago farfara*,—corn bindweed, *Convolvulus arvensis*,—corn mint, *Mentha arvensis*,—narrow-leaved stoloniferous bent, *Agrostis stolonifera angustifolia*, —black foxtail grass, *Alopecurus agrestis*,—com-

mon knotgrass, *Polygonum aviculare*,—wild carrot, *Daucus carota*,—hedge parsley, *Torilis infesta*,—fool's parsley, *Æthusa cynapium*,—and fennel, *Anethum fœniculum*.—The principal weeds which impoverish the soil and encumber crops are wild mustard, *Sinapis arvensis*,—black mustard, *Sinapis nigra*,—wild radish, *Raphanus raphanistrum*, —rape charlock, *Brassica napus*,—corn poppy, *Papaver rhœas*,—blue bottle, *Centaurea cyanus*,—stinking mayweed, *Anthemis cotula*,—and corn marigold, *Chrysanthemum segetum*. These abound most on light soils in dry districts, and may generally be regarded as indicating careless, negligent, or unskilful farming; and can be kept down or extirpated only by good husbandry, assiduous tillage, and careful supervision of rising crops.—The principal weeds which never rise in the crops or come into the sickle, but which at the same time so infest or overrun land as to impoverish it, are groundsel, *Senecio vulgaris*,—annual meadow grass, *Poa annua*,—chickweed, *Stellaria media*,—shepherd's purse, *Thlaspi bursa-pastoris*,—spurrey, *Spergula arvensis*,—wild chamomile, *Matricaria chamomilla*,—goosefoot, *Chenopodium album*,—lamb's lettuce, *Fedia olitoria*, —flixweed, *Sisymbrium sophia*,—common fumitory, *Fumaria officinalis*,—and sand mustard, *Sinapis muralis*. These are specially abundant on over-cropped, and scourged and exhausted lands; and when they become plentiful and luxuriant, can seldom be extirpated without summer fallowing and laying down to grass.—The chief weeds on dry, sandy, calcareous pastures or on light loamy grass lands are the dwarf or stemless thistle, *Cirsium acaule*, — common chamomile, *Anthemis nobilis*,—star thistle, *Centaurea calcitrapa*,—great white ox-eye, *Chrysanthemum leucanthemum*, — ploughman's spikenard, *Conyza squarrosa*,—cheese rennet or yellow ladies' bedstraw, *Galium verum*,—wild thyme, *Thymus serpyllum*,—long-rooted hawkweed, *Apargia autumnalis*,—sheep's sorrel, *Rumex acetosella*,—common knotgrass, *Polygonum aviculare*,—yellow rattle, *Rhinanthus crista-galli*, — and common carline thistle, *Carlina vulgaris*. The most formidable of these are the thistles, the sheep's sorrel, and the knotgrass. The chief on loamy, clayey, and damp pastures are yellow goat's beard, *Tragopogon pratensis*,—marsh thistle, *Cirsium palustre*,—melancholy or various-leaved thistle, *Cirsium heterophyllum*,—the meadow thistle or English thistle, *Cirsium anglicum*,—common butterbur, *Tussilago petasites*,—common ragwort, *Senecio jacobea*, — common daisy, *Bellis perennis* — black knapweed, *Centaurea nigra*,—broad-leaved dock, *Rumex obtusifolius*,—common cow parsnip, *Heracleum spondylium*,—several sedges, *Carices*,—and several orchises.

The chief weeds which are liable and ready to overrun so much of the surface of the ground as to render the produce of farm crops of little value, and which serve as indicators of temporary barrenness and as instigators to special diligence and exertion on the part of farmers, are,—corn cockle, *Agrostemma githago*,—common daisy, *Bellis perennis*, — common fumitory, *Fumaria officinalis*, — corn bindweed, *Convolvulus arvensis*, — goose-grass, *Galium aparine*, — corn poppy, *Papaver rhœas*,—broad-leaved dock, *Rumex obtusifolius*,—curled dock, *Rumex crispus*,—groundsel, *Senecio vulgaris*,—common butterbur, *Tussilago petasites*,—colt's-foot, *Tussilago farfara*, —chickweed, *Stellaria media*, — black fox-tail grass, *Alopecurus agrestis*,—sedge, or carnation grass, *Carex*,—stinking may-weed, *Anthemis cotula*,—common couch grass, *Triticum repens*,—corn thistle, *Cnicus arvensis*,—common cow-parsnip, *Heracleum spondylium*, — crow garlic, *Allium veneale*,—mare's-tail, *Hippuris vulgaris*,—cheese rennet, or yellow ladies' bed straw, *Galium verum*,—shepherd's needle, *Scandix pecten-veneris*,—sheep's sorrel, *Rumex acetosella*,—great white ox-eye, *Chrysanthemum leucanthemum*,—corn marigold, *Chrysanthemum segetum*,—black bindweed, *Polygonum convolvulus*,—corn buttercup, *Ranunculus arvensis*,—corn horse-tail, *Equisetum arvense*,—blue-bottle, *Centaurea cyanus*,—wild mustard, *Sinapis arvensis*,—yellow goat's-beard, *Tragopogon pratensis*,—corn mint, *Mentha arvensis*,—tall, oat-like soft-grass, *Holcus avenaceus*, — narrow-leaved stoloniferous bent grass, *Agrostis stolonifera angustifolia*,—common ragwort, *Senecio jacobea*,— black knapweed, *Centaurea nigra*, — ploughman's spikenard, *Conyza squarrosa*, — darnel, *Lolium temulentum*, — wild oats, *Avena fatua*,—smooth brome grass, *Bromus secalinus*,—rest-harrow, *Ononis arvensis*,—dwarf or stemless thistle, *Cirsium acaule*,—and star thistle, *Centaurea calcitrapa*. These plants, besides indicating more or less a bad state of things by their very presence, also show to a considerable degree the comparative fertility or barrenness of land by always being more luxuriant on fertile than on barren soils; and most of them are not at all nice as to either the composition or the condition of land, but will grow with more or less readiness on all kinds of soils.—A list of plants which spring up spontaneously among the herbage of sterile or exhausted pastures and meadows, and also a list of grasses of harsh, innutritious, or noxious nature, which take possession of pastures, downs, moors, bogs, and wastes, to the extensive or total exclusion of good grasses, have already been given in the article Barren Soils.

Some weeds have valuable medicinal properties; a few possess an ornamental character, and lend to the fields and wastes where they grow some of the gentle attractions of the parterre; and many or even most may be applied to some useful purposes of the farm, and made to yield some little compensation for the injury which they have done to the soil or the crops, or for the trouble which they occasion to the cultivator. Sow thistles and some others afford good and grateful food to rabbits and hogs; the cow parsnip is

readily eaten by both hogs and cattle; young thistles, when partially dried, are readily eaten by horses and asses; wild mustard, wild radish, black mustard, and rape charlock, when drawn before they begin to form their seeds, are much relished by cows, and may even be made into hay; and several other of the most common and bulky weeds are more or less agreeable to farm stock, and, when allowed by neglect or oversight to grow in considerable quantity, and cut down in a succulent stage of their growth, may be profitably sent to the forage department of the farm yard. Nettles, ferns, bulky hedge-weeds, and all other coarse, innutritious, or ligneous weeds may be collected for manure, and, according to convenience and quantity, may either be burnt in heaps, with the view of only their ashes being used, or placed in alternate layers with earth and lime in order to undergo slow and steady decomposition and to form a compost. In all cases, however, in which weeds are made to contribute something by way of return to the soil, whether by express use of them as manure ingredients, or by burning them in the course of summer fallowing, thorough care must be exercised to destroy all their seeds and vivacious roots.

A theory has been got up by a few pseudo-scientific agriculturists, that the growth of weeds is beneficial to the cultivation of farm crops, and even essential to the maintenance of fertility in the soil; and this wild theory has been advocated in such strong terms as the following:—"It is no less lamentable than true that, notwithstanding all the splendid talent which has been exhibited from Tull to the present day, this very obvious fact (that all natural vegetation enriches soil) should not have been long ago adopted as a fixed and leading principle in all agricultural and horticultural operations. It stares us in the face in the forests and prairies of North America, the pampas of Buenos Ayres, the dirty summer fallows of England, and everywhere, and in everything. The principle of a clean naked fallow (fortunately a rare occurrence) is utter annihilation. Had farmers and gardeners been able to eradicate weeds, as they are called, the soil would have been a *caput mortuum* long ago. But weeds, like the principles of liberty, destroy, hack, hew, and persecute them as we may, rise again in due time, not to injure, but to fertilize and benefit. To the want of vegetable food is entirely to be attributed the frequent failure of grass, clover, turnips, sainfoin, &c., in England, under the improved system of farming; and the cleaner the land is kept, it is to be suspected, the more they fail. To say the land is tired, proves something is wrong, but explains nothing. We may be quite satisfied that the crops under the old wretched system of farming were much better than under the new, in proportion to the manures, skill, management, &c., applied in both instances. Weeds, misplaced except in summer fallows, were the old farmer's salvation, but he did not know it. Weeds do not rob the soil; they either enable the farmer to do so or prevent him, as the case may be; they keep up the fertility of it; they rob the crops, but not the soil." This piece of declamation—for argument it is not—resembles the shovelling of a load of rubbish into a tilt cart; and the last clause, by a single touch, tilts all back again to the ground. Since weeds "rob the crops," who cares what else they may do? or what common sense farmer will not treat them as "robbers," and kick them out and keep them out as well as he can? "Crops" are all a cultivator cares for,—the sole drift and object of all his labour; and whatever things "rob" them, be they vermin or plants, thieves or thistles, are his enemies, and must be watched and opposed and driven from his farm; and it is just because intruding plants appear among his crops, and therefore rob them, that they are weeds at all. He wishes to appropriate all the available nutriment in a piece of land to the nourishment of crops which he expressly sows or plants upon it,—and he even puts a great deal of extra or artificial nutriment into the land upon the nonce for the due or ample feeding of these crops; so that whatever other plants steal in among the crops, to live upon the land, and devour part of the nutriment, he regards as "robbers" or "weeds,"—their mere presence there constituting them weeds, and their feeding and flourishing there constituting them robbers. Nor can he be reconciled to them by the prospect of their being made by and by to disgorge what they devour, or of their dying on the spot where they lived, and bequeathing their carcases as payment for their food and lodging. Some are voracious eaters of the choicest and rarest ingredients of the food of the cultivated plants, and consequently reiving robbers and downright starvers of the crops; most appropriate much food at the moment, and also hinder the crops from getting ample air and sunshine for the enjoyment of the main body of the food, so that they considerably or largely defeat the objects for which the farmer tilled and fertilized and sowed; and all, before they can be made to give back to the soil what they take from it, give a great deal of trouble, compelling the farmer to spend upon the punishment of *robbers* what could be tenfold more profitably employed upon the nourishing and tending of *productive* plants. Crops and weeds, in fact, are antagonist things,—or at best, the same things in antagonist conditions. Crops are selected or improved plants raised on prepared ground, under the help of artificial appliances, with a view to a maximum produce; and, in so far as they either need or can receive assistance from other plants, they can economically obtain it only on one or two or all of three antecedent principles of ordinary manure, green manure, and rotation of crops, and never on the absurd, starving, contemporaneous principle of sharing with them bed and board. Plants are

weeds only when they "rob" crops, or intrude upon them; and are not weeds at all where no crops are grown. There are no weeds in prairies and pampas and natural forests. Everything there luxuriates in wildness; and the most powerful plants take possession, and keep it, at the expense of the weaker; and any two or six or ten of similar strength, or co-ordinate habits, or tastes for different elements of food may exist together,—and die down in successive generations only to enrich the land, with the help of exuviæ and bird-droppings, and of ammoniacal rains and disintegrating action and chemical agency, for the use of sturdier and more stalwart future races. Nothing is removed from the land by human harvestings; and a perpetual fertilization is going on. Yet even on prairies and pampas and cleared natural forests, with a soil continually enriched and never once cropped during four thousand years, and possessing such a store of phosphatic, nitrogenous, and other rare saline principles as might grow thirty successive crops of wheat without aid from artificial manuring, all the rank herbage must be cleared away and kept away in order to the obtaining of cultivated produce; and no man but an idiot or a maniac would, either with or without tillage, throw seed wheat upon them in expectation of getting the best possible crop of wheat in company with their rankest possible growth of herbage. When cultivation begins, wild vegetation must end; or when crops are at a maximum, weeds are at a minimum. Even too where cultivation was never attempted or has long been abandoned, and where natural vegetation has had as ample scope to do its utmost as on the richest of the prairies or pampas or natural forests of America, if the subsoil be not duly porous, and if the soil and the situation be either too moist or too dry, fertilization has its limits, and a very different process sets in. What shall be said of the bogs and morasses of Europe, the vast fens and savannahs of America, the moors and heaths and wilds of many famous old uplands of Asia, and the arid deserts and burning sands of Judea and Idumea and Mesopotamia? All these were once good and productive territories,—grateful to flocks or fit for the uses of the husbandman; and now, after revelling for centuries or millenniums amid all the glories which 'weeds' or wild plants could give them, they are truly and all over one hideous *caput mortuum*. We have somewhere said in some former article, and we here say again, that the man who imagines weeds to be beneficial to crops ought by all means to sow thistles and docks and to get them up into luxuriance, as the best possible preparation for wheat.

"All plants which grow naturally among a crop that has been sown," remarks Sir John Sinclair, "may be regarded as enemies to that crop. The destruction of such plants, therefore, must be considered as one of the most important branches of the agricultural art; for if that is neglected, or even but slovenly performed, the crops may be reduced to the amount of one-fourth or one-third of a fair average crop, even upon the very best soils. Besides, it merits consideration, that if weeds are suffered to exist, the full advantages of manuring land, and many other improvements, can only be partially obtained. Nor is this all; the mixture of weeds in the soil prevents the crops from receiving the beneficial influence of the atmosphere, —sucks up that moisture so essential for the growth of the crop sown,—tends more than any other circumstance to injure the crop when lodged by violent winds or heavy rains,—augments the risks at harvest (for a crop that is clean, may be ready for the stack-yard in much less time than is required to harvest it, when encumbered with weeds),—and the seeds of these intruders deteriorate the quality of the grain. Notwithstanding all the injuries thence sustained, how many are there, who hardly ever attempt to remove weeds in an effectual manner? This negligence is the more to be blamed, because, were farmers at the trouble of collecting all sorts of weeds, before they have formed their seeds, and of mixing them with rich earth, with lime, or fermenting them with dung, they would soon be reduced into a soft pulpy mass, and in this way, a pernicious nuisance might be converted into a valuable manure.—Various experiments have been tried, to ascertain the positive advantage derived from carefully weeding one part of a field, and leaving another part undone; among these, the following, made with peculiar accuracy, may be safely relied on:—1. Seven acres of light gravelly land were fallowed, and sown broad-cast; one acre was measured off, and not a weed was pulled out of it; the other six were carefully weeded. The unweeded acre produced 18 bushels; the six weeded acres, 135 bushels, or 22½ per acre, which is 4½ bushels, or ¼ more produce in favour of weeding.—2. A six acre field was sown with barley, in fine tilth, and well manured. The weeding, owing to a great abundance of charlock, cost 12s. per acre. The produce of an unweeded acre was only 13 bushels; of the weeded, 28. Difference in favour of weeding, 15 bushels per acre, besides the land being so much cleaner for succeeding crops.—3. Six acres sown with oats; one acre ploughed but once, and unmanured, produced only 17 bushels. Another six acres ploughed three times, manured, and weeded, produced 37 bushels. This experiment proves, that oats require good management, and will pay for it as well as other crops. Ten bushels of the increased produce may be fairly attributed to the weeding; and the other ten to the manure.—The importance of weeding, both to the individual and to the public, is such, that it ought to be enforced by law. At any rate, a regulation of police, for fining those who harbour weeds, the seeds of which

may be blown into their neighbours' ground, can have no injustice in principle. In England, the petty constable might be required, by precept from the high constable, to give in presentments to the Quarter-Sessions, containing a list of all persons who suffered weeds to run to seed in their hedges or lands, such presentments to be particularly specified to the court. Those referring to the coltsfoot, to be given in at the Ladyday sessions; and those referring to thistles, rag-weed, &c., to be given in at the Midsummer sessions. An order of court might then be made, for the immediate removal of such nuisances; and if not complied with, the offender should be fined a sum not exceeding five pounds, one half to the informer, and the other half to go for the relief of the poor. If, in consequence of such a system being enforced, from four to five bushels of wheat, fifteen bushels of barley, and ten bushels of oats additional, were raised in all the fields in the kingdom, whose crops are injured by weeds, the benefit would be well worth the labour and expense, and the farmers would soon find, that however anxious they may be to have their lands tithe-free, yet to have them weed-free is of still greater importance. On the whole, keeping his land in a clean state ought to be a principal object with every farmer; and if this be not carefully attended to, he may rest assured of paying dearly for his neglect. But the losses which he suffers, do not remedy the injury which the public sustains from his slovenly conduct."

"In several countries," says the same writer, "the legislature has interposed its authority for the destruction of weeds. By a regulation in France, a farmer may sue his neighbour, who neglects to destroy the thistles upon his land at the proper seasons, or may employ people to do it at the other's expense. In Denmark, there is a law to oblige the farmers to root up the corn marigold, *Chrysanthemum segetum*. But the oldest regulation for that purpose, was probably in Scotland; a statute of Alexander II. about the year 1220, having been directed against that weed, which was considered to be peculiarly pernicious to corn fields. The statute is very short, and ably expressed. It denounces that man to be a traitor, 'who poisons the king's lands with weeds, and introduces into them a host of enemies.'—Bondsmen who had this plant in their corn, were fined a sheep for each stalk. Under the authority of that law, Sir William Grierson, a Scottish baron, was accustomed to hold *Goul* courts, for the express purpose of fining the farmers in whose growing crops three heads or upwards of that weed were found. Such a plan, if generally adopted, would soon extirpate weeds; and as by a clause introduced into many leases, (and which ought to be universal,) the landlord is empowered to cut down these weeds, at the expense of the tenant, if the latter neglect to do it himself, it is much to be regretted that so useful a regulation should not be generally enforced. The policy of some legislative provision for this purpose has been frequently suggested. A clause enforcing the extirpation of weeds, in hedges, along the sides of roads, passed the House of Commons, but was thrown out by the Lords. It is to be hoped, that so useful a measure, even on a more extensive scale, will soon be passed into a law. By some it is recommended, that the destruction of weeds on the sides of roads should be done at the parish expense; others, by the road-surveyors, and the expense to be stated in their accounts." In some of the best farmed parts of the Continent, the authorities not only order the weeds on commons, public lands, and all road sides to be cut down, but also order all the leaves of trees infested with caterpillars to be stripped off and destroyed; and if individuals neglect to keep down weeds and prevent the multiplication of noxious insects at the proper seasons, the parishes do them and charge the individuals with the expense,—and if the parishes neglect them, the districts do them and charge the parishes. Some similar law in Britain, with reference especially to all annuals and all light-seeded perennials, would evidently confer vast benefit on agriculture, and make a great addition to the national wealth,—not only increasing the produce of field crops, but appreciably diminishing the amount of farm labour, and correspondingly cheapening the market value of farm produce.

The prevention of weeds by several means which are fully in every farmer's own power, and which ought to hold a recognised place in the routine processes of every farm, is vastly more important than even prevention by the authority of some public law. All farmers, according to the nature of their practices, are either preventers or encouragers of weeds. One very effectual measure of prevention is to use care that all seeds of corn, brassicas, or other field crops sown upon a farm be perfectly free from intermixture with the seeds of weeds; for even a very small amount of intermixture,—such as may be found in many a market specimen of agricultural seeds, and such as will readily escape the observation or suspicion of a slovenly farmer —will, in some instances, produce an appalling quantity of weeds, and may so sadly befoul the very cleanest land that years of labour may be requisite to remedy the evil. Another measure of much consequence is to use care that no rubbish or sweepings or offal containing the live seeds of weeds be allowed to find its way to the farmyard or the dung-heap; for weeds of many kinds, comprising some of the most mischievous, when they go into a field through the medium of manure, take such stubborn possession as to resist all but the sturdiest and most persevering efforts for their extirpation. A third precaution is to keep the sides of fields, the sides of hedges, the sides of roads, and all waste or rubbishy spots about a farm in a clean condition, and on no ac-

count to allow any weeds there to run to seed; for however much stray seeds are brought in by strong winds from neighbouring or comparatively distant places, the grand supply for the propagation of new races of weeds is always furnished within a farm's own limits. Another important precaution, though properly but a subdivision of that which we first named, is to use only such grass-seeds as have been raised upon the farm itself, and saved from a very cleanly crop, or at least not to use any which have been imported from the Continent, or obtained from any unknown party in Britain; for the grass-seeds commonly sold in the market, particularly the seeds of rye-grass, often contain intermixtures of weed-seeds which cannot readily be detected by the eye, and which sometimes so sadly befoul comparatively clean land that after it has lain years in grass, and is broken up again for tillage, a vast quantity of weeds of different kinds formerly unknown upon it rush up in mixture with the first crop, and occasion great loss and trouble, And a fifth precaution, more important far than any of the rest, is to work well a wise system of rotation. "Upon every farm where steady and judicious management is exercised," says the writer formerly quoted, "weeds of all kinds may easily be kept under at a moderate expense, provided regular rotations of crops are strictly adhered to, and care used to prevent weeds from securing an effectual lodgment in the soil. Upon all clay soils, or those that are most infested with perennial weeds, summer fallow is the radical mode of destroying these adversaries; and if this mode is resorted to once in six years, and carried into execution with accuracy and precision, any injury from weeds, during that rotation, will be of small importance. But upon light soils, independent of the ordinary ploughings, harrowings, and rollings, the horse and hand hoe must be used as often as possible, to keep down and destroy the numerous host of foes, with which such soils are infested; and if these operations are duly attended to, much injury cannot be sustained, even upon the richest or driest soils, from the attack of weeds, whether of the annual, biennial, or perennial varieties."

"Though it is impracticable to extirpate annual weeds altogether, either by summer fallow or turnip culture, yet the number of weeds may be so much lessened, by these means, as to prevent them from materially injuring corn crops. Two measures are necessary for that purpose,—first, to bring the seeds within the limits of vegetation,—and secondly, to destroy every weed that vegetates, thus regularly lessening the original stock. As the seeds of annual weeds are naturally furnished with the means of preservation while stored in the ground, it is absolutely necessary to bring them into life, before their destruction can be effected. This is accomplished by the operations of ploughing, harrowing, and rolling, by which the ground is pulverized and reduced, whilst the seeds are brought to the surface, or so near it as to allow their speedy vegetation. All the seeds within two or three inches of the surface, may be expected to vegetate according to circumstances, such as, richness of soil, fineness of mould, and the degree of moisture which may prevail when the above processes are executed. When the first crops of weeds appear above the surface, a second ploughing should be given, by which that crop will instantly be destroyed, and a foundation laid for producing another crop. Harrowing and rolling should again be resorted to; and in this way, several crops may be annihilated, in warm and moist seasons, before the turnips are drilled; more especially if attention has been paid to harrow and roll the land after every ploughing, so that sufficient moisture may be preserved to insure vegetation. When under turnips, both the hand and horse hoe should be constantly employed whenever weeds appear; and upon no account should a single one be allowed to run to seed. By paying due attention to these measures, many farms which formerly were a nest of seed-weeds, are now brought into such order that the weeds are kept under subjection and easily managed. In this way the destruction of many annual weeds may be accomplished, before the turnip-seed is sown, and the seeds of almost every annual weed, locked up in the ground, may be brought to the surface, and within the reach of vegetation. Besides, the several horse and hand hoeings given to the turnip crop, serve to destroy every annual weed as fast as it appears; and if the seed-furrow given the corn crop which succeeds the turnips, is not taken deeper than the horse-hoeing furrow, (and a greater depth is unnecessary,) few weeds will appear in the corn crop which afterwards follows. As grass-seeds are always sown in the improved districts, with the corn crop that succeeds turnips, no annual weeds can appear in that season; but it very often happens in the succeeding year, from ploughing the clover stubble a little deeper than the seed-furrow given to the crop which succeeded turnips, that a fresh growth of annual weeds make their appearance. To get the better of these enemies, some experienced farmers have hand-weeded the crops which followed clover, at an expense not less than from ten to twenty shillings per acre, and evidently much to their advantage; whilst others have resorted to the drill husbandry to get quit of annual weeds. The great object of both was, to procure clean crops, each being perfectly satisfied, that if their crops were full of weeds, the productive powers of the soil would not only be deteriorated, but that the amount or value of those crops would be also considerably lessened.

"Owing to the nature of the soil and climate, many perennial weeds are much more abundant in Scotland, and also in Ireland, Wales, and the north and north-west of England, than in other

countries, where the soil is drier, and the climate more temperate. So far as respects couch-grass, there is no other way of getting rid of it, than by picking and gathering every root during the summer season, when the land is in preparation for turnips, or when the radical process of summer fallow is executed. The same observation may be made with regard to knot-grass, which, though not so general as couch, must be regarded as a most hostile adversary to improved husbandry. To get rid of these weeds, many farmers have employed girls with baskets to follow their ploughs, and to pick up every root as fast as it was turned up. A practice of this kind certainly deserves commendation; for were it steadily followed, the country would soon be freed from these destructive roots. In short, attention to the gathering of couch and knot grass must never be relaxed, otherwise these enemies will soon regain their primitive strength; but if that attention is constantly bestowed, the labour of every rotation will become more easy in the execution, and the expense will in a proportional degree be lessened. With regard to docks and thistles, the method of getting rid of them is perfectly obvious; all that is required being to fallow the ground well in the first instance, and to exterminate the plants afterwards whenever they appear. This may be accomplished by pulling them up by the root, in every corn-field, when the weather is moist, and cutting them over in all the grass lands before they have perfected their seeds; though cutting should only be resorted to when the weather is so dry as so prevent pulling these weeds out of the ground. The same attention ought to be paid to the destruction of nettles, ragweeds, mugwort, and the mountain daisy. Every one of these weeds ought to be pulled up by the root, if that measure can be accomplished; but where that is impracticable, they ought to be regularly cut down by the scythe, in which way their increase will at least be prevented. This operation should always be performed before their seeds arrive at maturity, otherwise the ground may thence be stocked with fresh seed, to an extent not much less than if the cutting process had been neglected. As to tussilago, the best time for destroying that plant, is, in the months of September and October, after the crops are cut, at which season the plants are at their full growth, and easily discovered. The method then to be used is, to pull up and carry off every stock or root that can be laid hold of; and it will be observed, by inspecting the roots at about an inch below the surface, that a number of buds, about the size of a pea, spring from that part of the root, which flowering, afterwards produce fresh seed. If these are allowed to stand till next spring, they will flower, and shed their seeds in spite of every possible attention, the flowers coming out early in April, according to the season; so that it is impracticable to prevent their increase by any other method than the one suggested. If this plan, however, is persevered in for a few years, success is indisputable; though it must be remarked, that much depends upon performing the operation of pulling, as early as the crops are cut,—for if delayed for any length of time, the leaves wither and fall off,—after which the roots cannot easily be discovered. If the weather is moist, there will be little difficulty in pulling up the roots to a sufficient depth; but should it be dry, or the ground hard, it is proper to furnish the pullers with a small piece of iron, split at the one end like the toes of a hammer, and about ten inches long, to enable them to get the root up from the required depth. A few boys or girls, under the direction of a careful overseer, will execute this work at a trifling expense; and care must be taken, that all the roots so pulled be carried off and destroyed, for, if allowed to remain at the sides of stone-walls or hedges, they will flower in the succeeding spring, and shed their seeds; which, being of a winged description, will fly about the field in all directions. Where land is much infested with this pernicious weed, it is proper to examine it in the spring months, lest any of the stalks should have been missed in autumn; and in this way, by attention and perseverance, ultimate success may be relied on. With regard to crowfoot, it is only to be destroyed by fallowing the land completely during dry weather. By that means, this baneful weed is easily destroyed; but if the season is wet, hand-picking must be resorted to, otherwise fields infected with it will only be partially cleaned. Briars and brambles are likewise injurious to arable lands; and their roots being placed below the operation of the plough, they cannot be pulled up. To get rid of them, they must be dug out with great care. On grass lands, the seeds of furze or whins, and of broom, more especially where the soil is of a soft nature, are also troublesome. They should be pulled up in the state of seedling plants, when the land is saturated with moisture, which can easily be effected."

WEEDING. See Weed.

WEEVIL. The snouted family of hard wing-cased beetles. It is one of the most destructive families of insects which plague the cultivators of the soil and the owners of agricultural produce; and possesses a manifold, searching, and melancholy interest, in particular, to farmers, practical gardeners, corn-merchants, maltsters, and foresters. Its characters are well defined, and enable a very superficial observer readiy to distinguish its species from those of all other families, except perhaps the wood-eaters. See the article Bostrichidæ. The snout or rostrum of a weevil is its grand characteristic; and this, in all cases, is an anterior process or projection, more or less elongated,—and does not consist of the parts of the mouth as in flies and other suctorial tribes, but is an extension of the head, having the usual oral organs situated at its ex-

tremity. The body is usually more or less arched lengthwise, and in many instances approaches to pear-shaped, with the thicker or hinder end somewhat acuminated; but in other instances is nearly cylindrical, and narrowed at each end The external crust is generally very hard, and well fitted to resist the injuries to which the insects would otherwise be exposed from the nature of their haunts, which are frequently among stones and loose earth. Such species, however, as live exclusively on plants, have often a softer integument, and are not unfrequently adorned with very beautiful colours, occasioned by a coating of minute scales. Few weevils are much observed on the wing; for, like the majority of the beetle-race, they fly but imperfectly; and many which confine themselves to the surface of the ground have their wing-cases soldered together at the suture, and are incapable of raising them. Another very distinctive mark of the whole family, is furnished by the antennæ, which are inserted on the rostrum, and commonly consist of eleven joints, the radical one of which is nearly as long as all the rest taken together, and is received into an oblique groove on the side of the rostrum; and the articulated portion, which is clavate at the apex, usually forms a right angle with this stalk or elongated radical joint, so that when the antennæ are extended, they present the appearance of a trident, of which the rostrum forms the central prong. Weevils composed the genus *Curculio* of Linnæus; but as they are very numerous, and exhibit almost endless modifications in form and structure, they have been distributed by modern naturalists into a multitude of genera. Not fewer than five hundred species have been described as inhabiting Britain. Both in the larva and perfect states, they feed exclusively on vegetable substances, principally on herbaceous plants, although no small numbers likewise attach themselves to trees and shrubs; and as a whole, they are very formidable enemies to both the farmer and the gardener. The larvæ of certain kinds are subterranean, and consequently consume roots; others destroy the flowers of fruit trees; and some feed upon seeds, while the perfect insects mutilate the leaves. Some of the best known and most mischievous species are noticed in the articles Calandra, Anthonomus, Phyllobius, Balaninus, Otiorhynchus, Apion, and Hylobius; but many species which are known or suspected to inflict great injury have as yet been very imperfectly observed.

Two species recently written into notice by Mr. Curtis have been ascertained to work prodigious havoc upon leguminous crops.—The worst of the two is called popularly the striped pea weevil, and scientifically *Sitona lineata*, or *Curculio lineatus*. It is elliptical in form and convex above, punctured and clothed with minute scales; and has more or less an ochreous or light clay colour, but, after losing its scales by age or accident, displays a black shining surface. The head is elongated and deeply punctured; the face is concave, and has a channel down the centre; the snout is short, stout, and notched; the eyes are lateral, prominent, orbicular, and black; the antennæ arise out of deep angular grooves toward the tip of the snout, and have a tawny colour and a fusiformly clubbed extremity; the thorax is deeply punctured, broader than the basal part of the head, and convex on the sides; the wing cases are broader than the thorax, elliptical, rounded at the apex, and finely punctured in the manner of striæ, with tints of alternately lighter and darker clay colour; the wings are very ample, and folded beneath the elytra; the six legs are ferruginous, short, and stoutish, and the tarsi or feet are four-jointed. The other species is called popularly the spotted pea-weevil, and scientifically *Sitona crinita* or *Curculio macularis;* and differs from the preceding principally in being of smaller size and of different colour. The head and body are predominantly black and shining, with a clothing or armature of greyish or rosy-tinted scales or short hairs; the thorax is marked with four dark stripes; and the elytra are rather rough, and have short bristles behind.—The spotted species chiefly devastates pease, but the striped devastates also beans, lucern, and clover; and both either destroy the plants as soon as they rise above the surface, or nibble the leaves and notch the edges as soon as they have expanded. Their habits of propagation, the economy of their larval and pupal states, and the surest methods of destroying them, are but very obscurely known; yet the following notices by Mr. Curtis of devastations done by the striped species, and of the likeliest methods of keeping down both species, may be acceptable and useful.

"Most farmers are very imperfectly acquainted with the economy of these insects; and it was a long time before gardeners could be convinced that it was a weevil which caused them so much anxiety. Some very naturally accused the sparrows; traps were set for rats and mice; lime strewed for slugs and snails; and toads were encouraged to extirpate the woodlice; but still the crops kept disappearing, as none of these precautions affected the wary enemy in his coat of mail. There were, however, both gardeners and farmers, whose close attention to the operations of nature, united with steady perseverance, which generally leads to the truth, who eventually succeeded in detecting the real cause of the mischief. In favourable seasons the weevils make their appearance at the end of March; but April is the month when they are most destructive to the pea-crops, — and one then finds that healthy shoots are daily, if not hourly, disappearing in a most marvellous manner, without any apparent cause, so that spaces of a foot in length, and sometimes the entire rows, are lost, or the few that may be left are so weak that the produce can be reckoned of little value. The year 1844,

if I may judge from the number of communications transmitted to me, appeared to be well suited to these weevils, which were actively at work in thousands in the vicinity of Hertford at the end of March, continuing their operations for a fortnight, and entirely eating off the second and third sowing, when the plants had grown from two to four inches high. At this period of the year, they issued from the ground from 9 to 10 o'clock in the morning, to feed all day upon the pease; and they retired under the clods of earth on the approach of evening. They were equally troublesome at Stafford the first week in April, when they ate off the early pease; and in the Isle of Wight these weevils were not less destructive, for there they attacked the beans as well. On the 30th of the same month, I received from Mr. Pusey an interesting account of this beetle, communicated by Mr. Robert Baker, stating that some garden marrowfat pease were drilled early in February, which were retarded in growth from the cold north-east winds and wet, and destroyed by the ravages of this insect, which notched all the leaves, and in many instances entirely defoliated the stem. It most abounded on light turnip-soil. Mr. Baker correctly observes that 'it is exactly the colour of the soil, and very difficult to detect, as upon the approach of any one, it falls down suddenly from the pea, and lies motionless for some time afterwards, as if dead; but if any one looks attentively forward a few yards, they may be observed in scores sitting upon the edges of the pea-leaves and gnawing away earnestly, with appetites as voracious as the turnip-fly, and almost as destructive in the result.' From the same source we learn that 'they do not attack the common hog-pea so vigorously as the garden varieties; but the marrowfat and early pease suffer most.' This was corroborated by the fact that the maple-grey pease nearly escaped, whilst the remainder of 8 acres in the same field were obliged to be ploughed up. It is somewhat remarkable that this beetle commences with the pease in March; then it affects the broad beans to such an extent, that I have not been able to find a single leaf in a field of many acres which is not greatly notched; and in August, and until the close of the autumn, its ravages are transferred to the crops of clover and lucern. On the 18th of that month, 1843, I received a communication from Mr. C. Parsons, of North Shoebury Hall, Essex, which is too valuable to be passed over. He says, 'I enclose you a beetle, very destructive in these parts to the young plants of clover, lucern, &c.; so much so, as often totally to destroy whole fields, and especially those of lucern, *Medicago sativa*, which they attack in such a way, that for several years past no one has been able to obtain a full plant, although going to the expense of sowing the land two or three times over. The damage is attributed by our farmers here to the turnip-fly, and the habits of these little weevils render it in the spring of the year exceedingly difficult to detect them, as the moment one approaches near, down they fall upon their backs amongst the clods, and remain motionless with their legs folded up. I have searched a long time in vain for them in fields where they were committing their ravages, in order to convince my neighbours what they were indebted to for the loss of their crops. At this time of the year they are readily enough obtained, as the pease, beans, and other papilionaceous plants often swarm with them. I have a field of pease that does so at this time, the remaining leaves of which they have completely riddled; and when a person walks in amongst them, you may hear a pattering like rain upon the leaves, occasioned by their dropping down. I last year sowed a small piece of lucern in July, that was untouched by them; now, whether at that time they are absent, or whether there is any interval between a first and second brood of them, would be very desirable to know, as we might then perhaps steal a march upon them.' Two years previous to this, viz., the 15th of September, 1841, Mr. William Trenchard transmitted me the following instructive observations from Marsh Farm, near Sherborne, Dorsetshire, which carry forward the economy of the weevils several weeks later:—'Walking along the headland of a field of broad-clover, from whence the barley had been carried about a fortnight, I was surprised to see that throughout, for the width of four or five yards from the hedge, the plant was very much injured, and in many parts quite destroyed, from having been bitten apparently by some insect. Nearly every leaf was eaten round the edges, and so deeply were they indented, that those parts of the leaf not eaten are withered from the sap not being able to ascend. Curious to know by what animal such ravages could have been made (for I suppose the headland is more than half an acre), I examined the clover to discover the depredator, but for a long time unsuccessfully, until at length having stood quite still and watched the leaves intently for a considerable time, I ascertained that it was done by a number of small brown beetles, which immediately, on moving near, hid themselves by getting under the leaves, and on a nearer approach they let go their hold altogether, and fell to the ground as if dead, but immediately recovered and crept among the roots of the clover, where they remained until all was again quiet. Being so exceedingly shy, it was a long time before I could see any of them actually eating, but by perseverance I eventually succeeded in observing several. They attack the edge of the leaf, holding it steady between their legs, whilst they eat down from top to bottom like a silkworm. To give some idea of their numbers, when I moved the clover with my hand or foot, they fell off by dozens.' It still remains to be ascertained where the eggs are deposited. This operation must take place, one would imagine, in the sum-

mer or autumn, unless the weevils hibernate, as they are ready to take the field in the early spring, and in April they abound on the broom and furze in Norfolk, Surrey, &c. It is equally remarkable that we are ignorant where the larvæ feed.

"Ignorant as we are of the early stages of these weevils, the only remedies we can at present apply will be in destroying or annoying them in their beetle state; and from their horny shells and power of contracting and protecting their members, it is difficult to find any application that will extirpate them without injuring the plant. For the garden, I should recommend the tarring or painting two strips of canvas, and placing one on each side of a row of pease early in the morning, and two or three hours after; by shaking the plants the weevils would fall down and be held fast by the adhesive surface. This might be repeated several times each day, until it would be seen that their numbers were sufficiently reduced to secure the crop. Of course the painting or tarring must be repeated whenever it is too dry to fix the objects falling down. Neither soot, wood-ashes, nor lime will injure the weevils, we are informed and can readily believe; yet by dusting over the pease early in the morning with any or all of these powders, whilst the leaves are damp, their food will be rendered so unpalatable that the enemy will be driven to forage elsewhere; and if a row of pease were sown near, which was left undusted, the beetles would resort thither, and when it was clear by the erosion of the leaves that the plague was congregated there, boiling water poured along the line would eradicate them, and thus the principal sowing might be saved; or the tarred canvas might be most efficiently employed, if that plan were preferred. Mr. Baker has found harrowing or hoeing beneficial when a field of pease is attacked by the weevils. It should be done whilst the dew is upon them, that the earth may adhere and make the plants unpalatable; and he says he has found this one of the most successful modes of checking the ravages of the turnip-fly."

WEIGHING MACHINE. A machine for promptly ascertaining the weight of any objects or commodities. The kinds of it in most common use are noticed in the articles Balance and Steelyard; and peculiar kinds, recently invented kinds, and kinds more or less specially adapted to the uses of the farmer, the miller, the corn-merchant, and other parties who deal in agricultural produce, are so numerous that we can afford only to notice a few of the most useful.

Smith's portable weighing machine, invented about 21 years ago by Mr. John Smith of Edinburgh, is a contrivance on the principle of the Roman steelyard for weighing bags or sacks of corn, flour, or other goods. The bag or sack to be weighed is placed on a stand on one side of the machine, which is provided with arms for holding the sack open so as to allow portions of the corn or other goods to be added or abstracted; and its weight is immediately ascertained by putting one or more small weights on a small platform on the other side. The machine, when in working order, stands like a frame upon the floor, but it is provided with an under-support and two small wheels,—and can easily be removed from place to place in the manner of a common wheel-barrow.

The balance weighing machine for sacks of corn, bags of flour, and similar bulks and commodities, presents a general resemblance to Smith's, and has as good or better adaptations to the barn, and possesses similar facilities for holding sacks and for removal from place to place; but it is constructed on the balance principle instead of the steelyard one, and requires an amount of weights equal to the absolute weight of the bodies weighed, and is made in various ways, either chiefly of cast-iron or with a frame-work of wood, and at cost prices varying from £5 to upwards of £8.

The hydrostatic weighing machine was invented by Mr. Milne of Edinburgh, and indicates the weight of a body by the rise of a column of mercury. A cylindrical cistern containing mercury communicates with a small tube, having attached to it a graduated scale; a loose piston floats on the surface of the mercury in the cistern; and a scale-board is attached to the piston-rod. Any body placed on the scale-board causes the piston to sink in the mercury, and to displace a portion of it equal to the body's weight; and the displaced portion rises round the sides of the piston proportionally to the quantity displaced, and also rises to a proportional height in the tube, and thereby indicates the absolute weight of the body on the graduated scale.

The weighing machines of Mr. James of London are constructed on a peculiar principle, and possess a wonderful variety of forms and adaptations. Their scale-boards do not rest upon a system of levers, as in the common forms of machines for weighing heavy bodies, but are suspended from the extremity of the beam, as in the ordinary balance, and at the same time are free from all embarrassment by chains or cordage. These machines obtained prizes from the French Government, and from the Highland and Agricultural Society of Scotland, and from the Royal Agricultural Society of England; and the report of the last of these says respecting them: "It would require more space than can be devoted to this subject to explain the causes of error incident to all weighing machines hitherto made, and from which Mr. James's are free. The principle is mathematically correct, and mechanically carried out, as is proved by placing the object to be weighed on any part of the scale-board, when it will be found to be balanced by the same weight. Scale-boards of the largest dimensions may be used; and it is hoped that

by means of this invention agriculturalists will be induced to ascertain the relative value of varieties of food in the fattening of cattle, by frequently placing them on the weighing machine; which will indicate the weight of the largest ox or loaded cart, with as much accuracy as the sack of corn or still lighter objects." The principle of these machines admits an unlimited multiplicity and variety of form, adapted to every possible commercial exigency, and also, by combination with various mechanical powers, produces machines which, while accurately serving every purpose of weighing, are at the same time perfect cranes, crabs, or turn-tables. The more prominent advantages of the invention are economy of first cost, the price being less than that of a common beam with its necessary appendages,—economy in time and labour during the operation of weighing,—durability, the machine seldom requiring adjusting, and admitting of the roughest usage without injury, and the centres not being exposed to wear and tear, except during the act of weighing,—the admitting of a greatly extended scale-board, without proportionally enlarging the size of the machine,—and the presence of an indicator or cock as in the common beam.—One form is a twenty hundred weight machine for weighing hay, straw, oil-cake, or any other description of agricultural produce; and it may have a moveable pen connected with its scale-board, rendering it applicable to the weighing of calves, sheep, and hogs, and also to the weighing of such loose articles as potatoes, turnips, and mangel-wurzel.—Another and somewhat similar form is provided likewise with a sliding frame for increasing the size of the scale-board at pleasure, so as to adapt it to the weighing of such bulky articles as hops; and has also an upright rod at the back of the scale-board, furnished with two small chains and hooks, for conveniently weighing packages of wool; and may further be constructed with a chain-enclosed pen for weighing sheep.—A third form, not far from akin to the preceding, has a large scale-board, or high pen, and ascents to the scale-board, for the weighing of cattle.—A fourth form is a five hundred weight machine for weighing by fractional parts. One pound in the small scale-board is equal to eight pounds in the large, so that to weigh one hundred weight of goods it is only necessary to place fourteen pounds on the small scale-board. By this means a considerable saving is effected in the purchase of weights, and weighing operations are conducted with great quickness, and much less labour.—A fifth form is a three hundred weight machine, with a rising back, for weighing sacks and sackfuls. The rising back may be adjusted to any required height; and two arms project from its top, furnished with hooks at their extremities, for keeping open the mouth of a sack.—A sixth form is near akin to the preceding, but has the scale-board so attached to the rising back that it may be raised to the height of a man's shoulder, or to that of a cart or waggon, so as to allow a weighed full sack to be shifted with great facility; and this form, independently of its convenient character as a weighing machine, is in fact a mechanical contrivance for raising full sacks to a convenient height for removal, with half the usual amount of labour required for lifting them from the ground to the shoulder or to a cart or waggon,—and it is therefore peculiarly suitable for farmers and millers.—A seventh form is a three-hundred weight pedestal machine, exceedingly desirable for domestic purposes, or for situations which require the combination of elegance with utility. Its exterior appearance is that of an ornamental piece of furniture, similar to the pedestal of a statue, or a quadrangular, pannelled, corniced, high, and narrow chest; its top, which forms the good's scale board, may be in marble if required, and will then serve as a handsome and useful small table; and its weighing apparatus is enclosed and completely hid from view. This form is eminently suitable for a large kitchen dairy; and it may also be provided with a moveable support for weighing sacks.—An eighth form is a machine with an even beam, with two scale boards of equal size, and with the beam-arms of equal lengths; and it is used in the same manner as the common balance, yet is so constructed as to have no embarrassment from chains or cordage, and as to be capable of all the advantageous peculiarities and adaptations of the seven forms which we have previously described,—particularly rising backs, enlarging and rising scale boards, pens, and hooks and arms.—A ninth form weighs on the principle of the steelyard, and also comprises rising backs, enlarging and rising scale-boards, and other conveniences similar to those already noticed.—A tenth form is a dial weighing machine without springs, simple, accurate, and delicate. A number of goods or a multitude of separate bodies are weighed by it with great rapidity; and as it requires no weights, the labour of shifting them, and the annoyance so frequently occasioned by losing or mislaying some of them, are entirely avoided; and, like all the preceding forms, it admits of any arrangement of the scale board.—An eleventh form is a weigh bridge, constructed on the parallelometal principle, ensuring great accuracy of result, with little or no liability to go out of repair; for when the bridge is not in use, it does not rest upon its centres, and therefore cannot be injured by any amount of traffic passing over it.—Other forms are different kinds of weighing cranes suitable for granaries, warehouses, docks, wharves, and railways, or indeed for any places and purposes where heavy goods or objects require to be both lifted and weighed. The construction of these cranes is exceedingly simple; the positions of the jib, winch, chain-break, and other parts of the ordinary crane, are in no way altered; nor are the movements of the crane at all obstructed.

They may be used as weighing machines, or as cranes at pleasure, a simple turn of the hand being all that is required to render the jib either fixed or vibratory. The length of the chain, or of the jib, and the weight which the cranes may be required to raise and weigh, or the purposes for which they are intended, are matters of no moment. In landing and weighing heavy goods, the weight is ascertained with all the accuracy of the beam while the goods are in a state of suspension, and the loss of time, labour, and expense, occasioned by shifting them from the crane to the beam, and back again from the beam to the crane, are entirely avoided.

WEIGHTS. In the article MEASURES we have given an account of the reformation of the English measures. The following tables exhibit the relations of some of the most important measures of weight.

1. *French Measures of Weight.*—The unit used in weighing is the kilogramme. It has been fixed by law, and is equal to the specific weight of the distilled water contained in one cubic decimètre. The kilogramme thus fixed was found to be equal to 2 livres (pounds), 5 gros, 35 grains, $\frac{15}{100}$ poids de marc, and to 2 lbs. 8 oz. 3 dwt. 6·355 grains troy, or 2 lbs. 2 oz. 4 drams, 16 grains avoirdupois weight, English. As the most common things of daily consumption are sold by weight in small quantities, a great difficulty arose in introducing this part of the system; and the old denominations of weight have therefore been allowed to remain, with some modification in their actual value, taking the kilogramme as the basis. The kilogramme is divided into 2 livres; the livre is subdivided into 16 ounces, the ounce into 8 gros, and the gros into 72 grains. This new livre, therefore, exceeds the old one (poids de marc) by $\frac{3}{100}$; so, to reduce kilogrammes into old measure, it is necessary to multiply by 2 and add $\frac{2}{100}$.

English Troy.	*French.*
1 grain (1-24th of a dwt.) - - =	0·06477 gramme.
1 pennyweight (1-20th of an ounce) =	1·55456 gramme.
1 ounce - - - - - - =	31·0913 grammes.
1 pound troy imperial - - - =	0·3730956 kilogramme.

English Avoirdupois.	*French.*
1 dram (1-16th of an ounce) - =	1·7712 gramme.
1 ounce (1-16th of a pound) - =	28·3384 grammes.
1 pound avoirdupois imperial - =	0·4534148 kilogramme.
1 hundred weight (112 pounds) =	50·78246 kilogrammes.
1 ton - - - - - - =	1015·649 kilogrammes.

1 millier = 1000 kilogrammes (weight of a tun of sea-water).
1 quintal = 100 kilogrammes.
1 hectogramme = 1-10th of a kilogramme.
1 decagramme = 1-100th "
1 gramme = 1-1000th "
1 decigramme = 1-10,000th "

2. *English Measures of Weight.*—The statute of 5 George IV., c. 74, made some slight modifications in the measures of weight, but retained, in the main, the existing measures. "The troy weight," say the Commissioners of weights and measures, "appeared to us to be the ancient weight of this kingdom, having existed in the same state from the time of Edward the Confessor; and there are reasons to believe that the word *troy* has no reference to any town in France, but rather to the monkish name given to London of Troy Novant, founded on the legend of Brute: troy weight, therefore, according to this etymology, is, in fact, London weight. We were induced, moreover, to preserve the troy weight, because all the coinage has been uniformly regulated by it; and all medical prescriptions or *formulæ* always have been estimated by troy weight, under a peculiar subdivision, which the college of physicians have expressed themselves most anxious to preserve." It was resolved, therefore, to continue the use of troy weight, and also, on account of the accuracy of the troy standard, to raise the avoirdupois weight from this basis. "We found," continue the commissioners, "the avoirdupois weight, by which all heavy goods have been for a long time weighed (probably derived from *avoirs* (*averia*), the ancient name for goods or chattels, and *poids*, weight), to be universally used throughout the kingdom, This weight, however, seems not to have been preserved with such scrupulous accuracy as troy weight, by which more precious articles have been weighed; but we have reason to believe that the pound cannot differ by more than one, two, or three grains, from 7,000 grains troy. It, therefore, occurred to us, that we should be offering no violence to this system of weights, if we declared that 7,000 grains troy should be hereafter considered as the pound avoirdupois." It was accordingly enacted that, from January 1st, 1826, the standard brass weight of one pound troy weight, made in 1758, should be the genuine standard measure of weight, and be denominated the imperial standard troy pound, containing 5,760 grains, and that 7,000 such grains should be a pound avoirdupois.

DIVISION I.—*Avoirdupois Weight.*

27$\frac{11}{32}$ grains - -	= 1 dram - -	= 27$\frac{11}{32}$ grains.
16 drams - -	= 1 ounce - -	= 437$\frac{1}{2}$ "
16 ounces - -	= 1 pound (lb.) -	= 7000 "
28 pounds - -	= 1 quarter (qr.).	
4 quarters - -	= 1 hundred weight (cwt.).	
20 hundred weight	= 1 ton.	

This weight is used in almost all commercial transactions, and in the common dealings of life.

Particular Weights belonging to this Division.

	cwt. qr. lb.	
8 pounds - = 1 stone		used for meat and fish.
7 pounds = 1 clove		
14 pounds - = 1 stone - =	0 0 14	used in the wool trade.
2 stone - = 1 tod - =	0 1 0	
6$\frac{1}{2}$ tod - - = 1 wey - =	1 2 14	
2 weys - = 1 sack =	3 1 0	
12 sacks - = 1 last - =	39 0 0	

A pack of wool contains 240 lbs. A truss of hay weighs 56 lbs., and of straw 36. A stone of glass is 5 lbs.; a seam 24 stone.

8 pounds - = 1 clove, - - -	used for cheese and butter.
32 cloves - = 1 wey in Essex, -	
42 " - = " in Suffolk -	
56 pounds - = 1 firkin - -	

Division II.—*Troy Weight.*

24 grains	= 1 pennyweight	= 24 grains.
20 pennyweights	= 1 ounce	= 480 "
12 ounces	= 1 pound	= 5760 "

These are the denominations of troy weight when used for weighing gold, silver, and precious stones, except diamonds. But troy weight is also used by apothecaries in compounding medicines, and by them the ounce is divided into eight drams, and the dram into three scruples, so that the latter is equal to twenty grains. For scientific purposes, the grain only is used; and sets of weights are constructed in decimal progression, from 10,000 grains downwards to one hundredth of a grain. By comparing the number of grains in the avoirdupois and troy pound and ounce respectively, it appears that the troy pound is less than the avoirdupois, in the proportion of fourteen to seventeen nearly; but the troy ounce is greater than the avoirdupois, in the proportion of seventy-nine to seventy-two nearly. The *carat*, used for weighing diamonds, is $3\frac{1}{6}$ grains. The term, however, when used to express the fineness of gold, has a relative meaning only. Every mass of alloyed gold is supposed to be divided into twenty-four equal parts: thus the standard for coin is twenty-two carats fine; that is, it consists of twenty-two parts of pure gold, and two parts of alloy. What is called the *new standard*, used for watch-cases, &c., is eighteen carats fine.

3. *Ancient Weights.*—It is well known that this subject is involved in considerable difficulty. The following table gives the estimates of different authors, in regard to some of the ancient weights.

	English Troy Grains.
Attic obolus	= 8·2 Christiani. 9·1 Arbuthnot.
Attic drachma	= 51·9 Chr. 54·6 Arb. 69· Paucton.
Lesser mina	= 3,892 Chr.
Greater mina	= 5,189 Chr. 5,464 Arb. 6,900 Pauc.
Medical mina	= 6,994 Arb.
Talent = 60 minæ	= ½ cwt. English.
	Grains.
Old Greek drachm	= 146·5 Arb.
Old Greek mina	= 6,425 "
Egyptian mina	= 8,326 "
Ptolemaic mina of Cleopatra	= 8,985 "
Alexandrian mina of Dioscorides	= 9,992 "
Roman denarius	= 51·9 = 1-8th Roman oz. Chr. 62·5 = 1-7th Roman oz. Arb.
Denarius of Nero	= 54 Pauc.
Ounce	= 415·1 Chr. 437·2 Arb. 431·2 Pauc.

Pound = 12 Roman ounces.

WEINMANNIA. A genus of ornamental, exotic shrubs of the cunonia family. Two or three species have been introduced to British collections from Australia, one or two from the Cape of Good Hope, and four or five from the tropical parts of America; and several more are known. Most are evergreens of from 4 to 8 feet in height, and carry white flowers in May and June, and love a soil of rich mould; but one or two are deciduous, and one or two red-flowered. Their leaves are variously pinnate, trifoliate, elliptic, and ovate. The bark of one is used in Peru for tanning leather, and is supposed to be employed also in adulterating cinchona.

WELD. See Dyer's Weed.

WELL. A narrow excavation faced round with masonry, for commanding a supply of water. It may either be shallow and open or deep and covered; and may obtain its supplies either by infiltration from the neighbouring surface, or by percolation from comparatively near ponds, streams, or reservoirs, or by ascent from deeply-seated and far-extending strata in the manner of natural springs and Artesian wells; and it therefore may afford water of almost any conceivable quality, from ditchy to limpid, from brackish to sweet, from very soft to very hard, and from saline to chalybeate or sulphureous; and it also may either be copious or stinted, either steady or fitful, and either uniform in the quality of its water all the year round or diversified according to season and weather. See the articles Water, Spring, Artesian Well, and Pump.

A district of drift or diluvial clay is the most favourable for the forming of wells. This substance constitutes the subsoil of a large portion of the champaign or arable parts of Britain; and though the clay or main bulk of it is impervious to water, it is both intersected with small veins of sand and other porous matter through which water percolates, and interspersed with numerous small boulders which lie like plugs upon pervious strata, and whose removal is followed by a permanent oozing or infiltrating or uprising of water. In ordinary conditions of argillaceous diluvium, a well seldom requires to be sunk to a greater depth than from 8 to 16 feet in order to command a copious and constant supply; though when the clay is hard and contains few or no interspersions and intersections of stones and sand, a well of less depth than from 30 to 50 feet may prove wholly useless.

A district of stratified rocks, in most places where they are but thinly or not at all overlaid with diluvium, or where they almost or altogether crop here and there out of the surface, is generally to the full as favourable for wells as a district of drift; for it often yields a good and plentiful supply at a depth of only from 6 to 8 feet; but it not unfrequently has the disadvantage of letting the water as freely out at one side of the well as it lets it in at the other,—so that, in some instances, the side of the well on which the seams of the rock dip downward require to be puddled.

Districts of deep, unctuous, homogeneous clay seldom have water near the surface or within the range of the clay itself, but generally afford it in great abundance, though sometimes of indifferent quality, at such considerable or great depth as reaches to the formations below the clay. The carse lands of Scotland, in general,

are quite impervious to water, but not very deep and nowhere far from rivers or estuaries; and they commonly afford a supply through any excavation which is merely deep enough to reach the level of the bed of the nearest river or estuary, yet can seldom command it of such pleasant quality as is common in drift and sandstone districts. The lands of the London great clay basin are as impervious to water as the carse lands, but greatly or even prodigiously deeper, so that they often need to be pierced to the depth of from 100 to upwards of 560 feet before they can command supplies. The chalk districts of Hampshire, too, are nearly as unfavourable as the worst parts of the London clay basin; for they sometimes will yield little or nothing till bored to the depth of from 300 to 400 feet, though they then yield in great abundance.

Districts of trap rocks, granite, and other amorphous or crystalline rocks, wherever they are bare and homogeneous, or want a deep covering of diluvium or a great intricacy from geognostic disturbance, are eminently unfavourable for wells. The effecting of excavations in them by blasting is very expensive, and may be perfectly useless; yet when they present many cracks and fissures, and are known or well conjectured to overlie a system of stratified rocks at a small or manageable depth, they may sometimes be easily and economically enough pierced, from the bottom of a blasted excavation, with an augur and rod in the manner of an Artesian well.

WENDLANDIA. An ornamental, greenhouse, evergreen, white-flowered, twining plant, of the moonseed family. It was introduced to Britain from Florida about 90 years ago; it constitutes a genus of itself, and is specifically called the poplar-leaved; it attains a height of about 10 or 12 feet, and blooms in June and July; and it thrives in any common soil, and is propagated from cuttings.

WERNERIA. A small, handsome, greenhouse, evergreen herbaceous plant, of the jacobea division of the composite order. It was introduced to Britain about 21 years ago from Quito; it constitutes a genus of itself, and is specifically called the rigid; and it loves a soil of sandy peat, and is propagated by radical division. It was named in honour of the distinguished mineralogist Werner.

WESTRINGIA. A genus of ornamental, Australian, evergreen shrubs, of the labiate order. Nearly a dozen species have been introduced to the greenhouses and conservatories of Britain; and most have a height of about 3 feet, and bloom from May till August,—two or three have pale blue flowers, and the rest have white flowers, —most love a soil of sandy peat,—and all are propagated from cuttings.

WEYMOUTH PINE. See Pine.

WHALE OIL. See the articles Blubber and Oil.

WHEAT,—botanically *Triticum*. A large and very important genus of grasses, of the terminally spiked order. About thirty species, besides a great multitude of varieties, at present belong to it; about as many more which formerly belonged to it, are now assigned to the recently constituted genus agropyrum; and several others which were formerly included in it, more properly belong to the genera secale, schlerochloa, and brachypodium. All the present triticums are hardy exotic annuals,—four of them varying in height from 6 to 24 inches, and possessing very little interest, and the rest varying in height from 2½ to 6 feet, and ranging in value from inferior economical plants cultivable only in their native regions to the richest cereal grasses of all the temperate parts of the civilized world. All or almost all the agropyrums are hardy perennials, and either worthless or mischievous weeds; most have a height of between 6 and 18 inches; four, including the notorious couch-grass with its several varieties, are natives of Britain; and nearly all the rest have been introduced as botanical curiosities, principally from Siberia, Tauria, and Continental Europe.

Ancient Wheat.—Cereal wheat, like cereal barley, was known at a very early age of the world, and figures in remote records of both sacred and civil history, and has been unintermittedly and extensively cultivated, in many parts of the world, from ancient times till the present day. So early as the time of the patriarch Jacob, "the days of the wheat harvest" seem to have been a recognised and signal period of the annual seasons. When the hail-plague fell on Egypt, previous to the exodus of the Israelites, "the wheat and the rye were not smitten, for they were not grown up." The land of Promise, when the Israelites were about to be conducted into it as their inheritance, was described to them as "a good land, a land of brooks of water, of fountains and depths that spring out of valleys and hills, a land of wheat, and barley, and vines, and fig-trees, and pomegranates, a land wherein they should eat bread without scarceness." In the peculiar constitution which was established over them for the joint guidance of their political conduct and their religious behaviour, they were bound to "observe the feast of weeks, of the first-fruits of wheat harvest, and the feast of ingathering at the year's end." When Gideon was summoned by a special call from the Divine Being to go forth as their Judge, and to deliver them from the Midian oppression, he was found "thrashing wheat by the wine-press to hide it from the Midianites." During the long and close league which subsisted between Solomon and the king of Tyre, for the supply of cedars from Lebanon for the building of the temple at Jerusalem, "Solomon gave to Hiram year by year twenty thousand measures of wheat for food to his household, and twenty measures of pure oil." The impartation of great prosperity

and lofty happiness is metaphorically described as a "feeding with the finest of the wheat;" and a vivid declaration of the immeasurable inferiority of human ethics to the word of God, is made in the figurative interrogatory, "What is the chaff to the wheat?" And a number of other statements and allusions occur in the ancient inspired writings, all showing as these do, that, in the very remote times when these writings were penned, wheat had long been a regularly and generally cultivated crop, that it was raised and gathered and thrashed by the heads of families and leaders of the people, and that it was held in high or even paramount esteem as a rich and grateful bread-stuff. Clear monumental evidence exists, too, of wheat having figured from the most remote times as a favourite plant on the banks of the Nile; and grains of it, possessed of vitality, have been found within the cerements of some Thebean mummies. But the wheat of Palestine appears to have been of a much better kind than that of Egypt; and the wheat of some districts of Palestine had the reputation of being better than that of others. It may even be presumed from the passage, "In the sweat of thy face shalt thou eat bread," that a knowledge of wheat was coeval with the first man,—and from several passages in the later books of the sacred scriptures, that material improvements in selecting good varieties of it, in preparing the ground for it, and in managing and storing its crops, were effected at least one thousand years before the Christian era.

The Romans of the time of the Cæsars were well acquainted with the advantages of classifying wheats into widely different varieties, and of severally using these for the soils and seasons to which they were respectively best adapted; and they seem generally to have arranged them into two great groups under the names of triticum and far, and to have divided each of these into several kinds. See the article FAR. "Columella mentions three kinds of triticum. The best he calls robus, which he says excelled the others both in weight and brightness; the second he calls siligo, which he says is deficient in weight; and the third kind, he says, is a spring wheat, of the nature of the siligo, and he adds that it is very useful to the farmer, when, by any accident, he is prevented from sowing in the autumn. The other kinds, he tells us, are not profitable, and are cultivated only by those who value themselves upon having a great variety. Of far, Columella mentions three kinds likewise. The first he calls clusinum, which is of a bright white colour; the second he calls venaculum, of which he says there are two sorts, the one red and the other white; and the third is a spring wheat, which he calls halicastrum, and says that it excels the others in goodness and weight. He adds, that it is necessary to have all these kinds both of triticum and far, as it seldom happens that a farm is so situated, that one kind is proper for every part of it; there being, almost in every farm, both wet and dry lands. Almost all the rustic writers agree in this, that far is most proper for wet clay land, and triticum for dry land. 'In wet red clays,' says Cato, 'sow far; and in dry, clean, and open lands, sow triticum.' 'Therefore,' says Varro, 'skilful husbandmen in their wet lands sow far, rather than triticum.' Columella says, 'that triticum thrives best on dry land, and that far is less hurt by wetness.' Though triticum, in general, is represented as best adapted to dry soils, yet that kind of it called siligo is mentioned as proper enough for wet lands. Columella joins it with far, when he says, 'wet and stiff clays do well enough for siligo and far.' He observes that siligo is the whitest kind of the triticum, but inferior in weight,—that it answers very well in a wet seed time, and is proper for land over which water is in danger of running; and he adds, that it may be got with very little difficulty, as triticum, when sown upon land that lies low and wet, after the fourth crop, is turned into it. Pliny likewise observes that the siligo is proper for wet lands; and he mentions some soils on which it is turned into triticum."

The Botanical Characters of Wheat.—The distinctive characters of the genus triticum, in the old or extensive sense of it, are terminally spiked inflorescence,—two-valved and quite or nearly equal glumes,—alternate, two-rowed, many-flowered spikelets, transverse or so placed that the edges of the florets are towards the rachis,—and two paleæ surrounding the seed, the external or lower one either armed or pointed, and the internal or upper one cleft at the point. The rachis or shaft is jointed; the spaces between the joints are called the internodii; the spikelets, rising one above another on each side of the rachis, constitute the spike, or ear, or head; the glume or lowermost shield of each spikelet corresponds to the calyx of non-gramineous plants, and each of the florets to a corolla; some certain florets in each species, in general, are fertile, while others are barren; and the aggregate inflorescence of the several species differs very widely in the length and form of the rachis, the size and shape and packing of the spike, the comparative length of the glumes, and the number and fertility of the florets, and, above all, in the various properties of the seeds.

The distinctive characters of many of the species are sufficiently obvious and invariable to serve the purposes of the most stringent classification; but those of some others, particularly of such as are very extensively cultivated and as run much into varieties, either shade so greatly off through these varieties, or are so liable to change under the influences of climate and soil and time of sowing as to render the drawing of any precise line of demarcation between different species in some cases exceedingly difficult, and in one or two quite impossible. "Some wheats of an ap-

parently peculiar nature," remarks the author of the Useful Knowledge Society's Treatise on British Husbandry, "have been introduced to Britain from other countries,—as the Egyptian, the Polish, the Siberian, the Zealand, and the Talavera wheats,—and additions are being constantly made to the stock from various parts of the world; but, although differing in the proportions which they contain of nutritive matter, as well as in some particulars connected with their growth, yet they have all sprung from one origin,—and, being composed of similar elements, they are applied to the same purpose. Botanists, indeed, class some of them as distinct species; thus, for instance, the Egyptian wheat produces several ears from the same stem, which is not the case with any other sort; but, when repeatedly sown upon poor land, its supernumerary ears become gradually diminished, and it at length loses all appearance of variety. In like manner, other kinds of wheat, produced in soils and climates more favourable to vegetation than our own, have flourished when first grown in this country, and have appeared to become habituated to our atmosphere, yet in a series of years have degenerated; while other sorts, imported from a more northern climate, or taken from land of an inferior quality, have, on the contrary, been improved. The same circumstance occurs with respect to those species generally distinguished as winter and spring wheat; for although they seem, from their time of growth, to be of a different nature, yet one can be at pleasure transformed into the other by the common means of culture. Thus, if winter wheat be sown in the month of February, or the beginning of March, a portion of it will ripen, though the lateral shoots will be weak, and the crop will only be moderate. If, however, the seed thus produced be sown the next spring, it will throw out stronger stems, will tiller with more luxuriance; and, if the operation be repeated in the following year, it will then be found converted into the nature of summer wheat. If, on the contrary, spring wheat be sown in the month of October, and the next winter prove severe, the crop will perish, or can only be saved if it be completely covered by a heavy fall of snow. Should the weather continue mild, the seed will then, however, produce a tolerable crop, which will ripen earlier than autumn wheat; the seed obtained from it will in the following year take longer to ripen than that of the former season; it will also tiller better, and partake so much more of the nature of the winter species, that, if sown in the month of May, it will not produce a crop. Thus, also, however early the true winter wheat may be sown in autumn, it will not produce stems in the same year; but the real spring wheat will do so if sown any time before midsummer." Similar remarks might be made, with more or less force, respecting other supposed specific characters,—either such comparatively broad ones as those which distinguish the Egyptian wheats from the common cultivated wheats, or such comparatively narrow ones as those which distinguish the winter wheats from the spring wheats. Yet the instabilities and gradations in specific character, even though they were both greater and more numerous than they are, affect mainly the niceties of classification, and address themselves principally to systematic botanists; and they neither prevent mutational characters from being as true indexes of intrinsic constitution and adaptations as fixed ones, nor ought to deter agriculturists from appreciating classifications which, whether serviceable or worthless to the purposes of exact botanical science, may in some way or other be decidedly useful to the purposes of farming economy.

The aggregate properties of the seeds and herbage and habit of wheats and wheat-grasses challenge a ready and useful classification of them into British cereal wheats, or such as may be profitably cultivated for their grain in Britain,—foreign cereal wheats, or such as can be profitably cultivated for their grain in some other countries, but not in Britain,—economical herbage wheat-grasses, or such as may be profitably cultivated for their green forage or for pasture in Britain,—and weedy, noxious, and uninteresting wheat-grasses, or such as cannot be profitably cultivated for any purpose either in Britain or in other countries. Among the first of these classes are all the common winter wheats and spring wheats, the square-eared, the turgid, the stiff, the Egyptian, the Polish, the Bengal, the zea, the spelt, and the one-eared wheats; among the second class are the proud, the Linnæan, Gærtner's, the broad-spiked, the shell-seeded, the two-seeded, the dark-headed, Cevallos's, Cienfuegos's, Bauhin's, the three-seeded, the small-veined, and the villous wheats; among the third class are the dog, the rushy, and the crested wheat-grasses; and among the last class are the notorious couch-grass, the greater part of the agropyrum genus, and the Spanish, Cretan, field, and squarrose wheat-grasses.

The cereal wheats, throughout all their species and varieties, possess a tendency, stronger in some kinds and weaker in others, when sown together either in mixture or in juxtaposition, to form hybrids and to effect an interfusion of characters. Yet, as to the great properties of at once texture of ear and grain, chemical composition of seed, and economical adaptation to different climates and uses, they readily admit of classification into hard wheats, soft wheats, and Polish wheats. "The hard wheats are the produce of warm climates, such as Italy, Sicily, and Barbary; the soft wheats grow in the northern parts of Europe, as in Belgium, England, Denmark, and Sweden; the Polish wheats grow in the country from which they derive their name, and are also hard wheats,—and it is from their external form that they are distinguished from

other wheats. The hard wheats have a compact seed nearly transparent, which, when bitten through, breaks short, and shows a very white flour within. The soft wheats are those usually cultivated in Britain; they have an opaque coat or skin, and which, when first reaped, gives way readily to the pressure of the finger and thumb. These wheats require to be well dried and hardened before they can be conveniently ground into flour. The Polish wheat has a long chaff which is much longer than the seed, a large oblong hard seed, and an ear cylindrical in appearance; it is a delicate spring wheat, and not very productive in the climate of England,—hence it has only been occasionally cultivated by way of experiment. The hard wheats contain much more gluten, a tough viscid substance which is very nutritious, and which, containing a portion of nitrogen, readily promotes that fermentation, or rising, as it is called, of the dough, which is essential to good light bread. The quantity of this varies with the soil and climate, from 5 per cent. in some soft wheats to 30 per cent. in the hardest and most transparent. It is this quantity of gluten which causes the Italian wheats to be used exclusively for the rich pastes which form so large a portion of the food of that nation. The soft wheats contain the greatest quantity of starch, which fits them for the vinous fermentation, by its conversion into sugar and alcohol. For brewing or distilling, therefore, the soft wheats are the best." [Rham's Dictionary of the Farm.]

The cereal wheats, when viewed with reference to the form of their ears or the aggregation of their spikelets, may be classified into the common, the compact, the turgid, the compressed, the nodding, and the meagre. The common have a slightly compressed spike, and are either awned or beardless, white or red, and comprise all the ordinary winter wheats and spring wheats of Britain; the compact have a square beardless spike, and possess in other respects a close affinity to the common wheats; the turgid have a compact bearded spike, generally but not always square, and comprise, among other kinds, the rivet, the Turkey, the St. Helena, and the Egyptian wheats; the compressed have large, broad, bearded, compressed ears, elongated spikelets, and large shining chaff, and comprise the hard wheats of the Mediterranean and of South-Eastern Asia, and the Siberian, Tangier, and hard Sicilian wheats; the nodding have long, loose, bearded, nodding spikes, and comprise the Polish wheats; and the meagre have long, erect, thin spikes, and comprise the zea, the Bengal, and the spelt wheats.

Beardless and bearded, or awnless and awned, are very obvious characters of the cereal wheats, and might seem to afford a ready criterion for arranging them into two great classes, and are apt to be eagerly viewed by most superficial and vulgar observers as far more distinctive features than any which can be found in the florets or the seeds; yet, though they coincide to a certain extent with some of the classifications which have reference to the form of the ear or the aggregation of the spikelets, they do not of themselves possess any real indicational value, either botanical or economical. The beards or awns of almost any grasses, and particularly those of wheats, are so dependent on climate, culture, soil, and other circumstances for size, for persistency, and even for existence that, in many instances, they fail to indicate with permanence or certainty even a subvariety of any species. Some wheat-awns are but a degree longer than a mere point, and others are one, two, or several inches long; some are so laxly seated as to be easily blown away by winds when the grain is ripe, and others are almost as stubbornly persistent as those of the common barleys; some appear with tolerable steadiness in all the species of a genus or group, and others are altered or suppressed or produced in a single variety by a mere change in the circumstances of climate and culture. The only real value of the distinction between beardless and bearded wheats, is that, in the case of the common cultivated British sorts, the beardless ones have commonly larger ears, less remote spikelets, and larger and less elongated grains than the bearded ones; but even this rule is very far from being constant. And as to a prevailing custom of identifying beardless common wheats with winter wheats, and bearded common wheats with spring or summer wheats,—this is much more inconstant than even the rule we have stated, and has sometimes a tendency to lead to serious practical error; for though most of the beardless common wheats, both white and red, are really winter wheats, yet a few are just as really spring wheats, or have not sufficient hardiness for autumnal sowing,—while, on the other hand, some of the bearded common wheats, both white and red, are really winter wheats, or are as hardy and require as long a time to attain maturity as the generality of autumn sown beardless wheats.

The cereal wheats suitable for cultivation in Britain, as well the compact, the turgid, and the compressed kinds, as the common kinds, may, with reference to their comparative hardiness and earliness, be very properly classified into winter wheats and spring wheats; every kind being a winter wheat which is hardy enough for autumnal sowing, or which does not ripen soon enough or bear a sufficient produce when sown in spring,—and every kind being a spring or summer wheat which cannot withstand the rigours of our winter, or which has the power of running so rapidly to maturity that it may be sown in the month of April or in the early part of May,—and every kind, of course, being both a winter wheat and a spring wheat which possesses suitableness alike or nearly alike for autumnal and for vernal sowing. And when, ac-

cording to the current usage of most farmers and seedsmen, winter wheats and spring wheats are restricted in classification to the common eared wheats, they may be understood as generally distinguished from each other also by the winter kinds having both larger grains and more straw than the summer kinds, and yet as so closely akin or specifically identical that they always fuse into each other through their extreme varieties, and may at any time be converted into each other by means of persevering culture. To distribute the common-eared wheats, therefore, into two species under the names of *Triticum hybernum* and *Triticum æstivum*, we regard as wrong, both because it sanctions an improper classification of these wheats themselves, and because it withdraws the distinction of winter and spring from all other wheats; and to group the common-eared wheats into one species, under the name of *Triticum sativum*, as Mr. Lawson does, we regard as both truer to nature and more convenient for practice. A popular name or rather synonyme of the common winter wheats is Lammas wheats.

White wheats and red wheats, downy-chaffed wheats and smooth-chaffed wheats, are subgroups of the common-eared wheats, and particularly of the common winter wheats. The difference in colour arises chiefly from the soil, —many white wheats becoming gradually darker and ultimately red when cultivated on stiff, wet, clay lands, and many red wheats becoming gradually yellow and eventually white when cultivated on rich, light, mellow soils; and the grain undergoes the change of colour more rapidly than the chaff and the straw,—so that, in the case of subvarieties and of specimens which are in the actual course of transition from the one extreme of colour to another, wheats occur with red grain and white chaff or white straw, and wheats also occur with white grain and red chaff or red straw. Yet the colours have very different degrees of constancy in the case of downy-chaffed and smooth-chaffed varieties; and almost all stubborn or permanent reds have far thicker and coarser skins, a much hardier constitution, and a far better adaptation to very stiff and plastic soils than either the mutable reds or the whites. "There are two distinctions," says the author of British Husbandry, "which run through every species of winter or Lammas wheat, and these consist in the colour of the grain, which is either white or red; and there are also two general varieties of these, the grain of which may be classed as the thick and thin husked, or the downy-chaffed and the smooth-chaffed. The red wheat, or thick-skinned quality, is usually grown upon the strongest clay land, and degenerates slightly when sown upon soils of a lighter description. It is of various shades of a reddish brown, or deep-yellow tinge, and generally retains the same hue, whatever may be the quality of the ground on which it is produced. The outer husk is coarse in proportion to the humidity of the soil, and consequently lowers the value of the grain; which, accordingly, bears a price in the market of from 12 to 15 and sometimes 20 per cent. less than fine qualities of the white. It is, however, so hardy, and so much better adapted to ensure the production of a crop on wet and adhesive soils, that it is very generally sown on land of that description. On fine loams, or soils of that kind which are usually considered as good barley-land, the white or smooth-chaffed wheat is, however, preferred, from the thinness of the husk rendering it more profitable to the miller. The downy-chaffed variety was formerly in the greatest repute; both from its generally producing the whitest and the finest flour, and from the grain in consequence of the shortness of the straw, and the closeness of the ear, being less liable to be shaken out by the wind at harvest-time, than the smooth-chaffed tribes,—qualities which peculiarly adapt it to land of so rich a nature as to endanger the lodging of the crop. In consequence, however, as it is supposed, of the husk retaining the dew and moisture longer than the other sort, it was found more liable to be affected by mildew, and to be in other respects so much more tender, that it has fallen much into disuse; and the thin-chaffed wheats are now more generally cultivated, particularly throughout Scotland."

We shall only notice further the classification of the common-eared wheats made by Mr. Lawson, under his species of *Triticum sativum*. The first are varieties generally termed white beardless wheats, having whitish coloured ears or spikes, and light coloured grain or seed; and which are generally cultivated as winter wheats. Those enumerated are common white wheat, Hunter's wheat, Mungoswells wheat, Uxbridge wheat, Chiddam wheat, white Essex wheat, Jeffray wheat, Gregorian wheat, white golden drop, Talavera wheat, white Dantzic wheat, red Dantzic wheat, white velvet or woolly-eared wheat, white Hungarian wheat, white Flanders wheat, white Naples wheat, white Touzelle wheat, and white beardless Odessa wheat.—The second are varieties generally termed red beardless winter wheats, from the reddish colour of their spikes or ears, and their being more particularly adapted for winter sowing. Those enumerated are common or old red wheat, blood red wheat, golden or red Essex wheat, red Kent wheat, Lammas or red English wheat, red golden-drop wheat, purple stalked golden-drop, white stalked mouse-tail red wheat, red-stalked mouse-tail wheat, sulphur-coloured wheat, red beardless Caucasian wheat, velvet or woolly-eared red beardless wheat, red velvet or woolly-eared wheat of Crete, and Hickling's red wheat.—The third are white wheats, more particularly adapted for spring sowing; but which, from having no awns or beards, or at least very short ones, belong to the group generally termed winter wheats. Those enu-

merated are Leghorn or Tuscany wheat, white beardless Tuscany wheat, common white beardless spring wheat, white spring wheat of Fellemberg, and hard spring wheat.—The fourth are red beardless wheats, which are more particularly adapted for spring sowing, but generally not included under the specific name of spring wheats in consequence of their having almost no awns. Those enumerated are red beardless Tuscany wheat, and common red beardless wheat of France.—The fifth are white bearded wheats, generally termed summer wheats, but really as hardy and requiring as long to arrive at maturity as the generality of the beardless winter wheats. Those enumerated are the common winter bearded wheat, white bearded Shanry wheat, light yellow-bearded winter wheat, woolly-eared white bearded wheat, white bearded Tuscany wheat, Chinese bearded spring wheat, Victoria wheat, common bearded spring wheat of the French, Tuscany wheat, Cape wheat, and small Sicilian bearded spring wheat; and the seven last of these, from the white bearded Tuscany wheat and onwards, are particularly adapted for spring sowing.—The seventh are red, awned, or bearded wheats, generally denominated summer wheats, but really as hardy and requiring as long to arrive at maturity as the generality of the beardless winter wheats. Those enumerated are velvet or woolly-eared red bearded wheat, fern wheat, red-bearded Mendoza wheat, and red Chinese wheat; and the three last of these are particularly adapted for spring sowing.—All these varieties, and also a number of others, will afterwards be described.

The Wheat-Grasses.—None of the foreign weedy or uninteresting non-cereal wheats require to be described; the principal British one—the most mischievous by far of all grassy weeds—is described in the article Couch-Grass; and the other indigenous species are the only non-cereal wheats which possess any pretension in this country to a cultivable character or economical adaptation, and will form the proper subject of the present short section.

The rushy or sea-rushy wheat-grass, *Agropyrum junceum*, called by Linnæus *Triticum junceum*, is a somewhat abundant inhabitant of the sandy sea-shores of England. Its root is perennial, and comprises numerous woody fibres, and is widely and profusely creeping; its herbage is glaucous and rigid, and looks as if in thorough keeping with its sandy habitat; its stem is simple, inclining, smooth, polished, of a bright violet tinge below, striated above, and from 12 to 24 inches high; its leaves are involute and sharp-pointed; and its flowers bloom in June and July. This plant serves in the same way as the *Arundo arenaria* and the *Elymus arenarius*, for binding the loose sands of the seacoast, and preventing them from drifting inland and desolating the country.

The dry or bearded or fibrous-rooted wheat-grass, *Agropyrum caninum*, called by the old botanists *Triticum caninum*, inhabits woods, lanes, and the shade of hedges, on calcareous soils, in both England and Scotland. Its root is perennial, and differs from that of couch-grass in the essential character of being fibrous and without a rhizome; its stems are very smooth and about two feet high, yet do not give the herbage an average height of more than six or eight inches; its leaves are nearly upright, lanceolate, taper-pointed, flat, thin, rough on both surfaces, and of a bright green colour; and its spikes are awned, bloom in July and August, and generally bear a considerable quantity of seeds. This plant is readily and rapidly raised from seeds on every kind of dry or porous soil, and produces a large quantity of early spring herbage, and might therefore be advantageously cultivated on poor lands in some situations as a substitute for spring-feeding rye-grass; but it yields a very inconsiderable aftermath, and is seriously objectionable on account of its awns, and does not by any means possess a sufficient aggregate of good qualities to warrant the sowing of it upon any kind of prime or even middle-rate land.

The crested wheat-grass. *Agropyrum cristatum*, called by the old botanists *Triticum cristatum*, inhabits dry upland hedges and similar situations, in various parts of Britain, particularly in Scotland. Its roots comprise several long, strong, woolly fibres, and possess special adaptation to a sandy soil; its stems are ascending, simple, rigid, slender, leafy throughout, hairy at the top, and from 10 to 20 inches high; and its ears bloom in July, and mature their seeds in August. This plant yields better early spring herbage than most of the alpine grasses, and produces an abundant and very nutritious aftermath; and it well deserves cultivation, as a pasture-grass on light heath soils.

The loliaceous wheat-grass, or dwarf sea wheat-grass, *Brachypodium loliaceum*, called by the old botanists *Triticum loliaceum*, inhabits the sandy sea-coasts of both England and Scotland. Its root is annual, and comprises many long fibres; its stem is rigid, wiry, leafy, very smooth, polished, either erect or decumbent, very various in luxuriance, and from 2 to 15 inches high; its leaves are linear, acute, and almost smooth, and become involute when dry; and its ears develope and bloom in June and July. This grass is of some use in its native sandy habitats, but does not recommend itself for cultivation.

The Common-Eared Cereal Wheats.—We comprise, under the name of common-eared cereal wheats, all the varieties of what are usually called winter wheats and spring wheats, or common beardless and common bearded wheats, constituting the *Triticum hybernum* and *Triticum æstivum* of botanists; and in grouping and describing the chief, we shall follow the arrangement of Mr. Lawson, noticed in a former section, and shall also avail ourselves in some degree of his descrip-

tions,—adding, however, a great deal of important information from entirely different sources.

Common white wheat is the beardless winter wheat, with whitish spikes and light-coloured grain, cultivated in any district where one or more of the superior or very distinct varieties of winter wheat have not yet come into general use. It does not constitute any one distinct variety, but rather comprises an almost countless number of varieties and subvarieties of white wheats, not even excluding the velvet-eared and some of the bearded sorts. The common white wheats of East Lothian and the Carse of Gowrie, according to specimens preserved in the Highland Society's Museum at Edinburgh, weigh 63 lb. per bushel; the common white wheat of Morayshire, according to a specimen preserved in the same place, weighs 62½ lb. per bushel; and a common white wheat of Scotland, called in general terms 'Scotch white,' yielded, in a well-conducted comparative experiment reported in the Royal Agricultural Society's Journal, 24 cwt. 62 lb. per acre.

Hunter's wheat was first discovered by the late Mr. Hunter of Tynefield, East-Lothian, growing on a field in Coldingham Moor, Berwickshire; and during the last 40 or 45 years, it has been very extensively cultivated, and held in very high esteem, throughout a large portion of the south-east of Scotland. Its ear is medium-sized, thick, tapering a little toward the point, and slightly pendant to one side; and its grain is rather large, elongated, tapering very slightly towards the extremity, plump, and of an uniform dull white or very light brownish colour throughout. Specimens of this variety have been found to weigh from 63½ to 65½ pounds per bushel, and to yield 5¾ quarters per acre. A Hunter's wheat is reported on in some recent English comparative experiments; but it must either be a totally different wheat from the Scotch Hunter's, or have been obtained from very deteriorated sources of seed; for, in these experiments, it gave exceedingly unsatisfactory results.

Mungoswells wheat is the produce of a few ears presenting a superior appearance, which Mr. Patrick Shirreff, Mungoswells, East-Lothian, discovered in a field about 20 years ago. It is generally accounted a few days earlier, and tillers more freely in spring, than Hunter's wheat; and it is also said by some cultivators of it, but denied by others, to be more prolific. In sample, it so very much resembles Hunter's, that the two have often been mistaken for each other by dealers.

The Uxbridge wheat originated in the neighbourhood of Uxbridge in Middlesex. Its ear is large, very compact, tapering very little towards the point, and pendant a good deal to one side; and its grain is rather small, short, plump, and of a very white colour, and forms a beautiful sample, and is preferred by the London millers to the grain of any other variety. "From the trials which have been made of the Uxbridge wheat in this country," says Mr. Lawson, "it appears to be perfectly suited to our climate, very prolific, and deserving of attention from cultivators. It may be considered two or three days later in ripening than the Mungoswells wheat."

Chiddam or Chidham wheat originated in the south of England, and was introduced about 15 years ago to Scotland. It is a prolific variety, and a free grower, and tillers freely in spring. Its grain is slightly more elongated than that of Uxbridge wheat, rather thinner in skin, and more transparent or flinty like; and its flour forms a lighter bread, but darker coloured and more open than that of some of the other most esteemed white wheats. The Chiddam wheat is well-known and much appreciated in some of the best agricultural districts of England, and has been a favourite subject in some recent comparative experiments; yet, notwithstanding its admitted excellence and prolificity, it has been pronounced by some good judges very little or not at all superior to the common white wheats of the districts in which it is best known. Its average yield is probably about 65¼ pounds per bushel.

White Essex wheat resembles the Uxbridge wheat in its ears, and Hunter's or Mungoswells in the size and shape of its grains; but differs from them in being of a whiter colour, more transparent, and thinner skinned. It yields about 65 pounds per bushel; and is much esteemed by the English millers. It ripens about four days later than Hunter's wheat. Its straw is considerably longer than that of any of the varieties hitherto mentioned.

Jeffray wheat is shorter in straw than Hunter's wheat, and five or six days longer in arriving at maturity; and its ear and grain are smaller, and taper more toward the point.

Gregorian wheat is hardy, and tillers well in spring, and is deservedly esteemed. Its straw is more stiff and upright than that of Hunter's or Mungoswells wheats; its ear is longer and less bent to a side; its spikelets are more remote; and its grains are shorter, rather lighter in colour, and more transparent.

The white golden drop wheat differs from most of the common eared wheats, and resembles the turgid wheats in the circumstance of having generally four grains on each spikelet; but it resembles most common eared wheats, and differs from the turgid wheats, in the aggregate of its other characters. Its appearance, whether as a plant or as a grain, is neither coarse nor strong; its straw is rather above the average length; its ears are a good deal pendant; its awns scarcely constitute a beard, and appear only toward the point of the spike, and are seldom longer than the florets; its chaff has a dull white or very light brown colour; and its grain is large sized, of a light brownish yellow or copper colour, and of medium quality. This variety was discovered

by Mr. A. Gorrie, in 1834, in a field of common white wheat.

The Talavera wheat was introduced to Britain about 35 years ago from Spain. Its straw is about average length; its ears are long, thin, and upright, and taper to the extremity; and its grains are very large, and of a whitish semitransparent colour. It ripens about a week earlier than any of the common winter wheats; but, in most of many trials throughout the Scottish Lowlands, and even in some favourably circumstanced trials in England, it has been found so impatient of vernal frost or so deficient in vernal tillering, as not to seem at all suitable for autumnal sowing. It has also been much mixed and confounded with other varieties, and considerably graduated into subvarieties of its own; insomuch that, even about 14 years ago, a genuine unmixed sample of it could scarcely be procured; and a kind of it called the Bellevue Talavera has, since about that time, been the best known and most esteemed in England.

The Bellevue Talavera, soon after its introduction, was tested comparatively with three other prime varieties by Colonel Le Couteur, one of the best British authorities on the culture of wheat, and was spoken of by him in the following terms in 1840:—"This admirable variety is invaluable where it is adapted to the soil and climate. The seed being large, a greater quantity of it should be allowed than usual. This wheat has succeeded in the north of Scotland, and is sufficiently hardy to withstand the winter in its grassy state; but it is otherwise more valuable as a spring crop; without doubt it may be sown as late as the first week in February, in all the milder parts of England, with a prospect of reaping quite as good an average crop from it as from any other wheat, but with a certainty of obtaining more flour than from most. There is no tendency to degenerate observable in this wheat, as far as the experience of five or six years goes; nor, from its early habits, is it at all likely to become intermixed by fecundation from other varieties, though sown about the same period, as it will, in such cases, flower a fortnight or three weeks before them. It is not more liable to disease than ordinary white wheats, and affords a very fine clear white straw; it is indeed one of the Italian bonnet-making varieties. There is, however, one disadvantage in it, which is, that the ear is so heavy that it is apt to break down, though not break off, when swept by a gale about the period of ripening; but it has a countervailing good quality of ripening the grain equally well though bent down, as is the case with spring wheats, which ripen their seed well though quite laid, which with winter wheats is doubtful. Another peculiarity is the tenacity of the chaff to the ear, more remaining on it after passing through the thrashing-machine than any other variety I am acquainted with."

The white Dantzic wheat was introduced to Britain from the countries on the south side of the Baltic; but, though a beautiful and prolific wheat as grown in these countries, it loses very much of both its beauty and its prolificity when grown in Britain, and at the same time is later than most of our ordinary winter wheats in coming to maturity. Its straw is of medium length; its ear is long, tapering, small, and thinly set; and its grain is elongated, very small, and of a beautiful white colour. But in a recent comparative experiment on well-drained clay soil, in favourable circumstances in England, it produced abundant straw and a coarse and indifferent sample of grain, and was greatly less prolific in grain than the other varieties with which it was tried, particularly the Bellevue Talavera, which yielded 36 bushels per acre, while the white Dantzic yielded only 26.

The red Dantzic wheat, also, was introduced from the countries on the south side of the Baltic; and, in spite of its distinctive name, it is far more a white wheat than a red one; and, with the exception of a slightly darker shade of colour in the grain and of a light reddish-brown colour in the ear, it bears a marked resemblance to the white Dantzic, at once in botanical characters, in economical adaptations, in period of ripening, and in comparative habits in its native regions and in Britain. Two samples of mixed Dantzic wheat in the Museum of the Highland Society at Edinburgh weigh at the rate of respectively 61½ lb. and 62½ lb. per bushel.

The Jersey Dantzic is an excellent variety, but appears to be misnamed. "The seed of it," says Colonel Le Couteur, "is described as having been raised from a single ear, originating from seed procured from Dantzic, selected from the finest high mixed. It is, however, suspected to be identical with some excellent sorts, called in Sussex, Kent, and some parts of Surrey, the Chittums; in other parts, Pegglesham; in Berkshire, Trump; in Essex, Hardcastle; in some counties, Old Suffolk; in Scotland, Hunter's White; and assuming several other names. This wheat is not quite so hardy as the hoary white or velvet eared; it is, nevertheless, considered sufficiently so to succeed throughout the kingdom, excepting the northern parts of Scotland. In rich soils, it tillers amazingly, and produces a longer straw than the hoary; nor is it so liable to sprout in a moist climate from being smooth-chaffed. In very severe, moist, and stormy weather, it will be laid sooner than the hoary. It ripens a week earlier at least than the hoary, and should be reaped while the grain can be marked by pressure from the thumb-nail, as it is rather liable to shed if over ripe. In a dry season this wheat will afford a beautiful, clean, white straw, fit for bonnet-making or any purpose of thatching; it is firm and tenacious. In wet seasons, it is rather subject to rust."

The white velvet, hoary white, woolly-eared, downy Kent, stuffed, or hedge wheat, has long

been known and much esteemed in the south of England, particularly in Kent and Sussex, and was introduced thence to France and Scotland. Its straw is short; its ears are small, close, and compact; its chaff has a white colour, and is covered with a fine velvety down; and its grains are middle-sized, well formed, and of a semi-transparent whitish colour. "This wheat," says Colonel Le Couteur, "will withstand the most severe weather. The season 1837 to 1838 was a very trying one both as to wetness and severity of cold, the thermometer having fallen to 18° below freezing; but the crops of this wheat raised by my neighbours were perfectly insensible to it, and of great produce. This wheat is not remarkable for its early maturity, though it cannot be called a tardy variety. It is not subject to degenerate, and if attention is paid to sowing the seed pure, and annually, or even occasionally, varying the manure intended for it, it is possible that it may never degenerate. The only objection to it is the huskiness or velvety ear, which in damp weather is retentive of moisture; and in snatchy seasons the grain is more apt to sprout than the smooth-chaffed varieties. It is not much affected with dust-brand; and when pickled and limed, has never been found with smut-balls. It is little liable to shed, even when over-ripe, and will resist very heavy gales without being laid or broken." This wheat is now cultivated pretty extensively in France; but has not been found at all suitable to the comparatively humid climate of Scotland.

The white Hungarian wheat was introduced from England to France and from France to Scotland; and it is extensively cultivated in the Orleanois and in some of the northern districts of France under the name of English wheat. It has a nearer resemblance to the Chiddam and the Uxbridge wheats than to any other which we have yet described; and it is 6 or 7 days longer in arriving at maturity than most of the common winter wheats. Its ear is white, of medium length, very compact, and square-like, and terminates abruptly or without tapering; each of its spikelets contains four grains; its chaff is smooth and thin; and its grains are small, short, rounded, white, and slightly transparent, and constitute a remarkably beautiful sample, and weigh at the rate of 66 lbs. per bushel.

White Flanders wheat is held in great esteem in the northern parts of France. It appears to differ little from the white Essex wheat, and possibly may have been derived from that variety, and perhaps owes all its difference from it to the effects of climate and cultivation.

White Naples wheat is much cultivated in the southern parts of France; and was introduced a considerable time ago to the neighbourhood of Paris, but was found to be not hardy enough for that climate; so that, in British cultivation, it can rank only as a spring wheat,—though it is perhaps too late in ripening, and too subject to induration from the influence of our climate to take even that rank. Its ear is long and not very compact; its terminal spikelets have awns of from a quarter of an inch to one inch in length; its chaff is delicately tinged with a dull yellow or copper colour; and its grains are large, considerably elongated, and of a yellowish white colour, and weigh well in sample.

The white Touzelle wheat also is cultivated in the south of France, and has been found too tender to endure the winters in the latitude of Paris. Its ear is rather more compact than that of the white Naples wheat; its chaff is of the same colour, but so exceedingly thin and brittle as to allow the fully ripe grains to be readily shaken out by even a light wind; and its grains, when grown in the neighbourhood of Paris, have a brownish-yellow colour, but, when grown in the south of France, are much whiter.

The white beardless Odessa wheat is the best and the only meritorious of a considerable number of varieties of wheat which have been introduced at various times from Odessa into France. It is extensively cultivated in Auvergne, but is more sensibly affected by cold than the common wheats of that province; and it has been found as suitable in France for spring sowing as for winter sowing; but, as tried in a comparative experiment in the vicinity of Edinburgh, it was nearly a fortnight later in arriving at maturity than the common winter wheats of Scotland. Its ear is rather loose and irregular, and has a colour inclining to light brown; and its grains are long, above average size, and whitish coloured, and taper slightly towards the point.

The Hopetoun wheat or Shirreff's Hopetoun wheat originated in an ear of wheat culled in 1832 from a field on the farm of Drew in East-Lothian; and was brought into cultivation by Mr. Patrick Shirreff, and sold for the first time in 1839. "After numerous trials in East-Lothian for two seasons," said Mr. Shirreff in 1841, "this variety is rising in public esteem, and has been successfully grown in many parts of Scotland, as well as in Gloucestershire, Kent, and Buckinghamshire. Everywhere this variety has put forth ears of large size, supported on tall and strong straw, and yielded grain of fine quality; and in England it is represented to have been much less affected this season with red gum, blight, and mildew, than other varieties growing contiguous. Last year a comparative trial was made by Mr. George Bell on the farm of Inchmichael, Perthshire, with Chevalier and Hopetoun wheats, the crop of the latter being represented as too thickly planted. Both kinds yielded 36 bushels per acre; but the grain of Hopetoun wheat was best in quality, and weighed 2 lbs. per bushel heavier. Another comparative trial was instituted in East-Lothian by Mr. Alexander Begbie, on the farm of Seggarsdean, with Hunter, Chidham, and Hopetoun wheat, the latter being thinnest in plant, and the

yield was found to be 34, 30, and 37 bushels respectively." The Hopetoun wheat has been a favourite subject in recent comparative experiments in England; yet, though found superior to most of the older common varieties, has been excelled in various respects by several new kinds.

Whittington's white wheat is very hardy, and, when sown early in autumn, affords much herbage, very fit for being eaten down by sheep in the spring; but it is rather a late wheat, ripening a week or ten days later than the Jersey Dantzic. Its straw is abundant; and its grain is large, full, plump, rather of a whitish-red tint, and a little thick-skinned, and weighs about 62 lb. per bushel. This has been somewhat a favourite variety in recent comparative experiments; but it has pretty generally disappointed expectation, and is apt to blight in certain situations, and is not liked by millers.

Brown's ten-rowed Chevalier or ten-rowed prolific wheat, is an admirable variety on soils and situations congenial to it, but is somewhat nice as to climate, and succeeds but poorly on some lands where other wheats prosper. Its straw is long and abundant; and its grain affords a beautiful sample.

The Russell white wheat has moderately short straw, and a compact head; and, though by no means a new variety, is decidedly superior to many newer kinds which have obtained a greater notoriety; but is too delicate in habit to suit any but the most favourable soils. An interesting and most singular subvariety of it was selected in 1833 by Mr. Rivers of Sawbridgeworth, "This," says Mr. Rivers, "combined with an extraordinary stiff straw a singular clustered ear, forming a cluster at the top of densely set grains, making a perfect five set, constituting 110 entire grains in the one ear, more resembling an artificial figure carved in ivory than a natural product. I have been much gratified since in experiencing its permanency, having the most beautiful appearance in the field, growing about 4 feet 6 inches high, with a very stiff straw, and the most violent winds and rains cannot lodge or lay it."

Other varieties of beardless white wheat, which have more or less commanded the attention of British agriculturists,—some possessing a high degree of reputation, most of quite or comparatively recent origin, and nearly all of the class of winter wheats, — are Hillyard's snowdrop, Jonas's prolific, the silver drop, the golden swan, the Taunton, Smither's Hereford, Sewell's, Hickley's prolific, Baxter's, Brodie's, the Carrington, the Cheltham, Courtney's six-rowed yellow or six-rowed Chevalier, the Chinese small, the dwarf cluster, the tall cluster, Colonel Le Couteur's compact, Colonel Le Couteur's round, Colonel Le Couteur's early Cape, the Duke William, the eclipse, the Eltham, the Heartswood, Hickling's yellow, Incledon's prolific yellow, the Indian, the Kentish, King William yellow, the Malaga, the Oxford prize, the painted-stalked, the Paris, the pearl, the salmon-coloured, the Lark yellow, the Saumur yellow, the striped chaffed early yellow, Vilmorin's, and Whitworth's prolific.

The old or common red wheat has been almost wholly superseded in Britain by some of the newer and more prolific varieties of red beardless winter wheat; but it is still cultivated to a considerable extent, under the name of *froment rouge ordinaire sans barbes* or common beardless red wheat, on tenacious soils or very strong clays in the north of France. Its ear is medium-sized, and almost upright; its spikelets are not very closely set; and its grains are elongated, and of a dull reddish colour.

The blood-red wheat is very prolific, and has for a good many years past been more extensively in favour thoughout large districts in Britain than any other kind of red winter wheat. Its straw is long and rather stout, and is not apt to become lodged; its ears are large and of rather a bright brownish-red colour, and taper very slightly to the point; its spikelets are close and spreading; and its grains are medium-sized, slightly triangular or cornered on the sides, and of a dark yellowish or copper colour, but are most yellowish or copperish at the thickest end, and are generally darker and more transparent at the other end. This wheat is usually less esteemed than any of the ordinary white winter wheats, and is often estimated by millers and bakers at two or three shillings per quarter less than any of these; and yet a mixture of it with a white sort, in the proportion of a fourth or so of the red, is frequently preferred to a pure or unmixed white,—and such a mixture is made by many English farmers in sowing the crop, and is thought by them to be specially economical, some seasons, as they reckon, being most favourable to the red, and others most favourable to the white, so that every season or any one acts averagely on the mixture.

The golden wheat or red Essex wheat is also a very hardy, prolific, and much esteemed variety. It bears considerable resemblance to the blood red wheat; but its ears are longer and less compact, and taper more toward the point,—and its grains are longer, not so round and plump, and more obtusely angled on the sides.

The Kent red wheat is well known and much esteemed in the south of England, and has been a favourite subject in some recent comparative experiments. Its ear resembles that of the golden wheat; but its grains are much larger, of a darker and more uniform colour, more transparent, and comparatively hard and flinty,—and they weigh at the rate of about 64 lb. per bushel.

The old red Lammas wheat, or red English wheat, bears a marked resemblance in general character to the Kent red wheat, and probably is a mere duplicate of that variety modified by climate, soil, and culture. It was long ago in-

troduced from England to the north of France, and has been cultivated there with considerable success; yet, in consequence probably of the winter being generally colder there than in the south of England, it is found less resistive of the frosts in the neighbourhood of Paris than the common red wheat. The French consider it as yielding a finer sample than any other of the red wheats. It is liable to be shaken when fully ripe, and should, therefore, be cut a day or two before arriving at full maturity. Its ears are more waved than those of the red Kent wheat, thinner, and not so much reclined to the side; and its spikelets have a bright red colour toward the extremity, but are lighter and more copperish toward their base.

The red golden-drop wheat is similar to the blood-red wheat, in at once general character, agricultural adaptation, and economical value. Its straw is shorter; its ear is similar; and its grain is about the same size, lighter and more uniform in colour, and more elongated and rounded on the edges. It also requires a few days longer to arrive at maturity.

The purple-stalked golden-drop wheat was picked up in a field of common wheat, in 1834, by Mr. Gorrie of Annat Garden. It resembles the red golden-drop wheat; but its ear is darker-coloured and more compact, its grain is rather brighter in colour, and its straw, especially a few days before ripening, has a dark purple tint. It is a good variety.

The white-stalked mouse-tail red wheat, and the red-stalked mouse-tail red wheat, were also picked up in a field of common wheat by Mr. Gorrie of Annat Garden; but they are comparatively unprolific or of inferior quality. The ear of the former is long, thin, tapering, and pointed; and the grain is elongated, and of a brownish-yellow colour, irregularly interspersed with dark semi-transparent spots or blotches. The ears and the grain of the red-stalked are darker-coloured than those of the white-stalked; and the straw has a purple colour.

The sulphur-coloured wheat is rather a good variety. Its ear is somewhat more compact than that of the two mouse-tail kinds, and its grain is shorter, plumper, and of a yellow sulphury colour.

The beardless red Caucasian wheat is one of the earliest red winter wheats, and is sometimes sown in France as a spring wheat; but it is of poor quality, and not much deserving the British farmer's attention. Its ear is long, upright, and of a dull-red colour; its spikelets are remote, large, and spreading; its chaff is thick and hard; and its grain is elongated, semi-transparent, rather above the medium size, hard and flinty.

The red velvet-eared or red woolly-eared beardless wheat is of medium productiveness; but, like the white velvet-eared wheat, it is little esteemed in consequence of its woolly ears being apt to retain moisture in damp weather, and to become discoloured and liable to sprout. Its ear is short and compact; and its grain is slightly elongated, of a dark red colour, and flinty.

The red velvet-eared or red woolly-eared wheat of Crete is of a somewhat superior quality. Its ear is compact, downy, and of a deep red colour; its spikelets are large and spreading, and contain each four and often five grains; and its grains are short, slightly angular, and of a reddish opaque yellow colour.

Hickling's red wheat, or Hickling's prolific red, is a productive but rather coarse variety. Its straw is long, stout at the base, and tapering at the top; its ear is short, thick, close, and heavy; its chaff is white; and its grains occur four in the row across the ear, and have a dark orange-red colour, and are short, plump, and thin-skinned.

Smoothey's or Boishall red wheat was discovered by Mr. Thomas Smoothey, Boishall, near Halsted, Essex. The straw is fine; the ears are short, thick, and closely set; and the produce of the grain has been rated as high as seven quarters per bushel.

The Waterloo red wheat was first raised at Midham, in Suffolk. The straw is long, strong, and stiff; the ears also are long, strong, and stiff; and the grains are longish, round, thin-skinned, and of a light orange-red colour.

Other varieties of beardless red or brown wheat, which have more or less commanded the attention of British agriculturists,—some possessing a high degree of reputation, most of quite or comparatively recent origin, and nearly all of the class of winter wheats,—are the marigold or Rattling Jack red, the thickset Suffolk, Hobbs's brown or Essex brown, the Burwell brown, the Britannia red, the red Champion, Hobbs's red marigold, Spalding's red or Spalding's prolific red, the Colne white chaff, the Bristol, Sharp's or Goody's or Crabb's, Seyer's, Sewell's, Piper's thickset, the branching red, the Cambridge brown, the Cape early red, Clover's red, the creeping red, the Dantzic common red, the Flanders long-eared red, the La Manche red, the Marianopoli red, the Touzelle red, and the Waterloo red.

The Leghorn or Tuscany wheat is cultivated in the south of Europe for the purpose of making straw-plait for bonnets; and was introduced to Britain with the view of being used here in the same way, but has been entirely superseded by the common rye. "The name of Leghorn or Tuscany wheat, however," says Mr. Lawson, "appears not to apply to any one particular variety, but rather to a mixture of white, red, bearded, and beardless sorts. The white beardless varieties seem, however, to be the most numerous. The whole seem to belong to the early or spring sorts, which is no doubt caused by their being sown in their native country always in March, on light sharp sandy soils on the banks of the Arno. When intended for plait, the seed is

sown very thick and the plants pulled when in flower, or before the grain is formed, when they are generally about eighteen inches in height. It is then bleached and tied up in the same manner as we do flax, previous to selecting the portion of the stalk to be used in the manufacture, which is that between the ear and the first knot or joint of the straw."

The white beardless Tuscany wheat was picked out about 20 years ago from a field of Leghorn wheat by Mr. A. Gorrie, and has been cultivated as a spring-sown grain wheat. Its ear is long; its spikelets are not very closely set; and its grains are light-coloured, clear, transparent, and thin-skinned, and weigh at the rate of about 63 lbs. per bushel. This wheat is very productive.

The common white beardless spring wheat is cultivated as a spring wheat in the central districts of France to as great an extent as any of the winter sorts; but, as introduced or imported into Britain, it generally is much mixed with the common white bearded spring wheat of France. Its ear is long, small, and tapering; its spikelets are remote; and its grain is short, plump, and of a dull yellow or brownish colour.

The Fellemberg white spring wheat, or white spring wheat of Fellemberg, is also a French spring wheat, and seems to be a very vigorous grower; but, in consequence of its seeds being small and very hard and exceedingly liable to be shaken out when ripe, it is not much cultivated. Its ear is very white; its spikelets are broader and more closely placed than those of the common white beardless spring wheat; and its grains are small, slightly elongated, of a clear transparent reddish colour, and very hard or flinty.

The hard spring wheat is likewise a French spring sort; and is regarded by the French as merely a subvariety of the Fellemberg wheat; and was originally obtained by them from the same district as that wheat. But its chaff is stronger, and its grains are less flinty and not so liable to be shaken out. Even this wheat, however, is not much cultivated.

The red beardless Tuscany wheat ripens almost as early when sown in March as if sown in Autumn. Its ear is large, rather compact, and of a darkish red or brown colour, and bends to one side, and presents a considerable resemblance to that of the blood-red wheat; and its grains are larger, more pointed, and of a more uniform yellowish brown colour than those of that variety. If sown at the same time as the blood-red wheat, it ripens 8 or 10 days earlier.

The common red beardless wheat of France is rather a poor variety, and has not been much cultivated by the French. It was originally introduced to France from the north of Germany. Its ear has a pale red colour; its spikelets are closely set; and its grain is reddish, of medium size, and rather hard or flinty.

The common winter bearded wheat is a comparatively worthless variety, and has gone almost entirely out of cultivation, but may be frequently seen mixed in small quantities with common white winter wheat. Its ear is thin, short, and tapering to the point; its awns are considerably longer than the ear; and its grains are small, elongated, of a light reddish colour, and rather hard or flinty.

The white bearded Shanry wheat was picked out of a field on the farm of Shanry by Mr. A. Gorrie, and is a very superior variety of bearded winter wheat. Its ear is longer and more compact than that of the common winter bearded wheat; its awns are much shorter; and its grains are larger, softer, and of a light yellowish colour.

The light yellow bearded winter wheat is hardy and productive, and was at one time very much cultivated in France; and though now extensively superseded by the white beardless varieties, it is still a good deal cultivated in several large districts, and is much esteemed by both millers and bakers. Its ear is compressed; its awns are long and spreading; and its grains are medium-sized and of a reddish yellow colour.

The woolly-eared white bearded wheat was picked up by Mr. A. Gorrie along with the Shanry wheat; and it differs from that variety simply by having its ears covered with fine wool or down. "There are doubtless," remarks Mr. Lawson, "many sub-varieties of this as well as of the other downy or woolly wheats, possessing various degrees of merit; but as cultivators seem to have a prejudice against woolly wheats in general, the varieties are hitherto little known."

The white bearded Tuscany wheat was originally selected by Mr. A. Gorrie from a quantity of Leghorn wheat, and has been cultivated as a spring-sowing grain wheat, and yields a sample of very superior quality. Its ear differs little from that of the white bearded Shanry wheat, except in having rather longer awns; and its grain is longer, plumper, and of a very light colour,—and comes sooner to maturity, and is better adapted for spring sowing.

The Chinese bearded spring wheat was introduced to Britain from Germany by the late Mr. Loudon, and reintroduced from Russia by Mr. Lawson; and it showed, at its introduction, an extraordinary and almost destructive liability to rust. Its ear is nearly similar to that of the white bearded Tuscany wheat; and its grain is white, slightly transparent, a little elongated, and well filled, and forms an excellent sample.

The common bearded spring wheat of the French was at one time the most extensively cultivated spring wheat in France; and it comprises one variety with whitish grains and another with reddish grains. Its ear is small and more pyramidal than that of the light yellow bearded winter wheat; and its grain is shorter, and, in the case of the whitish subvariety, a shade lighter in colour.

The Tuscany straw-hat wheat, or *Froment blé de Toscane à chapeaux*, is a French modification of the Leghorn or true Tuscany, and very much resembles the common bearded spring wheat of the French, but grows rather taller, and is a shade yellower in colour when ripe; and it differs from the white bearded Tuscany wheat in both the ear and the grains,—the former being smaller and less compact, and the latter smaller, flinty, and of a light reddish colour.

The Cape wheat is also a French sort, and is reckoned by the French farmers one of their best spring wheats, but is found by them to be liable to degenerate unless the seed be often changed, and is also found to be more suitable for the south than for the north of France. Its ear is white and long; its awns are spreading; its spikelets are closer than those of most bearded wheats, and are also spreading; and its grain is larger, elongated, whitish-coloured, and generally plump, and forms rather a superior sample.

The small Sicilian bearded spring wheat differs from all the preceding varieties of bearded wheats, in the closeness of its ear, in the hard-like, smooth, shining appearance of its chaff, and in the shape and texture of its grain. Its ears are rather under the medium size; its awns are upright and longer than the ear; its spikelets are contracted, and slightly imbricated; and its grains are rather above the medium size, slightly elongated, and flinty.

Among other and more recently introduced white bearded spring wheats may be mentioned Colonel Le Couteur's early white spring wheat, the macaroni small hard wheat, the Naples white bearded wheat, the Tremoise black-jointed spring wheat, the Barbary hard chaffed wheat, and Gale's Hampshire wheat,—the last characterised by Colonel Le Couteur as "very enormously productive."

The velvet-eared or woolly-eared red bearded wheat is an early, hardy, prolific winter wheat, and might probably be found suitable as a spring wheat. Its ear is long, downy, rather compact, and of a dark reddish colour; its chaff is hard, and does not allow the seeds to be easily shaken by the wind; and its grains are large, flinty, and rather coarse.

The Victoria wheat, or Victoria red spring wheat, was observed by Humboldt in the neighbourhood of Victoria, in Caraccas, and was introduced thence to Britain by Sir R. K. Porter. In its native country, it ripens in 70 or 75 days from the time of sowing, and is very productive; and in an experiment, at Annat Garden in Scotland, it was sown on the 10th of June, and cut nearly ripe on the 16th September. Its straw is rather shorter than that of common wheats; its ears also are short, but pretty compact, and whitish coloured; its awns are spreading, and fully as long as the ears; and its grains are rather small, comparatively long, reddish-coloured, slightly cornered, and flinty.

The fern wheat began to be cultivated in the Carse of Gowrie in 1829; and, when sown there in the last week of March, ripens as early as any of the winter wheats sown in the previous October or November. Its ear is about 6 inches long, compressed, and of a light reddish colour; its awns are spreading, and considerably shorter than the ear; its spikelets are spreading, and very remote, and often contain each four grains; and the grains are elongated, of a bright light reddish colour, and rather flinty,—and they weigh at the rate of 63¼ lb. per bushel. This wheat is very liable to smut, and very apt to shake when over-ripe, and should not be allowed to stand beyond a state of moderate ripeness.

The red bearded Mendoza wheat was introduced to Britain from Mendoza by Sir John Sinclair. It bears a considerable resemblance to the fern wheat; but has stronger chaff, and larger and coarser grains.

The red Chinese wheat resembles the small Sicilian spring wheat in all its parts, except the colour of its chaff and grain, which are of a dark reddish hue.

Among other and more recently introduced red bearded spring wheats may be mentioned the Caucasian red wheat, the Capriola rosa red wheat, the Cape red spring wheat, the hedgehog red wheat, the Narbonne red wheat, and the transparent red wheat.

The Compact-Eared Cereal Wheats.—The compact-eared wheats are distinguished from the common-eared beardless wheats by the extreme shortness of their internodii, the compact setting of their spikelets, and the square form of their ears; and they constitute a group which almost all botanists treat as a distinct species, under the name of *Triticum compactum*. But they really are so closely allied to the common-eared wheats that they might fairly be viewed as a mere sub-species of them; and, in a sense, they actually comprehend all such common-eared wheats as are popularly called thicksets, or as have unusually short internodii or very closely set spikelets. "I have received specimens of compact wheat from France and Sweden," says Professor Low, "and have cultivated them without observing any change of characters. Whether, however, the characters which distinguish it are sufficiently permanent to entitle it to be regarded as a species, has not been determined; in the meantime, following the authority of Host, I have placed it amongst the species." Loudon represents it as a specific wheat introduced to Britain from Austria in 1819.

The Chili square wheat is one of the most marked varieties of compact-eared wheat. Its straw is white, very smooth, stiff, and upright; its ears are white, very smooth, upright, a little compressed on two sides, and seldom more than 1½ inch in length, and about ¾ of an inch in breadth; its spikelets are narrow, two or three seeded, and placed so remarkably close on their

rachis, about six to the inch, as to form with it an angle of about 45°; and its grains are small, elongated, and of a whitish colour, and amount to about 40 in each ear.

The small square spring wheat is also a very marked variety of compact-eared wheat. Its straw is stiff and upright; its ear is more square or less compressed than that of the Chili square wheat, of a brownish-red colour, stiff, upright, about 1½ inch long and ¾ of an inch broad; its spikelets are as closely set as those of the Chili square wheat, and considerably more spread, and generally three-grained; and its grains are small, slightly elongated, and well filled, and form a beautiful sample.

The square Sicilian spring wheat is reckoned by the French one of their earliest spring wheats. The awns on the point of its ear are elongated to rather more than the length of the spikelets, while those of the Chili square wheat and the small square spring wheat are almost a-wanting; and its grain is more flinty and has a brighter red colour than the grain of the small square spring wheat; but in other respects, the square Sicilian spring wheat and the small square spring wheat are very similar to each other.

Three other varieties of compact-eared wheat which have become known to British farmers, are the small square red wheat, the American square wheat, and the duck's-bill wheat; and Colonel Le Couteur says respecting the last of these, "It is very productive, but sheds greatly, and is not very farinaceous."

The Turgid-Eared Cereal Wheats.— Turgid wheat, *Triticum turgidum*, is a species containing many well marked varieties, comprising a considerable range or diversity of character, and connecting some compact-eared-like wheats on the one hand with the Egyptian wheats on the other. Awns are present in all the turgid wheats, but sit only on the corolla and not on the calyx; and, in most cases, they drop off or become easily detached by the winds when the plants ripen, and then leave them with a beardless appearance. The ears are compact, and become heavy and somewhat nodding as they fill with grain; those of some varieties are smooth, and those of others downy, woolly, or velvety with fine soft hairs; those of most varieties display four equal sides, and those of others have the attachment of the spikelets to the rachis on the two narrowest sides; and the awns and angles of most are arranged in four straight parallel lines. The spikelets are closely set, and generally much spread. The glumes have a greatly tumefied form, and very prominent dorsal nerves; and they terminate abruptly, and have acute points. The grain is large, crowded or compactly set in the ear, and irregularly angular-shaped or depressed; and it is hard, coarse, and of inferior quality, and forms but an indifferent sample. The turgid wheats are best suited to strong clay soils, rich tenacious soils, or stubborn and refractory argillaceous soils,—particularly such as occasion the common-eared wheats to become lodged, or as cannot well bear them to perfection; for the turgid wheats have such strong straw that, notwithstanding the heaviness of their ears, they can usually accommodate themselves to the stiffest soils, and vigorously resist the most prostrating weather. They have also the advantage of being decidedly productive in both straw and grain; and their straw, though too hard and firm and semi-solid to be relished by cattle, is admirably adapted, by these very qualities and by its length, for the purposes of thatching. The turgid wheats, however, generally belong to the latest class of winter wheats, and are suitable only to the earliest districts of Britain; and they will probably rather lose a good deal of the favour they have already attained, than acquire any more, among British farmers.

The Mongoke smooth white turgid wheat was introduced to Britain from the Continent by Mr. Lawson in 1833. Its straw is very long and almost solid; its ear is very large, white, and square, or has the lateral florets so pressed in as to render the aggregate form somewhat cylindrical; its awns are long, straight, and rigid; and its grains are long, irregularly shaped, large, white, and thick-skinned.

The Tagan rock smooth white turgid wheat is one of the earliest and most esteemed turgid wheats. Its straw is shorter, softer, and more hollow than that of the preceding variety; its ear is scarcely so long, and a shade darker in colour; its spikelets are not so close; and its grain has a yellowish-brown colour, seldom transparent or flinty, and is smaller and more regularly formed than that of most other kinds of turgid wheat.

The Lozere turgid wheat is much cultivated about Lozere, and is there often used, boiled or cooked, in the same manner as rice. Its ear is shorter, less closely set, and less regularly shaped than that of the Tagan rock smooth white turgid wheat; and its grain is whitish-yellow, thin-skinned, and of excellent quality.

The red smooth turgid wheat, the large red wheat, or the red upright wheat of Gatinais, is very much cultivated in the central districts of France. Its ear is long, square, compact, and of a dull reddish colour; its glumes are very smooth and shining; and its grains are soft, reddish, angular or slightly compressed on the sides, and of medium quality.

The Chinese turgid wheat, or Doragana wheat, was introduced from St. Petersburg in 1834. Its ear is white, large, square, very compact, and slightly pendulous; its glumes are shining and a little elongated; and its grains are rather large and flinty.

The cone wheat, white cone wheat, cone Rivet wheat, square wheat, pendulum wheat, antifly wheat, or German thickset wheat, is one of the best known and most esteemed turgid wheats in

Britain. It takes its name of cone from the somewhat conical form of its ears,—square, from the somewhat quadrangular setting of its spikelets,—pendulum, from the pendulous position of its ear as it approaches maturity,—and antifly, from its having almost wholly resisted the wheat-fly at a time when that insect worked great havoc among most other varieties of wheat. Its straw is long, strong, and hollow; its ear is very white and velvety, about 4 inches long and $\frac{3}{4}$ of an inch broad at the base, tapering towards the point, quadrangular, compact, and very regular; its principal awns are straight, about as long as the ear, and placed in four straight rows along the angles,—its subordinate awns rise in two rows from the outer paleæ of the middle fertile florets, and lie close on the ear,—and all generally break off when ripe, particularly in windy weather, leaving the whole ear apparently beardless; its lower and central spikelets contain each three or four fertile florets, and the upper ones generally two; its glumes and paleæ are short and very round, and the latter scarcely cover the seed when ripe; and its grains are soft, whitish yellow, a little compressed and wrinkled, and considerably larger than those of the ordinary common-eared wheats. This wheat is nearly a fortnight longer in ripening than the common white winter wheat; it is a vigorous grower, and is thought to be rather an impoverishing crop for the soil; it yields a scanty supply of foliage, yet is one of the most beautiful wheats when growing which can well be imagined; and, in favourable circumstances, it often yields several bolls of grains per acre more than the common wheats,—but the sample is inferior, and not well liked by bakers. It is found to answer best on strong clay soils.

The red, grey, or blue cone wheat, or red, grey, or blue Rivet wheat, bears a general resemblance to the preceding variety; but its ears have a reddish-blue or ash colour, and its grains are darker in colour than those of the white cone wheat, and rather more flinty. It is cultivated in England and the north of France, generally on strong clay soils; and it is very hardy in constitution, and very late in ripening.

The common Rivet wheat of England is cultivated on the strongest clay soils in the south of England, but is so late in arriving at maturity that it may be regarded as unfit for the north of England, or for any part of Scotland. Its ear is smaller and less compact than that of the white cone wheat; its awns are less liable to be broken off or blown away when ripe; its glumes and paleæ are considerably larger and more elongated; and its grains also are longer and more flinty.

The Pole Rivet wheat of England is also cultivated on strong soils in England, and is very late in ripening; and it is likewise much cultivated in the southern and eastern districts of France. Its ear has a lightish-brown colour, and is more compressed and irregularly shaped than that of the common Rivet wheat of England, and—contrary to the general rule of turgid wheats—it has the insertion of the spikelets into the rachis on its broadest side; its awns fall off when ripe; its lower spikelets contain each four fertile florets, and its upper ones three; and its grains are long, reddish, and flinty.

The Turkey wheat, or the Turkey great turgid wheat, appears to be a subvariety of the Pole Rivet wheat of England; and it is from a fortnight to three weeks later in ripening than the common white winter wheat. Its ear is larger, thicker, and more regularly square than that of the Pole Rivet wheat of England, and has a reddish-ash colour; and its grains are larger and of a darker colour, and form a rather coarse sample.

The St. Helena giant wheat, or St. Helena giant turgid wheat, was introduced to France from St. Helena, and reintroduced from Dantzic. Its ears are larger and more irregularly formed than those of the preceding varieties of the turgid wheats; its lower spikelets are more enlarged, and diverge in a zigzag manner to the sides; and its grains are large, about $3\frac{3}{4}$ lines long, flinty, and similar in quality to those of the Turkey wheat, but more prolific. This wheat also is late in ripening.

The Petanielle wheat, or Petanielle black turgid wheat, is distinguished among all the other turgid wheats for the height of its straw, the dark colour of its ears and awns, and the largeness and abundance of its grains; and it came into much demand about 16 years ago in the neighbourhood of Paris, and was introduced there from the south of France. Its awns fall off when ripe; its glumes and paleæ have a shining bluish-black colour; and its grains are harder and darker coloured than those of other turgid wheats, and at the same time possess all their peculiar defects.

The Egyptian wheat, Egyptian cone wheat, Abyssinian wheat, Smyrna wheat, reed wheat, compound-eared wheat, or branching-eared wheat, is sometimes undistinguishable from the ordinary turgid wheats, but at other times has a ramified or compound ear of a form as if several ears were tied together, and is therefore treated by most botanists as a distinct species under the name of *Triticum compositum*. It certainly is almost unique in the property of producing a compound ear; but it by no means possesses this property essentially or constantly; and seems merely to be a true turgid wheat in poor or ordinary circumstances, with a constitutional power of developing compound ears on rich soils or under good or favourable conditions of culture. Its straw is stiff, long, and nearly solid or filled with pith; its glumes and paleæ are slightly downy, and have a glaucous reddish colour; and its grains are short, whitish-brown, and rather flinty. Its produce in grain is very abundant under favourable circumstances of soil, climate,

and culture; but its grain yields a smaller proportion of flour or meal than most other kinds of wheat; and its flour is scarcely superior to that obtained from the finest barley. It is cultivated in Egypt and in the south-east of Asia; it has been known in Germany for about 250 years, and cultivated in France for about 80 or 90 years; it was introduced to Britain from Egypt about the end of last century; and it has been experimentally cultivated, under different names, in various parts of both England and Scotland; but it does not seem to be well suited to British agriculture,—for it is very liable to be laid, it is retentive of moisture at the time of harvest, it does not display any such luxuriance and productiveness here as it does in other countries, and it is decidedly objectionable on account of the qualities of its grain and flour.

Three other varieties of turgid wheat which have become known to British agriculturists are the Losanna red turgid wheat, Mumford's gigantic wheat, and the American thumb wheat; and the first and second of these are always single-eared, while the third possesses the peculiar earing habit of the Egyptian.

The dark-eared or dark-headed wheat, though usually classed by botanists as a separate species under the name of *Triticum atratum*, is also sufficiently akin to the cone wheats to be regarded as a mere variety of *Triticum turgidum*, though at the same time it has some affinity to the *Triticum spelta*. It was introduced to Britain from Austria in 1820; and has been made the subject of some comparative experiments; but does not recommend itself to cultivation by any properties or habits of superiority to the Rivet wheats of England.

The Compressed-Eared Cereal Wheats.—These comprise the stiff, hard, or hairy wheats of botanists, constituting the species *Triticum durum*. They are characterized by large, broad, compressed ears, generally very short in proportion to their breadth,—by elongated spikelets,—by large, hard-like, shining chaff,—and by long-shaped, hard, and flinty or horny grains; and all are awned, and have stiff, short, upright straw, and broad foliage. "These wheats," says Mr. Lawson, "are in general very early, and may be sown in spring. Their cultivation has been several times attempted in Britain, but with little success, owing partly, no doubt, to the unsuitableness of our climate, and partly to their peculiar hardness, and, in the estimation of our bakers, inferiority of their samples. The chief range of their cultivation lies along the shores and in the islands of the Mediterranean, and along the shores of the Levant, as also in Arabia, Persia, and some parts of India. The Arabs cook some of them in the same manner as they do rice, which they all resemble in the hardness of their grain. Wheats of this sort are often imported for the London markets, but were at first very much disliked by millers, from the ordinary millstones being unsuitable for grinding them."

The hard Sicilian wheat bears some slight resemblance to the common-eared wheats, and may be regarded as forming a connecting link between the compressed-eared wheats and them, through the medium of the small Sicilian bearded spring wheat. Its ear is about 3 inches long and $\frac{1}{3}$ of an inch in diameter, and has a square form approaching to cylindrical; its awns are considerably longer than the ear; its glumes and paleæ are long, smooth, white, and shining; and its grain has a lightish-red colour, and is medium-sized, elongated, hard, and horny.

The Georgian wheat is much more strictly a compressed-eared and hard-grained wheat than the preceding. Its straw is short, upright, and quite solid; its ear is compact, sub-cylindrical, a little irregular toward the base, about 2 inches long, and from one-half to five-sixths of an inch in breadth; its spikelets are long and pointed; its awns are about twice as long as the ear; its glumes and paleæ are long, whitish, and slightly downy; and its grain is about one-third of an inch long, less than one-sixth of an inch in diameter at the middle, slightly triangular, curved towards the ends, of a light red colour, and very hard and flinty or horny.

The Siberian wheat has considerable affinity and resemblance to the Georgian wheat. But its straw is a little hollow; its ear and spikelets are shorter and more compact than those of the Georgian wheat, of a light brownish colour, and more distinctly downy; and its grains are rather shorter, and equally hard and flinty.

The Morocco or Tangier wheat has hard, upright, and generally hollow straw, a larger and more irregularly shaped ear than either the hard Sicilian, the Siberian, or the Georgian wheat, and grains of the same colour and hardness as these wheats, but of larger size. "This sort," says Mr. Lawson, "together with several more varieties in mixture, differing from it chiefly in colour, was sent to this country several years ago by the British Consul at Tangier; they were tried in several parts, but their cultivation has been abandoned, or they are only to be met with in collections."

Three other kinds of hard wheat which have become known to some British agriculturists are the Ishmael wheat, the Manfredonia wheat, and Dr. Rolland's Nepaul hard wheat; and the last of these differs so far from the rest as to make some slight claim to be considered a different species, or at least a very distinct variety.

The Loose-Eared Cereal Wheats.—These are the Polish wheats, constituting the botanical species *Triticum polonicum*. But though generally termed Polish, they really are natives of various parts of Africa and south-eastern Asia; and they are also popularly called wheat of Cairo, Mogadore wheat, Grecian wheat, Polish rye, and Astrachan rye. They are readily distinguished from all

other wheats by their long, loose, and chaffy-like ear, and by their large grains. The ear is awned, and nods to a side; the awns are about three times as long as the glumes, and very brittle, and easily break off when ripe; the glumes are more than an inch in length, or twice as long as the florets; four florets are contained in each spikelet, and seldom more than two of them, when the plant is grown in this country, are fertile; and the grains are about half an inch in length, of a reddish colour, transparent, and very hard. Polish wheat is cultivated in Africa, some parts of Asia, Spain, Germany, and Poland; and it was introduced to Britain so long ago as the latter part of the seventeenth century, and has been subjected in this country to a great many experimental trials, and has been thought to be valuable on account of its productiveness of flour; but it is too tender in constitution, and too extensively subject to infertility in our climate, to be ever likely to become a favourite with British farmers.

The Meagre-Eared Cereal Wheats.— These are wheats with small, thin, slender, or otherwise comparatively inconsiderable ears, of medium character between the ears of the bulky cereal wheats and the ears of the mere wheat-grasses; and they comprise, among other kinds, the species called zea or far, Bengal wheat, starch wheat, and one-grained wheat.

The zea or far, *Triticum zea*, is the spelt wheat, or *Triticum spelta*, of Host and some other continental writers; and it is popularly supposed, though we think quite erroneously, to be the grain termed zea by the Greeks and far by the Romans. Its straw is rigid; its ears are long, almost awnless, thin, and upright; its spikelets are not so long as two joints of the rachis, and are so firmly attached to the rachis, that, in thrashing, they do not separate from it but break it, each spikelet retaining a joint; its florets on each spikelet amount to three, and the middle one is barren; its glumes and paleæ adhere almost as closely to the grain as the spikelets do to the rachis; and its grain is elongated, triangular, reddish, and flinty. This wheat is cultivated on inferior soils in some parts of Continental Europe; but is seldom met with in Britain, except in botanical collections.

Bengal wheat, *Triticum Bengalense*, was introduced by Mr. Lawson from Germany in 1834. "It bears some resemblance," says Mr. Lawson, "to the *Triticum zea* in the shape and remoteness of its spikelets, which adhere with equal firmness to the rachis; the straw and ears are, however, much longer, the latter containing about thirty-six grains, which are longer and more easily detached from the chaff than those of *Triticum zea*. It is of a more luxuriant growth, and has an awn from two to three inches in length. This is altogether a much superior variety to *Triticum zea*, and is remarkable as being the earliest wheat in the whole (of the Highland and Agricultural Society of Scotland's) collection."

Starch wheat, *Triticum amyleum*, is the spelt wheat or *Triticum spelta* of most British botanical authors; and it is both far more varied in character and far more economically useful than the *Triticum zea*. "Spelt," says Professor Low, "is much cultivated in the south of Europe; it is grown extensively in the southern provinces of France, in Switzerland, Italy, in several parts of Germany, and in Arragon, Catalonia, and other parts of Spain. Spelt could be raised in this country with facility, and, it is probable, on soils low in the scale of fertility; it has been cultivated in Scotland 600 feet above the level of the sea." Its specific characters are compressed, awned, slender ear,—long, smooth, overlapping, or closely imbricated, three-floreted spikelets, with generally but two perfect seeds,—adhering rigid chaff, similarly persistent to that of the zea and the Bengal wheat,—and long, irregularly triangular, reddish, transparent, but not hard grain. It comprises winter and spring, long-eared and short-eared, whitish and brownish varieties; and in cases where its chaff is red, its grain has a correspondingly darker colour. The root-leaves of the winter starch wheat or winter spelt are narrow and prostrate; the ear is long and slightly bent to one side; the spikelets are each about as long as three joints of the rachis, and contain generally two but sometimes three seeds, especially toward the base of the ear; and the chaff is whitish, rigid, and shining. The spring or summer starch wheat, or spring or summer spelt, differs little from the preceding, except in having stronger or more upright root-leaves, and in ripening about 10 or 14 days earlier. The ear of the red two-rowed starch wheat or spelt, or brown two-rowed starch wheat or spelt, is of a reddish-brown colour and slightly glaucous, particularly before ripening; and its grain is a shade darker in colour than that of the two preceding varieties. The ear of the white broad-spiked starch wheat or spelt is considerably shorter, much broader, thicker, and more compact than that of any of the three preceding; and its spikelets are more frequently three-grained, and about as long as four joints of the rachis. The ear of the red or brown broad-spiked starch wheat or spelt resembles that of the white broad-spiked in form, but has a reddish-brown colour, with generally more or less of a glaucous or bluish hue, particularly before ripening. "Amongst the Alps of Switzerland," says Mr. Lawson, "the winter spelt is found to withstand the severest winters, at altitudes far above that at which the range of the naked or commonly cultivated sorts terminate. And, independently of its grain, it might be substituted as an herbage plant for yielding a crop of green food for cattle early in spring, in late cold districts, from its tillering well, and yielding a considerable quantity of foliage. It is sown in October, and the spring

sort in February or March. The flour of the spelt wheats contains more gluten than that of the common sorts; it makes a superior very white bread, and is much used by confectioners for pastry."

The one-grained wheat, *Triticum monococcum*, is allied to the spelts, and is cultivated, on poor soils, in the mountainous parts of Continental Europe; and it was introduced to Britain so long ago as about the middle of the seventeenth century. Its straw and leaves are very small and rigid; its ears are small, very much compressed, and two-rowed in a manner similar to common barley; its spikelets are close, imbricated, and about as long as four joints of the rachis; each spikelet contains only two florets, the one fertile and long-awned, the other barren and short-awned; and the grain is small, triangular, transparent, soft, and mealy. The flour of this wheat makes a good dark-coloured bread, but is more particularly adapted for gruel. "The one-grained wheat," says Mr. Lawson, "is equally hardy with the spelt wheat, but far inferior to it in quality and produce; however, it thrives on the poorest, dry, calcareous, sandy soils where few other of the cereal grains would subsist, and yields straw, which, although short, is, from its firmness and durability, well adapted for thatching; for which the straw of the spelt-like wheats in general seems much better adapted than for fodder."

Comparative Trials of Different Wheats.—Peculiar kinds of wheat suitable for particular soils, particular situations, particular times of sowing, and particular purposes, are so comparatively few in number and so comparatively marked in character as to occasion little difficulty of selection, and sometimes not even to allow any alternative for choice; while kinds which possess only indistinct peculiarities, and are suitable for ordinary soils, ordinary situations, ordinary times of sowing, and the most ordinary purposes of culture, are so aggregately multitudinous and so individually ill-defined, as often or even usually to render it exceedingly difficult, on any one farm or in any one district, to select such as may prove most profitable. Thus, if an inexperienced farmer wish to ascertain the most suitable wheat for an excessively stiff soil, or for a poor soil, or for a cold or elevated situation, or for sowing at the latest possible period in spring, or for the best thatching adaptations of the straw, or for the most glutinous qualities of the grain, he may readily discover it, and will be liable to scarcely any hesitation or mistake in doing so, simply by perusing the brief accounts of the principal kinds in our six preceding sections; but if, on the other hand, he wish to ascertain the kind which will best compensate him by ordinary routine cultivation on any kind of good low-lying farm of the mixed husbandry, whether the soil be clay or loam, whether the time of sowing be autumn or spring, and whether the main consideration be the grain alone or both the straw and the grain, he may at first feel rather hindered than helped by the accounts which we have given, and may in a little while feel himself more confounded than instructed by the display of many kinds, all seeming to compete with one another for superiority,—and, if he seek relief from his perplexity by an appeal to the opinions or usages of his neighbours, he will, in almost every case, be either thrust deeper into difficulty or driven back on the guidance of mere empiricism or chance. Though numerous varieties of prime or very good wheats seem to be very nearly equal in value, and though all have necessarily been described by us under determinate characters which were severally assigned to them under circumstances of apparently normal development, yet all differ more or less widely from one another in such constitutional habits and minute adaptations as most materially affect their comparative value on any one farm, and each differs more or less widely from itself in the younger or older stages of its existence as a variety and in the greater or less congeniality of the circumstances of its culture. Hence, a variety which is of prime-rate profitableness under one set of circumstances of climate, soil, manure, rotation, sowing, and tillage, may be only second-rate or fifth-rate or tenth-rate profitable under a different set of these circumstances; and a variety which was eminently productive in any given circumstances when it was young, may become very inferiorly productive in exactly the same circumstances when it turns old. Every extensive cultivator of ordinary market wheat, therefore, ought to find out for himself the varieties which best suit the conditions of his own farm and farming; and this he will do either by ascertaining the result of comparative experiments conducted by some intelligent neighbour under precisely similar conditions, or by instituting a set of such experiments himself. The latter is the more satisfactory method; and may easily be done simply by selecting all the seemingly prime kinds which promise to be suitable for the soil and culture, and by planting equal surfaces of ground with each at such depths and distances as will afford all the fullest play for their utmost possible luxuriance. As examples of the kind of way in which experiments should be conducted, and of the nicety and diversity of the results which may be ascertained, we shall here insert reports of two admirable experiments by respectively Mr. John Morton and W. Miles, Esq., M. P.

"The intelligent farmer of arable land," says Mr. Morton, "expects a greater crop, the more he has been able to improve the texture of the soil, and the better the nature and state of the manure which it contains. He expects it, because he knows that it depends on the nature of the food given to the plants, and the manner in which they are provided with a constant supply of it. The crop does not, however, depend only on this; for as two beasts fed in exactly the same manner may not be equally pro-

fitable, owing to a difference between them regarding the quantity and quality of the meat they afford, so two different kinds of wheat, though sown on land precisely similar, and in equally good condition, may give unequal returns, owing to a difference between them regarding the quantity and quality of the flour they afford. Hence the importance, too often overlooked by farmers, not only of preparing the land for the crop in a good and sufficient manner, but also of selecting that kind of seed which experience has pointed out as being most valuable and productive. It was with a view, not only of ascertaining the relative value, hardiness, and other properties of several of the most commonly-planted wheats, but also of effecting an improvement in the best of them, that the following experiment was commenced on the 1st of November 1837. To insure accuracy in the results, it was necessary that the seeds of each variety should be planted so as to have them all at equal distances. To effect this, two boards were used, each six inches wide, nine feet long, and half an inch thick. Along the centre of each board was a row of holes, three inches apart and one inch in diameter. A dibble was made to fit into the holes, having a shoulder at the distance of 2½ inches from the point. When the board was placed on the ground, and the dibble put through each hole in succession, a series of holes was thus made, two inches deep, and three inches apart from centre to centre. After this had been done through the first board, the second, which was touching it, and parallel to it, was served in the same way; and then the first was taken up, and placed on the other side of the second. By proceeding thus, the whole ground was finished, and then one grain of wheat was dropped into each hole. The rows were thus exactly six inches apart, and the grains in the rows were three inches from one another. The regularity with which the planting was performed was thus mathematically accurate. The ground planted lies on the lower edge of the great oolite formation, and the soil is a stone-brash, about ten inches in thickness. Crops of potatoes had been taken off it for a succession of eight years; and it had been manured every alternate year, with a compost of equal bulks of stable-dung and earth, at the rate of about twenty cubic yards per acre. It was sixty-seven feet in length; and three rows of each variety of wheat were planted, except the first and last numbers, of which there were four rows. The outer row of each of these, however, was not taken into account, because their roots had a much greater extent of ground for their growth than the others, whose roots touched one another all round. The end plants of each row were also rejected for the same reason. Sixty-six feet in length of ground were thus taken up, and three rows of each variety occupied in width 1½ foot: the ground occupied by each variety was thus ninety-nine square feet, the 440th part of an acre.

Although the tabular form in which this experiment is detailed explains itself by the headings of each column, yet it is considered necessary to give a somewhat fuller account of it. The seed from which the first ten varieties were raised was carefully selected from specimens of each obtained in the ear. The others were from samples; and here, also, the greatest care was taken that the seed from which each was raised should be the best and plumpest that could be obtained. The first five columns need no explanation beyond what is given at the head of each; the sixth shows the number of grains lost from casualties. If the frost had been the only agent in the destruction of so many of the seeds, this column might have been considered as a very accurate index of the relative hardiness of each variety. This, however, is not the case, for the havoc which the birds made must also be taken into account. It was thought, at the time, that more injury was sustained, from the latter cause, by those varieties planted on the 21st, than by any of the others; but this does not appear to have been the case, for, if the

great loss sustained by these had been wholly owing to the havoc committed by the birds, it is evident that the varieties marked Nos. 12 and 15, would not have been so slightly injured, while Nos. 11, 13, 14, and 16 suffered so severely. The figures in this column may, therefore, be said to indicate with tolerable accuracy the relative ability of each variety to withstand the effects of a severe and changeable winter, such as that during which the experiment was made. The number of plants of each variety which came to perfection, is placed opposite the name of each in the seventh column. This was ascertained by pulling each as they respectively ripened, and counting the plants of each before proceeding to the others. In this way, by a simple subtraction, the numbers contained in the sixth column also were ascertained. When all the plants of any variety had been pulled, the number of ears also belonging to them was counted, and the results are placed in the eighth column. By dividing these by ninety-nine, the number of square feet which each variety occupied, we obtain the number of ears in each square foot; and this is placed opposite the name of each wheat, in the ninth column. The average number of ears to each root, ascertained by dividing the number of ears by that of the roots, is placed in the tenth column. This column shows the degree in which each species possesses the important property of spreading and shooting out stems, or, as it is technically termed, of tillering; and it will be seen that they vary in this respect greatly. After having been pulled and dried, the wheat was carefully rubbed out; and after the light and imperfect grains had been separated, the weight of the remainder was taken, and placed opposite each sort in the eleventh column. The thirteenth column contains the number of bushels per acre raised from each variety. As the quantity produced was so small, there was some difficulty in obtaining the particulars which this column contains. The mode adopted was this. The average weight of several of the varieties was ascertained by weighing eight pints of each, to be at the rate of sixty-four pounds per bushel, some being rather more, and others less. The number of bushels were then obtained from the weight of wheat per acre, by dividing it by sixty-four. The weight of straw, which is placed in the fifteenth and sixteenth columns, was ascertained after the roots had been cut off, and after it had remained out sufficiently long to dry it perfectly. After the earth had been removed from the roots, which had been cut off with about two inches of the stem, they were weighed, and the result placed in the seventeenth and eighteenth columns. The object of this was to ascertain the amount of vegetable matter left in the soil after the wheat crop has been removed, and the result greatly exceeds any conception of it that had been previously entertained. The inferences which, it is presumed, may be drawn from the above details, are the following:—1st. With regard to the hardiness of the varieties, which, as we have already said, may, to a certain extent, be deduced from the particulars contained in the sixth column, that they may be placed in three classes,—Nos. 5. 6. 8. 12. 15. 4. and 2. being the hardiest; Nos. 13. 14. 16. and 10. being the most delicate; and Nos. 1. 3. 7. 9. and 11. occupying an average station. 2d. With regard to the property of tillering, of which we have already spoken, that Nos. 12. 14. 16. and 1. possess it in the greatest degree; that Nos. 3. 13. 4. 5. 6. 15. 8. and 2. possess it in the least; and that Nos. 7. 9. 10. and 11. hold a medium rank. 3d. That with respect to the relative value of each variety mentioned in the table, No. 12. is undoubtedly the best of any, in productiveness, and in being sufficiently hardy; that No. 13. is as undoubtedly the worst of any, as will be seen by a reference to any of the columns; and that the others vary greatly, some possessing nearly three times the productiveness of others."

"In Sept. 1841," says Mr. Miles, "I chose for my experiment a one-year old clover ley, on a sandy loam, gently sloping to the north-north-west. The crop of clover had been very good, nearly 50 cwt. an acre; from some part of the field I had taken a second crop, feeding the remainder with sheep and young beasts; no visible difference, however, was afterwards apparent in the grain crop, either in quantity or quality, from these distinct modes of treating the second crop of clover. The field was ploughed on the 20th of September, and, having been laid out in half-acres for the ploughing-match of the Bath and West of England Society, was continued in the same state for the experiment, each half-acre being separated by 27 inches of grass-balk. The sorts selected for trial were, of white wheats, No. 1, Bellevue Talavera, No. 2, Chidham, No. 3, Silver drop, No. 4, a seedling—Jonas's prolific, No. 5, Sheriff's, and No. 6, golden swan; and of red wheats, No. 1, Burwell, No. 2, red champion, No. 3, Britannia, No. 4. Mr. Fisher Hobbs's red marigold, and No. 5, old red Lammas. To each of these wheats 3 half-acres were allotted, except to Mr. Jonas's seedling, of which I had but sufficient seed for an acre: the quantity sown per acre was 2 bushels and 1 peck. On the 27th of September, previously to breaking up the clover, 10 bushels of ½-inch bones were sown broadcast over the field. On Tuesday the 12th of October, I commenced putting in No. 1 white with a Suffolk drill, and finished No. 5 red on the Friday following. On Tuesday the 26th No. 2 white appeared; on the following Saturday all the whites were up; on the 3d of November the red wheats were partially, but without any apparent priority of germination, showing. The appearances of the white wheats were—No. 1, sixth; No. 2, first; No. 3, fourth; No. 4, third, No. 5, fifth; No. 6, second. No. 1 came up very indifferently; indeed it seemed, from the incessant rains, which had continued almost without intermission from the time of sowing to this period, to have perished in the ground; and as this wheat never afterwards improved, but was entirely hoed in again in February, it may be considered as having totally failed with me. Last year, however, in which there were several very sharp frosts and a good deal of catching weather, I reaped a most capital crop of Bellevue Talavera, nearly 5 quarters an acre, which had been sown in October, 1840. This wheat in our climate I consider essentially a spring wheat, and as such invaluable; for in the parts of the trial-field this year where the plant was very deficient, or had totally failed, I hoed it in from the 6th of February to the beginning of March, and the wheat so sown was ready for the sickle as early as those sown in October. On the 21st of November I found the appearances of the wheats thus noted:—Whites, No. 2, third; No. 3, fourth; No. 4, second; No. 5, fifth; No. 6, first: Reds, No. 1 and 2, first; No. 3, fourth; No. 4, second; No. 5, third. The first fortnight in January was very trying to the plant, as we had alternate sharp frosts and sudden thaws without snow. On the 22d the wheats were going off terribly, and the wire-worm was general in its ravages: I immediately put the heaviest roller I could get on the field and rolled it till the surface was as hard as a turnpike-road; still the damage apparently done was immense, and a neighbouring farmer guessed that the product of the field would not be above 16 bushels per acre: the rolling, however, stopped the progress of the wire-worm. On the 5th of February I began hoeing in Bellevue Talavera on those spots of the trial-pieces where the plant had nearly disappeared: of the whites the whole of No. 1 was put in afresh; of No. 5, about two-thirds of an acre: of the reds a little was put in in Nos. 1 and 2; nearly all in No.

3; and about half an acre in No. 5: so that of the white wheats Nos. 2, 3, 4, and 6, and of the reds, No. 4, were the only wheats which stood the winter for crop as first planted. On the 2d of April I find that the wheats on the whole were very bad; but from the 25th of March until the 23d of April, not sufficient rain fell at King's Weston to wet the ground, and at this period the wheats began to mend; their improvement being gradual, but extraordinary. I was absent from home during the blooming, but was informed by my farming-man that very little difference was perceptible between the flowering of the whites, and that the reds came into bloom from a week to ten days after the whites. On my return from London at the end of the first week in July, I found the general improvement still progressing; the tillering, considering the nature of the soil, had been extraordinary, and the ears were upright and full: I therefore carried out the experiment as far as was practicable, selecting 16 perches from each variety, cutting it with the scythe, and accurately weighing the grain and straw. On the 2d of August I marked out, as nearly as my eye could enable me to judge, 16 perches of average equal growth and occupying relatively similar positions in the field, from Nos. 2, 3, 4, 5, and 6, white; and from Nos. 1, 2, 4, and 5 red, similar quantities, but, excepting No. 4, not in relative situations to the white wheats; yet still, had the season been generally favourable, such 16 perches as I estimated would have been fair samples of the produce of these wheats. The white wheats, however, throughout appeared better suited to my land than the reds; and the result of the experiment has convinced me that, in soil and climate similar to that on and in which I have made the trial, the growth of the former should be encouraged rather than the latter. Before reaping, the appearance of the different wheats was as follows:—Whites, No. 2, third; No. 3, fourth; No. 4, first; No. 5, third; No. 6, second: Reds, No. 1, third; No. 2, second; No 4, first; No. 5, fourth. For the reason before specified, viz. the almost total destruction of the plant of No. 3, no portion of that wheat was measured off for the experiment. On Friday the 5th of August I cut with the scythe the whites, on the Monday the reds, and on the following Wednesday and Thursday carted the respective lots. The subjoined Table will show the results of the produce of wheat-straw and flour per acre of each kind, estimated from the product of 16 perches of each. I conceive, however, that, were the whole of the produce of each sort to be thrashed out, none of the crops would come up to this average; but the appearances of Nos. 4 and 6 white, and No. 4 red, were generally good, and the tabular results would not at most give 2 or 3 bushels per acre above their respective produce. Every attempt, however, as far as the season permitted, has been made to carry out the experiment with perfect fairness. I consider for the bulk of straw the yield of grain was extraordinary, and the samples of wheat of each kind can scarcely be surpassed, subjected as they were merely to the usual dressing. The miller declared that he had never ground better flour; but stated that, if he had any preference, he should give it to No. 2 white, and No. 1 red. In the process of converting the flour into bread, better than which I never have tasted, the plan recommended by Colonel Le Couteur was adopted, viz. '18 lbs. of the flour of each sort was placed to rise or sponge over-night with ½ a pint of yeast and 2 quarts of water. At nine o'clock the next morning 4 oz. of fine salt were added, together with as much water, milk warm, as each kind would imbibe to fit it for the oven, which was well worked up, *drawn up* (as it were) into strings to expose it to the air as much as possible in order to render it light, left to rise for 20 minutes, or ½ an hour, baked and weighed next morning.' The subjoined tabular statement will, I think, prove the necessity of carrying out all our experiments to the utmost, as otherwise great danger will arise of discarding valuable sorts, merely from their being in one or two instances less productive than others, which may be accounted for from the chances of the season, or other disturbing, but not sufficiently investigated, causes. Of the white breads No. 6 was the whitest, No. 4 the closest, and No. 2 the lightest; of the brown, or rather that made from the reds, No. 5 was the whitest and lightest; the others were much the same in colour and quality.

It will be perceived that No. 4 white was by far the most productive of the trial wheats; and as Mr. Jonas, when he presented this prolific seedling to me, sent me an account of its origin, I think I cannot do better than insert an extract from his letter, as it may encourage farmers, should they accidentally discover amongst their crops ears of corn of extraordinary productiveness, dissimilar to the bulk of the crop, and of apparently new habits, to preserve and cultivate such more generally than they do at present, for the purpose of raising valuable varieties. Mr. Jonas thus wrote in September, 1841:—'You will oblige me by accepting 3 bushels of white wheat, which I have raised from a single ear, and by growing it side by side with the trial-wheats of Liverpool. I have no fear of the result; but should the Liverpool selected wheats be more prolific and valuable than mine, I shall be highly gratified, as I should cease growing the sort I have thus raised and have some of that which was better. I would thank you not to sow this wheat before the latter part of October, or the beginning of November, as it is inclined to tiller early. I send you the exact quantities grown each year from this single ear, and I do so that you

may avail yourself of any opportunity or way you please of showing to my brother-farmers how short a space of time is required to raise a good sort of any grain,—

Years.			Produce.
1838 dibbled in 50 kernels (30 of which only grew)			14¾ oz.
1839	„	„	14¾ oz. „ „ 1 bush. 1 peck
1840	„	„	1 bush. 1 peck „ 45 bush.
1841	„	„	45 bush. „ „ 537 bush.

And had this wheat not been as much red-gummed as my other sorts, I believe I should this year have had 100 bushels more.'"

Soils and Tillage Suitable for Wheat Crops.—The soils most suitable for wheat are the argillaceous; and so peculiarly suitable are these as often to be comparatively termed wheat-soils; and they owe their suitableness partly to their comparatively firm mechanical texture, and partly to their comparative richness in alkalies and salts. The soils least suited to wheat are either such spongy or excessively porous ones as do not afford sufficient anchorage to the roots of the plants, or such extremely light ones, whether silicious or calcareous, as do not contain enough of saline matter for the secretions of the culms and the ears. Yet some clay lands are either too stiff or too plastic to be eminently or even moderately suitable without being ameliorated by means of draining, textural manuring, and very thorough tillage; and almost all light arable soils, except the very worst, provided they enjoy sufficient amenities of climate, are capable of being rendered suitable by means of claying, marling, or some other special preparation, combined with appropriate tillage and with judicious rotational management. The production of wheat, indeed, ought never to be forced on any land which may be more profitably devoted to other crops; yet, whenever it promises superior profit on land which is naturally unsuitable, it can easily be rendered practicable by means of due preparational appliances. Proper management in prospect of wheat crops, therefore, whether as to the selecting of land, as to the general rotation, as to the preceding crop, as to the preparatory tillage, or as to the prospective or immediate manuring, must exceedingly vary according to circumstances, and requires the exercise of a clear and comprehensive judgment; and, in a general view, subject to variations and exceptions, and aimed more at making suggestions to intelligent farmers than at giving any very detailed instructions to ignorant or unreflecting ones, and based principally on a review of the best existing practices, without any predominant bias from theory or from untested science, it will be found very well stated in the following long extract from a recent Prize Essay by Mr. Edward Roberts, in the 8th Volume of the Royal Agricultural Society's Journal:—"Whatever may be the nature of the soil, it should always be the aim of the farmer to grow full crops: partial and sometimes extensive failures will even then but too often occur; but to neglect making the best-known preparation, or only to prepare for half a crop, is an ill-judged notion, and has a direct tendency to unremunerating farming. In order to prepare for luxuriant crops, the land, when of a wet nature, must be liberated from all surplus water by proper underdraining; it must be clean from couch-grass and all other kinds of rubbish; not tired out by cross or improper cropping; must be judiciously manured, but not overdone with it, inasmuch as too much manure causes the growth of an unnaturally large quantity of straw, which, if the season happens to be wet or stormy, will be crippled and flat on the ground before the ears could come to perfection. When this happens, it both lessens the quantity and very much deteriorates the quality of the grain. The land being otherwise well prepared, it is perhaps upon the whole more desirable to have a little deficiency of manure than too much, as, if necessary, a partial top-dressing may always be added in the spring. The land must not be wheated oftener than the soil will admit. Some soils will bear it more frequently than others; and it is essentially necessary that the kind of seed should be adapted to the description of soil upon which it is to be propagated. An entire change of seed from hot land to cold, and from cold land to hot, will always be found advantageous, and especially from hot to cold soils, in which case it will frequently bring the harvest nearly a week earlier. In both cases, it is generally allowed to increase the yield, improve the sample, and preserve the stock in greater purity. It has now become very general to sow wheat after clover upon all classes of soils. This is doubtless one of the best systems of growing wheat. The roots of clover after becoming decomposed afford much nutriment to the growing wheat; and the firmness given to the land is another great recommendation. It has been frequently observed when the plant of clover has been deficient that the wheat-plant fails also. This, however, is not always the case: at the same time it serves to show a peculiar adaptation, on many soils, to the growth of wheat after clover.

"There are several other methods of preparing land, varying according to the nature of soils, which oftentimes produce crops of the first order. Some of these are as follows:—First, upon clayey soils, a full summer's fallow is occasionally resorted to as a preparation for the wheat-crop on much of the land in Essex, Hertfordshire, Bedfordshire, and other counties, particularly when the land becomes foul with couch-grass, &c., and cannot very well be brought into a thorough clean state of cultivation by partial fallows, connected with the growth of green crops. Considerable benefit is also derived from summer fallowing upon this kind of soil, as it causes a more perfect decomposition of its constituent parts. This latter effect has been proved in many cases, by experienced farmers, and has come under the observation of the writer. For instance, when

this kind of land has been repeatedly dunged, better crops have frequently been obtained after a full summer's fallow without dung, than after a good dressing of dung without a full summer's fallow. In some parts of the midland counties, upon the heavy soils, where a summer's fallow is the preparation for wheat, about July or the beginning of August, when the soil has been thoroughly cleaned and pulverized, it is formed into two bout stitches 1 yard wide, and manured in precisely the same way as for turnips, putting on from 8 to 10 cart-loads per acre: others spread the dung on the surface and plough it in, forming their land into stitches from 2 to 8 yards wide. In both cases, the land should remain untouched from this period till the time of sowing. In the latter case, the seed is drilled in rows from 6 to 10 inches asunder. When labour is plentiful, the dibbling process is often adopted, and then a less quantity of seed is sufficient. The horse-hoe is sometimes used to cut up the annual weeds immediately previous to sowing, which frequently grow very strong, and would be too much for the harrows to eradicate. When the former plan is adopted—namely, that of ploughing the land into two bout stitches—the plough is sufficient, and there is no necessity for the horse-hoe. The seed is sown under the furrow in the 'spraining' method; one seedsman to two ploughs, which merely reverse the ridges that were made when the land was dunged. Small light seed ploughs are kept for the purpose, which leave a narrow furrow. Many farmers object to this method because of the numerous furrows; but this is an erroneous idea,—for when wheat is drilled or dibbled, the space between each row is often more than the width of one of these furrows. Others object to it because the wheat comes up similar to the broadcast system, and they cannot very well hoe it in the spring; but this is no valid objection,—for if a fallow has been properly managed, the wheat will scarcely require hoeing, since, by continually moving the land during the early part of the summer, most of the seeds of annual weeds have been brought sufficiently near the surface for germinating; and the land being left quiet from the end of July until seed-time gives every encouragement for the weeds to grow; there are consequently but few seeds near enough to the surface for vegetating in the spring. Three men, with two ploughs and four horses, can put in by this system about 5 acres per day. Last year, upon an extensive farm known to the writer, more than half the wheat was sown in this way, and proved remarkably fine, even more so than that sown after clover. In some parts of Scotland, the wheat is sown with a drill-plough, which drills the seed, and covers it in with the furrow turned by the plough: the crop, of course, comes up in drills, and this method is considered to prevent the wheat losing plant on wet and loose soils. It is well known that wheat should be sown when the land is 'clung,' and it is considered better to wait and have a late season of sowing than to put it in when the soil is in a dusty state; which, upon some land, causes the wheat to become root-fallen, and upon soils of a closer texture, where this does not occur, the wheat seldom flourishes so well as when put in after rain. The land is never too wet for sowing wheat, provided it works at all kindly, and the seed can be effectually covered. There are, however, some soils of a peculiar mixture of sand and clay, which, if stirred when very wet, will run together, and afterwards in dry weather form a hard crust, which of course checks the growth of the plant. The best period for sowing wheat on cold clayey soils is from the last week in September to the middle of October, as it seldom becomes winter-proud upon such land. Many think that water-furrowing may be entirely dispensed with where the land has been thoroughly under-drained; but this opinion is not borne out upon very heavy tenacious clays. I have observed that upon such soils the surface-water has not gone off sufficiently quick without it.

"When this or any other kind of land has been previously got into a high state of cultivation, it is frequently cleaned and made ready in the autumn for dunging in the spring, and then sown with turnips or mangold, which are usually carried off in the autumn and the land sown with wheat. But sometimes the roots cannot be removed till late in the season; the time of sowing is then sometimes delayed till January or February, when spring-wheat is generally sown. Upon ordinary heavy soils that have a dry subsoil and do not require draining, white turnips, grown upon the fallows and fed off with sheep during the months of October and November, are an excellent preparation for wheat. When this plan is adopted, wheat is generally grown three times in a double four-course system of 8 years, namely—1st year, fallow for turnips; 2d year, wheat; 3rd year, beans or pease; 4th year, wheat: the next round being—5th year, fallow for swedes; 6th year, barley; 7th, clover; 8th, wheat. Upon some soils a heavier and better sample is produced after turnips than by any other preparation. Wheat is often sown after beans. In this case dung should be applied for the beans, which if kept clean will be a good preparation for wheat. This is preferable to dunging immediately for wheat, which often occasions blight; but, by having an intermediate crop of beans, blight is generally prevented, and better crops, both of wheat and beans, are produced. If farm-yard dung cannot be obtained for the beans, rape-cake drilled in at the time of sowing the wheat, at the rate of from 8 to 16 bushels per acre, will generally be found sufficient to produce a crop. On the heavy clay lands of Norfolk and Suffolk, barley has taken the place of wheat after fallow, and the wheat either follows clover or beans and pease; the rotation commonly adopted being—

1st year, fallow; 2nd, barley; 3rd, half clover, half beans or pease; 4th, wheat. The dung is applied to the pulse by the best farmers, and the crop is well hand or horse hoed. Wheat is drilled after beans, though hand-dibbled by many after clover. Farm-yard manure is used heavily on clover-layers, either on the young seeds during winter, or a short time before ploughing the land for wheat. The former method is preferred by many, because the clover has the benefit of the dung, and the wheat comes 'kindlier.' This system of exposing the manure to the atmosphere will appear to tell against the generally-approved method of ploughing it in: at the same time, admitting that much of its virtue evaporates into the air, yet the clover absorbs a portion of that part of the manure which suits its growth, leaving such properties to be taken up by the wheat which are peculiarly beneficial to it. The system of growing grain-crops on the retentive clayey soils of the eastern counties, is one that might be followed with some advantage on much of our heavy wet land, particularly that which is ploughed in 'high-backed' lands. In travelling through a heavy land district, how often do we see these wide and round lands laid up to an enormous height by repeated ploughings in one direction, under the fallacious idea of draining the land; but how seldom does it answer the intended purpose; though it has this advantage, that the crop in the furrow bears no proportion to that on the ridge. There is also great injury sustained in the cultivation of the land, particularly in the operations of drilling or sowing the wheat-crop; for there is not only the inconvenience, which arises from the rounded form of the land, in carting and tillage, but there is also a very great amount of injury from the treading of retentive land. This is in a great measure prevented by the system of clay-farming more particularly adopted in the eastern counties, Norfolk and Suffolk, which are the acknowledged seat of the origin of drill-husbandry. In those counties we see the width of lands or 'stitches,' as they are termed, adapted to the size of the drill, either for one stroke or for a bout of the machine; and the horses, in drilling, harrowing, rolling, and other tillage operations, invariably walk in the furrows without trampling the soil.

"Upon most of the light chalky or gravelly soils, wheat generally succeeds clover or trefoil; but in cases where the plant of clover fails, early pease are occasionally substituted; and as soon as the pease are removed, the land is sown with either cole-seed, white mustard, or tares, which are fed off with sheep, as a preparation for wheat, and generally succeeds perfectly well. The clover or trefoil is ploughed flat and shallow, the land rolled with a heavy roller. The grooved drill-roller and Crosskill's clod-crusher are both excellent implements for this purpose, though the drill-roller can be used when the land is too moist for the clod-crusher to make effective work, and it raises a greater quantity of mould for the drill. Rolling after the seed is sown, treading or folding with sheep, are means adopted for the purpose of consolidating the soil, and by that means preventing the plant being thrown out, and also for stopping the ravages of the wire-worm. The process of claying light sandy or gravelly soils is essential for the production of a good crop of wheat; it supplies materials that are wanting in the soil, improves its mechanical texture by making it more adhesive and less liable to be acted upon by continued drought. It is commonly found that a greater quantity of seed per acre is used on the light soils than on any other kind of soil. The end of October is considered the best time of sowing.

"Upon rich, deep, dry, loamy soils, wheat is successfully cultivated after potatoes, the potatoes being removed at the latest in October. It is no uncommon thing on some tracts of land—such as are extensively found in the neighbourhood of East Ham, Barking, Romford, Edmonton, Enfield, and other places—to grow wheat and potatoes alternately for many years together. But in order to carry on this system successfully, dung must be liberally used for the potatoes; no dressing beyond this is required for the wheat; the potatoes yielding from 300 to 500 bushels per acre, and the wheat from 30 to 40 bushels. Of course, as above hinted, to carry on this kind of farming, manure must be made rich and applied abundantly, or be obtained plentifully from large towns. Upon this description of land, 4 pecks of seed are amply sufficient; and it should never be sown till the end of October or the beginning of November; if at all earlier, it becomes winter-proud and produces too much straw. I have witnessed the large yield of full 50 bushels per acre throughout a field of 37 acres in the parish of East Ham, in Essex, where the seed was not sown till the middle of December, after a full crop of potatoes. Upon other strong yet rich loams, containing a larger proportion of clay, wheat and beans are successfully cultivated alternately. The beans, being kept perfectly clean, frequently supersede the labour of ploughing for wheat; in which case the land is harrowed previously to drilling or dibbling the wheat.

"Peat-soils are of so loose a texture that they require to be rendered as solid as possible by a good drainage—for peat holds water like a sponge, and when the water is carried off it contracts in a similar manner—by the admixture of clay or other inorganic substances, and by rolling and pressing before and after planting, to insure a medium quality of grain. As these improvements go on in the fens of Lincolnshire, Cambridgeshire, &c., &c. the quality of grain brought to market approaches nearer to that grown on sandy and loamy soils, while the quantity greatly exceeds the corn grown on light sands or gravels. The fen-farmers have one advantage with respect to the growth of a good

quality of grain, which is the absence of hedges and hedge-row trees. A preparation which appears adapted for peat-soils is to plough the land shallow, drill-roll, and hand-dibble the seed in the grooves formed by the roller, and then cover the seed with the harrow. The solidity given to the soil by this method is what is absolutely necessary on the spongy peat-soils. The rolling, and treading, and depth at which the seed is deposited prevent the plants being thrown out by alternate frosts and thaws; and, giving the root a good hold of the soil, in some measure prevent also the crops being lodged or becoming root-fallen. With respect to dibbling, we may observe, that it is acknowledged to be the means of obtaining a stiffer straw; and hence the propriety of hand-dibbling at a cost of 7s. or 8s. per acre on a loose peat.—On freshly broken-up grass-land, oats are preferred to wheat; though, after the surplus vegetable matter of the soil has been reduced by burning, tillage, and the mechanical application of suitable earthy matter, wheat can be grown of good quality. Of course these remarks on fresh broken-up land are general, though not applicable to every case.—It is an acknowledged fact, applicable to every description of soil, that the land prepared for wheat cannot be too stale or solid, provided it be free from weeds, and the surface sufficiently mouldy to cover the seed.

"If a sufficiency of farm-yard manure could be obtained, there would be little necessity for any other, inasmuch as it contains all the ingredients requisite for producing every kind of crop. But let it be understood that the dung should be composed of the excrements of animals well fed under cover. It has been before observed, that when dung is to be applied in liberal quantities for the benefit of wheat, it should, if practicable, be put on the land previous to sowing a preceding root or pulse crop; for thus those ingredients of the dung, which only tend in their first effect upon the land to force an over-abundant growth of straw, will have been extracted, leaving the land in a good state for wheat. Where root or pulse crops are not grown, the dung should be applied to naked fallows for wheat as early in the summer as possible. Though the practice of manuring immediately before sowing the wheat is objectionable, it is still adhered to in many parts of the country. A compost of earth and dung is highly beneficial on light chalky and silicious soils. Four or five loads per acre of farm-yard manure and half a folding with sheep are a good manure for wheat, and frequently adopted by the farmers of the midland counties. A very large proportion of land is manured for wheat by means of the sheep-fold alone, especially upon dry soils, where great benefit is derived by its solidifying the ground; it has also a tendency to kill the slugs and other destructive insects, or at least to put a stop to their ravages. Folding upon fallows is likewise adopted with advantage; upon loose light soils, folding after the wheat is sown is of advantage. Some farmers adopt the plan of ploughing green crops in; but others consider it a better plan to convert all green crops into animal manures, by feeding off with sheep or by soiling. Pigeons' and hen-house dung are frequently used as a top-dressing for wheat, and are almost sure to be beneficial on any soil. From 30 to 40 bushels are used per acre. Like all other light manures, it is best covered by means of harrowing or hoeing, or it may be drilled between the rows. Soot is much used as a top-dressing for wheat, and is commonly found very beneficial. From 40 to 60 bushels per acre are generally applied. It has a tendency to increase the quantity and improve the quality of the wheat, without forcing an undue quantity of straw. It should be sown in February or March at the latest. It is however frequently sown as late as the month of May; but if a dry summer follows, it is in that case of little or no value. As ammonia is the principal ingredient of this manure, it should be covered by means of the hoe or harrow, being liable to waste by evaporation; and, as it is a very light substance, calm and showery weather must be chosen for applying it. This manure is found to be peculiarly suited to the county of Hertford, and consequently a very large proportion of the soot made in the metropolis comes into this county. It has been used in Essex, Kent, Middlesex, and other counties, but in most cases without general beneficial results. Rape-cake is a valuable manure for wheat. It may be applied at the time of sowing the seed, or drilled between the rows in the spring. From 8 to 16 bushels per acre are generally found sufficient. It is best adapted to ordinary heavy soils that are well drained, or have a dry subsoil. Malt-dust, to the extent of from 30 to 50 bushels per acre, is occasionally used as a top-dressing for wheat. Bones may be applied with much advantage upon dry soils previous to sowing the wheat, at the rate of from 16 to 30 bushels per acre. Guano, at the rate of from 2 to 3 cwt. per acre, is sometimes advantageously used at the time of sowing the wheat. This manure is found most beneficial on poor loamy soils. The nitrates of soda or of potash are occasionally used at the rate of from 1 to 3 cwt. per acre, and applied broadcast in March or April. Chemical analysis has proved that wheat always contains a much larger proportion of potash than of soda; hence we may suppose that nitrate of potash is the best of the two: it is, however, the most expensive. As to the application of nitrate of soda to wheat when it has a yellow or sickly appearance in the spring, if finely pulverized, and sown in moist weather, it will in a few days alter the sickly hue to a luxuriant green. As it increases the quantity of straw, it is best suited to poor loams and gravelly soils. Common salt is sometimes applied before sowing the seed, at the rate of from 10 to 21 bushels per

acre, and is often beneficial in bringing the ears to perfection: it also causes a greater weight of grain, but seldom increases the quantity of straw. These are the principal manures that have been proved to be useful for wheat. There are many others; but even a bare enumeration would occupy too much space.

"More wheat is now produced per acre, by greater attention being paid in choosing the most prolific kinds. It should, however, be borne in mind that the most prolific are also very frequently of a coarse quality, and commonly lose in price what they gain in quantity. At the same time it is admitted by those who have put the question to a test, that the most productive are often the most advantageous to the grower. Instances, indeed, have occasionally occurred where heavy white wheat of the finest quality has been tried by the side of a coarser description, and has equalled it in quantity; but this must be considered an exception to the rule, and not the rule itself. On rich soils, where an abundance of straw is produced, short and stiff-strawed wheat yields the best crop, as the weak and long-strawed wheat is liable to be spoiled by being laid. Such varieties as Spalding's prolific and Piper's thickset are suitable for rich land. On very productive wheat-land in Norfolk, Piper's thickset produced such abundant crops, that on its introduction into that county it at once obtained the name of Protection wheat. On the contrary, short-strawed wheats like Piper's thickset are very inferior to long strawed wheat on land that yields a light crop. Mixed wheat (red and white) is sown in some parts of the country, care being taken to select two sorts that ripen at the same time. The advantages to be derived from a change of seed from a hot to a cold soil, and *vice versa*, have already been mentioned. Plants removed from one climate to another will in some measure continue in the same habit of growth. Thus seed brought from a warm country will produce an early crop, though it will be inferior in hardihood to plants grown from seed brought from a cold climate; and it will be found, that, whilst the latter improves by cultivation, the former deteriorates." See the articles Fallow, Rotation of Crops, and Manure.

The Sowing of Wheat.—The great amount of waste which usually occurs in the sown seeds of wheat, as well as in those of other grains, is noticed in the article Agricultural Seeds; the steeping of seed-wheat as a preventive of disease is noticed in the article Smut; the doctoring of seed-wheat, as well as the seeds of other farm crops, with the view of promoting fertility, is noticed in the article Seed; the comparative advantages of the thick and the thin sowing of seed-wheat, together with the proper conditions and covering of the soil in the deposition of the seed, are noticed in the article Sowing; the comparative advantages of the broadcast and the drill methods of sowing are noticed in the article Drill-Husbandry; and the process and properties of the dibble-sowing of wheat are noticed in the article Dibbling.

Wheat seed possesses in a very high degree the extraordinary faculty of being able to re-germinate after having been desiccated subsequently to its first germination. A specimen of wheat which had germinated was subjected by Saussure to a very powerful desiccation aided by the most energetic means which chemistry could supply, and at a temperature of even 158° Fahrenheit; yet it germinated again, even after an interval of several months. Wheat is also capable of resisting several successive alternations of desiccation and germination. If, in its first germination, the radicles have made a certain progress, no further development takes place in the second germination, but other radicles are formed. This valuable property of wheat accounts for the circumstance of its remaining several months in the ground, in dry seasons, before making its appearance; and the surprising vitality which it evinces has been exemplified in the wonderful fact that some wheat seed found among the cerements of Egyptian mummies, and therefore far upwards of two thousand years old, has germinated on being committed to the soil. A wise farmer, however, will not trust too much to the mere vigorous vitality of any seed-wheat for his crops, but will use all care that every specimen be perfectly sound and fresh, and will look only to the first germination of wheat-plants as likely to portend a productive and seasonable ripening.

Seed wheat ought always to be of the best quality which can be obtained; and, where choice is limited, a perfectly sound and fresh specimen of a second-rate variety ought to be preferred to a damaged or doubtful specimen of a first-rate one. A seemingly prime specimen, indeed, will sometimes produce an inferior crop, while a seemingly poor specimen will produce a good crop; but such a result must be ascribed to soil and season or other favourable circumstances, and may be supposed to arise in defiance of the peculiar condition of the seed; for just, as all other things being equal, the best sample of grain will produce the best flour, so the best specimen of seed-corn will produce the best crop. And in fact the well known rules for judging the comparative value of wheat grain for the miller apply very closely to the judging of its fitness for the sower. "It should be retained a minute or two in the closed hand, and then passed gently through it, to ascertain if the grain be plump, hard, dry, and smooth, with a certain sense of mellow fulness in the feel; for, if it handles rough, and does not slip readily through the fingers, it will be found thick skinned, damp, and unprofitable to the miller. Of whatever species it may be, it should also be carefully examined, to see that it be of a bright and healthy appearance, the grains of nearly equal size, and unmixed with the seeds of weeds and smutty or sprouted

corn. The smell should likewise be noted; for the least taint of its sweetness is a sure sign of its having been either damp or heated. The weight can be guessed within a pound or two in the bushel, by being poised in the hand by any one accustomed to examine samples; but accuracy of judgment can only be attained by long experience. The quality of any one species can thus be correctly estimated by any one who is in the habit of attending a corn-market; but large quantities are imported from abroad, and also made up for sale by the dealers of this country in a mixed state. The white wheat from the Baltic is generally mixed with red wheat, and is known in our markets under the denomination of 'good,' and 'fine-high mixed,' 'red-mixed,' and some more ordinary qualities,—the first weighing from 61 to 64 lbs.,—and the latter from 56 to 58 lbs. per bushel, running in the proportions of one-third white to two-thirds red; and the price varying from 10s. to 15s. per quarter less than the superior articles, in proportion to the quantity of red. This mixture, however, although not rejected by the millers—who frequently find the use of a portion of it indispensably necessary to the grinding of the new corn—yet renders it unfit for the use of the farmer as seed; for the different qualities could neither be advantageously grown on the same land, nor would they ripen at the same time. The wheat which is shipped in large quantities from Odessa, on the Black Sea, and which in scarce years sometimes finds its way to this country, it would be also dangerous to use as seed, for the length of the voyage generally occasions it to become heated." [British Husbandry.]

The proper quantity of seed will in a degree be determined by each farmer's theory of the comparative advantages of thick and thin sowing; but, irrespective of this, is powerfully controlled by the nature of the variety, the time of sowing, the nature of the soil, the stage of the rotation, the amount of apprehended accidents, the manner of sowing, whether broadcast, drilled, or dibbled, and a number of other considerations. Any spring wheat tillers worse than a corresponding kind of winter wheat, and, on that account, requires from one-half to three-fourths of a bushel more of seed per acre; and any kind of winter wheat when sown early requires less seed than when sown late,—and, when sown after summer fallow, requires less than when sown after potatoes,—and when sown after potatoes, requires less than when sown upon newly broken up grass land. "The nature and condition of the soil," remarks Mr. Roberts, "the variety of wheat, and the quantity of vermin that consume the grain before or after it vegetates,—all have some effect on the quantity of seed required. The poorer the land, the more plentiful must be the seed. On a poor gravelly soil, where an abundance of manure is not attainable, 10 pecks are requisite, drilled at from 6 to 8 inches; and we find, from observation of both wet and dry seasons, that when this quantity is at all sensibly decreased, or the intervals between the drills increased to a material extent, the crops suffer a diminution both in quantity and quality. When the land is good, very little seed is required, for it always branches out in the spring; but on poor land, when sown late, many of the plants die, at the same time that others on good land are preparing for numerous branches. Nothing definite, therefore, can be named as to the proper quantity to be sown. Upon the broadcast system, where 2½ bushels per acre are sown, it is generally allowed that, if drilled, 2 bushels would be equivalent, and if dibbled 5 pecks. As an instance of the effect of time I may mention that upon a poor heavy soil, if we commence in September with 2 bushels, by the middle of October we increase it to 2½ bushels per acre. It has been repeatedly proved that upon land of the best quality, and in high cultivation, if dibbled and put in perfectly regular, 4 pecks of seed per acre are better than more, inasmuch as it leaves a roomy and healthy space between the plants, encourages branching, and produces stiffer straw, with plumper ears, than when sown thicker, and upon the whole gives the most certain and fullest production that the land is capable of. Thickly-sown wheat on rich land grows much weaker straw, smaller ears, and is liable to fall down long before the usual time for coming to perfection. We have heard of transplanting wheat, and I can assign no good reason why it should not be more generally adopted. It is true it would be a somewhat tedious operation to plant many acres in this way; but when it is considered what a small portion of seed would be required, it might repay the farmer for his trouble and expenditure."

The time of sowing wheat is controlled by the state of the weather, the stage of the rotation, the quality of the soil, the character of the climate, and the nature and adaptations of the varieties of the plant. After summer fallow, in favourable weather and on suitable soils, winter wheat may be sown in Scotland as early as the beginning of September, and in the centre and south of England as early as the 20th of September; and either in the event of unfavourable weather after summer fallow, or in other circumstances of rotation and soil, it may be sown in Scotland at any time till the middle of November, and in the centre and south of England at any time till the last week of November. On very strong clays or cold soils, the sowing ought to be at the very earliest eligible period, and ought not if possible to be delayed later than about the middle of October in Scotland, or the end of that month in the centre and south of England; for such soils, when thoroughly drenched with moisture in autumn, are seldom in a proper state for harrowing till spring,—and wheat sown upon them in good condition in September, will take

a firm and deep hold of the ground before frost commences, and will escape all danger of becoming 'winter-proud,' and will be less liable to mildew, and ripen about a fortnight or so earlier, and afford correspondingly greater advantages of harvesting, than if they were sown four or five weeks later. On warmer soils, particularly good dry gravelly loams, in hearty and well-prepared condition after clover, the sowing ought not to be earlier in Scotland than about the middle of October, or in the centre and south of England than about the end of that month, and, if weather and other circumstances permit, may prove most successful in the second week of November in Scotland, and in the last week of November in the centre and south of England; for if the sowing on such soils be earlier than the former of these periods, the plants get too forward, and do not mat on the ground, and become weak, and spindle into long slender stems, and frequently lose their healthy appearance in spring. On the best kinds of these soils, indeed, the sowing of winter wheat, even in Scotland, may sometimes be advantageously done in spring; and on all of them, in some of the central and southern parts of England, this date of sowing has come to be systematically preferred by a few intelligent agriculturists to autumn or winter sowing. "So satisfied have I been for several years past," said Mr. George Webb Hall in 1842, "of the advantage of taking the spring for depositing wheat in the earth, upon certain soils and regulations, that on such I have abandoned autumn sowing entirely. The soils and situations to which I refer are—the silicious soils, the turnip and barley soils of agriculture, and, in fact, including all the land of our country which is not comprehended under the description of clay or very tenacious loam. It will be prudent to limit so extensive a range by two other principles—first, climate, varying as it does with aspect; and secondly, the condition of the land with regard to fertility, and the result of manure and good tillage, fitting it to bear a crop of wheat at all. Under these limitations, and they are not very exclusive, I am prepared to recommend the spring sowing of winter wheat in any season over a considerable portion of such land. The period of sowing is generally the last week of February or the first week in March, and the interval until harvest is about 25 weeks, as the season may be forward or otherwise. The produce in this time has been 40 bushels per acre, upon a light sandy loam, but in condition certainly for its duty. The sort has been generally the white Lammas or Taunton white; but it has not been limited to that sort; Essex white wheat has been sown with equal success, and similar progress as to time. The elevation at which it has been sown has not been limited; for I sowed it last year about 400 feet above the level of the sea; and a friend of mine, a highly respected and veteran improver of agriculture, George Tollett, Esq., of Beatley Hall, Staffordshire, tried it to his complete satisfaction in the unpropitious year, 1839. The chief cautions I would recommend are—first, selection of seed from good conditioned land, and a warm soil and situation; secondly, rather thick sowing, as a security for adequate plant and prevention of mildew, by obviating predisposition to it." The sowing of spring wheat after eaten-off turnips in Scotland, may be done at any time between the first of February and the middle of March, and has occasionally been done with tolerable success so late as the first or second week of April, but, when done after the second week of March, entails a risk of imperfect ripening and precarious harvesting; and the sowing of spring wheat in the centre and south of England may occasionally be done as early as in Scotland or so late as the beginning of May; but is generally most successful about the middle of April, in consequence of its then combining the advantages of escaping liability to white frosts and ensuring the greatest probability of gentle showers for the promotion of vegetation.

The operation of sowing wheat is so well understood by almost all farmers, and has been so fully explained, in its several accompaniments and methods, in the articles Sowing, Sowing-Machines, Broadcast Sowing, Drill-Husbandry and Dibbling, and in some parts of the preceding section of the present article, that nothing requires to be said here respecting it. The depth at which the seed is deposited in the broadcast method and in some of the ordinary practices of the drill method, varies in every part of the same field from less than one-fourth of an inch to upwards of two inches; and if we consider how very vigorously shaken wheat vegetates in the following year among sown grasses in spite of its being not at all covered by the soil, this variableness in the depth of the deposition might seem to be very little injurious, and really is far less so than most views of the case would lead us to suppose; yet, in every instance, a variable depth is apt to produce a variable vigour, or less depth than about two inches does not afford sufficient protection from the long beaks of rooks, and any depth which might be quite great enough on heavy wet clays may be much too small for friable loams, and especially for very light porous soils. A uniform depth in every case is desirable; and where 2¼ or 2½ inches would be suitable for stiff clays, 4 inches might be required by dry and porous loams. "For security against a severe winter," says Mr. Hillyard, "wheat seed should be deeply drilled in. Frost cannot kill the blades of wheat, if the roots are secured under a good covering of mould. There were great complaints in the spring of 1838, that a great portion of the wheat crops were at that time very thin of plant, and that many fields had been ploughed up. Mine were

never finer; and I feel satisfied that had other persons' seed been drilled in 4 inches deep like mine, there would not have been such complaints of loss of plant. I, then, could show proof for my assertion. In one of the bouts of the drill, in consequence of seed enough not being put into the machine, for 40 yards no seed had been deposited. On this being discovered, drills were made with a hand-hoe, and corn put in. This, which was put in about 2 inches deep, came up much sooner than the other put in 4 inches deep, and looked best till Christmas; but, from the frost getting to the roots of it during the severe weather we then had, every root went off in the spring."

The consolidating of porous soils immediately after sowing them with wheat is highly advantageous, both for giving the plantlets a firm root-hold and for preventing or diminishing the devastations of the wire-worm. "On light soils, in my opinion," says Mr. Hillyard, "there is no way so good for putting in seed wheat as with the presser; and as it is not possible to make such soils too solid for wheat, it would be well, should the weather be favourable, to roll after the seeding, and afterwards drive a flock of sheep several times over the land. It has often been said that growing wheat is not injured by a field of fox-hunters riding over it, and even produces more grain in consequence. On light soils it does not do the injury that might be expected from appearance, but on strong land it does great harm, for in all the holes formed by the horses' feet, and particularly if going down hill, water will stand, and the plants in these holes will die. But immediately after sowing, the trampling of horses does good. A late friend of mine in the Blues, who occupied a farm of light soil near Windsor, found it to be a great benefit to his wheat crops to have his troop walked up and down them, not galloped, immediately after sowing."

The After-Culture of Wheat.—A very thin or very sickly crop of autumn-sown or winter-sown wheat should not be too hastily broken up in spring; for after a few days of warm weather, it may suddenly revive, and may acquire vast increase of strength and fulness from luxuriant tillering; or, if it exhibit breaks and patches, it may be facilely and completely mended by inter-dibblings of some variety of spring wheat which may ripen nearly at the same time as the main crop, and may furnish a closely similar sample of grain. The after-culture of all tolerably healthy crops is directed mainly to the prevention of out-throwing by frost, of devastation by the wire-worm, of impoverishment by weeds, and of lodging and running to straw from excessive luxuriance; and it requires to be much more assiduous after a preparatory crop than after a summer fallow, and very much more so on any kind of loose or light soil than on a firm and cohesive one; and, in all its chief features, it is well described in the following succinct terms by Mr. Roberts:—"Pressing in the spring during dry weather, and before the wheat becomes too forward, is generally productive of good, though especially required on soils that are naturally loose and light in their texture, and on those soils which require draining; for where water saturates the surface soil, it becomes increased in bulk during winter by its conversion into ice in frost, which, of course, raises the soil, and when the frost goes away the plants are partially thrown out. This is accounted for thus:—The frost causes the ground to swell, and, as it rises, the root of course rises with it; when it thaws, the ground shrinks, but the root remains in its elevated position, and, by the action of alternate frosts and thaws, is at last thrown entirely aboveground. This must occur to the greatest extent on soils containing superfluous moisture, though it will occur on any soil, particularly those of a calcareous nature, when frost happens to follow immediately after rain. Therefore, when the soil treads loose in the spring, it is very important to use the heavy roller, or some other means of consolidating the soil. Crosskill's clod-crusher is highly beneficial for this purpose, but can only be used in very dry weather. Treading with sheep is also an effectual way of fastening the roots. On the loose soil of the fens the wheat is trodden by gangs of men and women, each treading along one drill; by this means the soil is consolidated effectually: it is not an expensive operation, and on the loose vegetable soil of the fens is more efficacious than rolling. The feeding off wheat with sheep in the early part of the spring, when likely to run to too much straw, is useful on rich soils. If the land be foul when the seed has been sown broadcast, it must be cleaned by hand-hoeing; but, if drilled or dibbled, the horse-hoe may be successfully used. In many places the practice is to hoe wheat, whether foul or not. As a general rule, hoeing should be begun as early in the spring as the weather permits. Harrowing is occasionally found beneficial, particularly when the ground is crusty and the root lies deep in the ground: it has the effect of loosening the surface, and, whether that be done by the hoe or harrow, an improvement will be seen in a few days by the fresh vigour of the plants. Harrowing light sands and gravelly soils obliquely across, or at right angles to the drills, is peculiarly advantageous, as it destroys the red-weed or poppy and other annuals that infest light land. For the destruction of the poppy it is recommended to harrow when the soil is slightly crusted with frost. When, from the extreme luxuriance of the crop in the spring, there appears a probability of its being laid, the process of flagging is resorted to as a preventive. Flagging is executed by means of the bagging-hook or scythe, separating the flag or blade from the stalk. This should be done about May, before the formation

of the ear; and in doing it the stalks will require examination, that the ears may not be cut off." Harrowing, however, ought to be done with caution, whether upon stiff hidebound soils for fear of predisposing the crop to mildew and tearing up the roots of the plants, or upon light and porous soils for fear of rendering them too open and of lacerating the crop; and it should be performed in every case with a due adaptation of the weight and action of the harrow to the amount of effect intended to be produced; and, whenever the cultivation of the wheat crop is combined with the raising of clover and grass seeds, most or all of the spring-culture of the young wheat must serve at the same time for the sowing of the grasses.

Wheat is an excellent nurse to a crop of clover and ryegrass, for its foliage is small and of comparatively short duration, and falls down almost as soon as it has attained full size, leaving the infant clover and ryegrass ample aeration to assist their growth. Spring wheat is often used for this purpose in England; and autumn or winter sown wheat is suitable for it in both England and Scotland. When spring wheat is used, the grass-seeds are sown simultaneously with it in the same way as with barley; and when winter wheat is used, the grass seeds are sown among the young wheat plants as early as convenient in April. The clover and grass seeds, preparatorily to their being sown, are mixed carefully together, and brought to the ground in sacks; the wheat-land, if open and clean on the surface, requires no preparation for them, but if foul or hidebound, may be scratched with either the harrows, the horse-hoe, or the hand-hoe, according as it is broadcast sown or drilled, or as it needs much action or little; the grass seeds may be sown either by hand or with the broadcast sowing-machine; and if the surface be loose, a rolling alone may be given to cover them in,—or if the surface be crusty and hard, or in any of the conditions which require decided after-culture for the wheat, either a double turn of the harrows may be given along the ridges and a turn of the roller across them, or any other amount of similar operations may be performed to suit the peculiar circumstances of the crop and the soil; and after these operations have been done, no further culture can be given to the wheat except to hand-pull any large weeds which may appear during the progress of its growth.

Excessive luxuriance of autumn sown wheat crops in spring, arising from unusual forwardness of vegetation during winter, and popularly designated by farmers 'winter-proud,' is a greater evil and requires nicer management than the brief remarks of Mr. Roberts upon it, in the passage quoted in a previous paragraph, might lead one to suppose; and in particular, it occasions a premature exhaustion of the vigour of the plants, causes them to mount speedily up into a great mass of straw, and divests them of power to produce a fair proportion of grain. "From the greater height to which the straw thus rises, and as well the weakness of its stems, the crop is also more in danger of being lodged by storms, and is found to be generally more liable to mildew. It is, therefore, in such cases, very commonly eaten down by sheep; or, by some farmers, it is occasionally, though very rarely, mown. The progress of vegetation is thus checked, and the apparent danger is avoided; but it requires great circumspection and practical experience to ascertain when it may be proper to adopt it; for although the temperature of the season may have pushed the plants too forward, yet a change may immediately take place, and their having been thus weakened, will throw them too much back. If the plants tiller with such strength as to grow in thick tufts which cross each other or that they appear likely to become lodged, then it may be safely adopted; otherwise, it is better to leave the crop to its chance, without meddling with it, and in no case should it be attempted unless the vegetation be extremely rank. The practice of feeding, though by far the most general, has yet been objected to, because the sheep prefer the tender blade in the heart of the plant, which ought to be preserved, and reject the coarse blades which ought to be taken off; but if adopted, such a number should be put upon the ground at once, as will eat the wheat down to the required distance promptly, and when removed, they should not be again returned to the land. If mown, the work should be very carefully performed, at such a distance from the surface of the land as not to touch the heart of the plants."

The Harvesting of Wheat.—The ripening of the grain of wheat must not be judged by the ripening or mellowing of the straw. In some circumstances, the root and the ear seem ripe, while most of the straw is still greenish or succulent; and in others, the straw, from the root upwards, loses its succulency, turns yellow, and gives the whole plant the appearance of ripeness, while the grain in the ear is still soft or almost pulpy; and only in cases of entire and uniform healthiness in the crop, and of steadiness and general favourableness in the season do all the parts of the plant arrive with perfect simultaneousness toward maturity. Some farmers contend that a crop which has become dead at the root while it still continues soft or pulpy in the grain, should be allowed to stand for some time enjoying the effects of air and sunshine before it be cut down; and others regard it as so completely defunct from all possibility of further nourishment or benefit that it ought not to stand another day; and both may be either right or wrong,—that is, right in one year and wrong in another,—according to the nature of the weather. All wheat, except such as is grown mainly or largely for sake of its straw, ought to be judged as to readiness for reaping solely by the grain; and this is always in a state of the highest fitness for the

purposes of the miller and the baker, and therefore in a state of truest ripeness, when in the medium stage between softness and solidity which farmers technically call "raw." If the grain be quite pulpy or too green, it shrivels in drying, and suffers loss in both quantity and quality; and if it be quite solid or too ripe, it exchanges a considerable portion of its nutritious principles for innutritious ones, and is also liable to be shaken out by the wind and to shed in reaping. Many rules have been proposed for enabling farmers to decide as to the precise moment when their wheat may be most profitably cut; but some overlook casual and important differences which occur in different crops and seasons, many proceed on false views of the true nature of ripeness, and most are empirical and allow the crops to stand too long uncut; and incomparably the best rule which has ever yet been proposed is to cut wheat when the grain is in the state called "raw," or in medium condition between pulpiness and solidity, or, as nearly as can be conjectured, about 14 days before it would become what is popularly termed ripe. This rule leads to a great saving in the produce above what would result from the ordinary practice, and is therefore of vast consequence to the interests of farmers and of the whole population; and it was worked out and proved, by Mr. Hannam of North Deighton in Yorkshire, in a course of masterly experiments and reasonings, which we must here detail at considerable length and in his own words.

"Having selected a field of old square-headed red wheat for the experiments," says Mr. Hannam, "on August 4, 1840, I cut a sheaf. At this time it was quite green, that is, both straw and ears were in full vigour and full of sap. Though the grain appeared perfectly formed, the chaff still adhered so firmly to it that it was scarcely possible to separate them by friction in the hands. When separated, it was large and plump, but so full of milk that the slightest pressure reduced the whole to a juicy consistency of pulp. This sheaf stood in the field for a fortnight, when it was housed. On the same day, August 18, I cut another. The wheat was of course yet 'green,' speaking positively, or 'not ripe,' if we speak negatively,—being what farmers commonly term 'raw,' that is, the straw, though appearing at a distance green, when examined closely was of a hue fast approximating to yellow, while, for about a foot upwards from the ground, it was quite yellow. The ears, too, were more open, the chaff tinged with various shades of yellow and green, and the grain itself, when separated, soft and pulpy, but not near so full of fluid as before. The judgment of the farmer will, however, best tell him the conditions of the wheat, both at this and the preceding cutting, when I say, that in another fortnight the whole field was ripe. At the end of this fortnight (September 1,) I housed the sheaf cut on August 18, and which had remained exposed to the weather in the interval, and cut a third. This I have said was 'ripe;' but by the term I don't mean that degree of ripeness when the straw breaks, the ears curl, and the grain shakes out, but that condition in which it is customary to commence reaping it,—when the straw, from the roots to the ear, is uniformly yellow, and has lost all symptoms of vivid health. On the 14th of September the third sheaf was taken from the field and carefully preserved, along with the other two, till the 1st of November, when, out of each sheaf, I selected 100 ears, and put each parcel into a separate bag. The straw from each of these parcels of ears was preserved carefully. The ears in one bag (No. 1, or that cut very green) were now thrashed, the chaff carefully separated, and the gross weight of the corn yielded ascertained by an extremely accurate balance. The weights of a fixed measure of a certain number of grains were next found: to avoid error, this was repeated several times. No. 2. (cut raw) and No. 3. (ripe) underwent the same process: for the results of which see the following table.

Comparative Weights of *Wheat* reaped at different periods.

Time of Reaping and Condition.	Gross Produce.	Equal Measure.	Equal Numberof grains.
No. 1. Aug. 4. (very green)	576	568	19¾
No. 2. Aug. 18. (raw) .	736	580	23¼
No. 3. Sept. 1, (ripe) .	650	570	22¾

As this table is merely comparative (the weights used being in parts, and decimal parts of the same, for the convenience of minute experiments,) it may not be unnecessary to give the following table of the absolute weights of each sample in ounces, drams, scruples, and grains Troy:—

	Gross Produce.				Equal Measures.				Equal Number of Grains.			
No.	oz.	dr.	scr.	gr.	oz.	dr.	scr.	gr.	oz.	dr.	scr.	gr.
1.	4	0	0	0	3	7	1	13	0	1	0	5¾
2.	5	0	2	13	4	0	0	13	0	1	0	17½
3.	4	4	0	6	3	7	2	0	0	1	0	15¾

The straw belonging to each sample was now weighed (all the parcels having previously been made of the same length, commencing from the bottom of the ear,) when the following was the result:—

Comparative Weights of 100 *Straws*, of an equal length, belonging to the Samples Nos. 1, 2, 3.

No. 1 (green,) = 550.
No. 2 (raw,) = 475.
No. 3 (ripe,) = 450.

The next thing to be ascertained was the quality of the produce, or the comparative worth of each description. Believing in the old saying, that

> "The proper value of a thing
> Is just as much as it will bring,"

on the 5th of November I attended market and asked the opinion of an extensive corn-grower as to the values of the respective samples, according to the prices of the day. His opinion was,

No. 1, . . . 61s. per quarter.
No. 2, . . . 64s. do.
No. 3, . . . 62s. do.

Putting the same samples into the hands of an extensive corn-factor and miller, his value, and what he would give to buy, was, for

No. 1, . . . 61s. per quarter.
No. 2, . . . 63s. do.
No. 3, . . . 61s. do.

Adding these values respectively together, and taking the mean price of each (by which we shall obtain as near an approximation to the truth as possible,) we have

No. 1, = 61s. 0d. per quarter.
No. 2, = 63s. 6d. do.
No. 3, = 61s. 6d. do.

The loss or gain on these samples, by reaping at different periods, will be best seen from the following

Table of the *Relative Weights* and *Value* of *Wheat* cut August 4, August 18, and September 1; that cut last (or ripe) being taken as the standard, and unity assumed as its value in each column.

No.	Weight of gross produce.	Weight of equal measures.	Weight of an equal number of grains.	Value.	Weight of the straw.
3, Sept. 1, (ripe,)	1	1	1	1	1
2, Aug. (raw,)	$1\frac{43}{325}$	$1\frac{1}{57}$	$1\frac{2}{91}$	$1\frac{4}{123}$	$1\frac{1}{18}$
1, Aug. (green,)	$\frac{288}{325}$	$\frac{284}{285}$	$\frac{70}{91}$	$\frac{122}{123}$	$1\frac{2}{9}$

According to this table, it is evident that the wheat reaped a fortnight before it was ripe has the advantage of the ripe in every point:

1st, In weight of gross produce $\frac{43}{325}$, or $13\frac{1}{5}$ per cent.

2d, Do. equal measures $\frac{1}{57}$, or nearly $\frac{1}{2}$ per cent.

3d, Do. equal number of grains $\frac{2}{91}$, or nearly $2\frac{1}{5}$ per cent.

4th, In quality and value $\frac{4}{123}$, or above $3\frac{1}{4}$ per cent.

5th, In weight of straw $\frac{1}{18}$, or above 5 per cent.

On the other hand that reaped a month before it was ripe, has an advantage of 22 per cent. in weight of straw, compared with the ripe, but in every other point has the disadvantage: Thus,

1st, In weight of gross produce $\frac{37}{325}$, or $11\frac{5}{13}$ per cent.

2d, Do. equal measures $\frac{1}{285}$, or rather more than $\frac{1}{3}$ per cent.

3d, Do. equal number of grains $\frac{2}{91}$, or better than $13\frac{1}{6}$ per cent.

4th, In quality and value $\frac{1}{123}$, rather more than $\frac{4}{5}$ per cent.

It may be here necessary to mention that the sample No. 3 (ripe) was very bold, but rather coarse, feeling rough in the hand; while No. 2 (raw) was quite as bold, but very fine and thin in the skin. No. 3 (green) was also a good and clear sample, but much smaller than either of the other. This will account for the apparently anomalous fact of there being scarcely any difference in the marketable value of the green compared with the 'ripe,' while there is a difference of 13 per cent. in favour of the ripe in weight of equal numbers of grains; for the sample being dry and good, the buyer lost little by this inferiority in the size of grain, as the weights of equal measures were the same,—the difference of $\frac{1}{285}$ scarcely making $\frac{1}{2}$ lb. in the sack.

"Before venturing to draw any deductions from these experiments, let us put their results in a still more practical point of view. Suppose we have three acres of wheat, one of which, reaped when ripe, yields us 30 bushels of corn and one ton of straw; what will be the gross value of the same? And what the value of the other two acres, according to the data furnished by the foregoing experiments, supposing each acre to be exactly equal in crop, and the one reaped a fortnight and the other a month before the ripe? Before answering this, we must fix a value for the straw—say 2d. per stone, which, taking into account that used by the farmer himself—and many cannot sell any—is as much as it is actually worth. Whence we have, for the acre of ripe,

30 bushels of wheat, at 61s. 6d. per quarter (the price of sample No. 3,)	£11	10	$7\frac{1}{2}$
1 ton of straw, at 2d. per stone,	1	6	8
Gross produce,	£12	17	$3\frac{1}{2}$

Let us next take the acre cut 'raw.' Before we can come to its value, we must first resolve the question, How much, in measure, will the acre produce us, supposing it to produce 30 bushels, if cut when ripe? In solving this, as we must assume each crop to be exactly equal if cut at the same time, it is obvious that, if we would determine the difference caused by reaping at an earlier period, we cannot found our calculations upon the gross weight of the two samples (Nos. 2 and 3;) for, although there is no doubt but that this weight was materially affected by the condition of the wheat at the time of reaping (indeed the difference in the weight of equal numbers of grains proves the fact,) it is possible that, in selecting the 100 ears from the sheaf, I might take out of one sheaf ears with a greater number of grains in them than those taken out of the other. This, then, would affect the total or gross weight; and, therefore, it cannot be taken into account in the present case, where both acres are supposed to have an equal number of grains. To the weights of equal measures, and of equal numbers of grains, both the result of many careful trials, this objection cannot be urged; and they are amply sufficient to enable us to tell the produce of an acre of 'raw,' when that of the 'ripe' is 30 bushels. Thus, in the first table, we have

	Weight of equal measures.	Weight of equal numbers of grains.
No. 2 (raw,)	580	23.25
No. 3 (ripe,)	570	22.75

Now put $m =$ this measure, and $n =$ the number of grains weighed of each sort; then

$n : 22.75 :: 1 : \frac{22.75}{n} =$ the weight of one grain of No. 3, whence

$\frac{22.75}{n} : 1 :: 570 : \frac{570\,n}{22.75} =$ the number of grains of No. 3 in the measure m. Again, similarly, $n : 23.25 :: 1 : \frac{23.25}{n}$, weight of one grain of No. 2, and

$\frac{23.25}{n} : 1 :: 580 : \frac{580\,n}{23.25} =$ the number of grains of No. 2 in the measure m. And $m \div \frac{570\,n}{22.75} = \frac{22.75\,m}{570\,n} =$ the space occupied by one grain of No. 3 (ripe); and

$m \div \frac{580\,n}{23.25} = \frac{23.25\,m}{580\,n} =$ the space occupied by one grain of No. 2 (raw.) Now, as there are the same number of grains upon each acre, and as the acre of ripe yields 30 bushels, we have

$\frac{22.75\,m}{570\,n} : \frac{23.25\,m}{580\,n} :: 30$ bushels : 30.1307313 bushels, the produce of one acre cut a fortnight before the ripe. Again, by reference to the second table, we have 1 and $1\frac{1}{18}$ as the relative weights of the straw No. 3 and No. 2; whence as No. 3 is supposed to produce one ton,

$1 : 1\frac{1}{18} :: 160$ stones : $168\frac{8}{9}$ stones, the weight upon the acre reaped when raw. And for the whole produce of the acre, we have

30.1307 bushels of wheat, at 63s. 6d. per quarter,	£11	19	$1\frac{3}{4}$
168 stones of straw at 2d. per stone,	1	8	$1\frac{3}{4}$
	£13	7	$3\frac{1}{2}$

Adopting the same course for the produce of the acre cut first, *i. e.* a month before the ripe, and which corresponds with sample No. 1, we get

$\frac{568\,n}{19.75}$ = the number of grains of the green in the measure m; whence $\frac{19.75\,m}{568\,n}$ = the space occupied by one grain of green.

But (*vide* above,) $\frac{22.75\,m}{570\,n}$ = space by one grain of the ripe; whence $\frac{22.75\,m}{570\,n} : \frac{19\,75}{568\,n} :: 30$ bushels : 26.1356 bushels, the produce of the acre cut a month before the ripe. And (*vide* 'Table of relative weights, &c.)

1 : $1\frac{2}{3}$ :: 160 stones : $195\frac{5}{9}$ stones of straw, the produce of the same; whence we have

26.1356 bushels of wheat, at 61s. per quarter . . .	£9	19	$3\frac{1}{4}$
$195\frac{5}{9}$ stones of straw, at 2d. per stone,	1	12	7
	£11	11	$10\frac{1}{4}$

The total products of the three acres stand thus:

No. 3, Reaped when ripe, . .	£12	17	$3\frac{1}{2}$
No. 2, Do. a fortnight earlier, .	13	7	$3\frac{1}{2}$
No. 1. Do. a month before the ripe,	11	11	$10\frac{1}{4}$

Showing a loss of £1 5s. 5d., or about 10 per cent., by cutting very green; and a gain of 10s. per acre, or nearly 4 per cent., by reaping in a raw state or a fortnight before it was ripe.

"From the above details, it would appear that it is the farmer's interest to cut his wheat before it becomes thoroughly ripe. Many, no doubt, will be disposed to doubt deductions of such importance drawn from such limited experiments. This objection the writer anticipates, because it is a natural one, which he felt himself, when he considered the most important conclusions which resulted. When, however, he retraced, step by step, his investigations, without any variation in that result, he could no longer refuse to believe it true till he proved it untrue. He is aware that there are other points of consideration in this subject—that there are peculiarities in the nature of land, of seed, or of season, and that there is, as in all man's investigations, a possibility of error,—any of which circumstances might materially affect the result of experiments upon so limited a scale as the present one; and for this reason he gave the subject a trial in the ensuing harvest, on a much more comprehensive scale; and not one single operation in that trial, neither reaping, stacking, thrashing, dressing, grinding, nor weighing, was carried on without his immediate superintendence.

"The field of wheat chosen for this experiment was an even average crop, the soil thin limestone, and the seed the old square-headed red,—the same experimented upon before. In order to make the experiment more valuable, and to fix more accurately the golden mean between the too green and the too ripe, I had 20 perches of adjacent furrows reaped at the following periods:—

No. 1,	reaped	August 12th,	stacked	August 26th.
No. 2,	do.	August 19th,	do.	August 31st.
No. 3,	do.	August 26th,	do.	September 5th.
No. 4,	do.	August 30th,	do.	September 9th.
No. 5,	do.	September 9th,	do.	September 16th.

On stacking the various cuttings, I took a sheaf from each parcel, for the purpose of exhibiting a sample of the grain of each at the annual meeting of the Wetherby Agricultural Society, held September 22, 1841. As in my former experiment, the sample of the ripe wheat, No. 5, appeared bold but coarse, while the green, Nos. 1 and 2, were finer in the skin, but smaller in size. The raw cut, No. 3, however, was unexceptionable as a sample; being equal in boldness and fulness of grain to No. 5, and superior to Nos. 1 and 2 in the thinness and uniform clearness of skin. Scarcely any difference was discoverable between 3 and 4; the latter was, however, rather more rough to the touch than the former. This superiority of the raw cut grain was observed and acknowledged by hundreds of practical agriculturists at the meeting alluded to, and was confirmed by the judges, who awarded to me one of the extra premiums, 'with a high commendation of the sample No. 3, reaped a fortnight before the ripe.' On February, 1842, the whole of the various cuttings were thrashed and dressed under my own eye, when the following were the results:—

	Bushels of Wheat.	st.	lbs.		st.	lbs.	
No. 1 gave	$2\frac{3}{4}$ weighing	11	12	and	22	7	of straw.
2 ,,	$2\frac{1}{2}$,,	11	1	,,	21	3	,,
3 ,,	$3\frac{1}{2}$,,	15	10	,,	20	8	,,
4 ,,	$3\frac{11}{16}$,,	16	6	,,	19	2	,,
5 ,,	$3\frac{1}{2}$,,	14	13	,,	18	0	,,

Having in my former trial ascertained the value of the various samples by the opinion of the market, and in this case confirmed it by the public decision of the judges at an agricultural meeting, I determined, in order to leave no loophole for doubt, to test their qualities at the mill, and to see in what, and to what extent, the difference of quality existed. Having, therefore, to prevent mistake, affixed my own seal to the sacks, and placed them under the care of Mr. John Hardcastle of Hunsingore Mills, near Wetherby, the gross quantity of each variety was ground and dressed with the following results:—

	Gross Quantity.	Weight of Grain.		Weight of Flour.		Pollard, or "Sharps."		Bran.		Waste.
No.	Bushels.	st.	lbs.	st.	lbs.	st.	lbs.	st.	lbs.	
1.	$2\frac{3}{4}$	11	12	8	12		12	2	1	1
2.	$2\frac{1}{2}$	11	1	8	6		11	1	11	1
3.	$3\frac{1}{2}$	15	10	12	6		12	2	1	5
4.	$3\frac{11}{16}$	16	6	12	3	1	3	2	5	9
5.	$3\frac{1}{2}$	14	13	10	11	1	9	2	5	2

"From the foregoing results, then, we deduce the following table of the quantities of flour, seconds, and bran, per bushel, from each parcel:—

	Flour.	Pollard.	Bran.	Weight per Bushel.
No.	lbs.	lbs.	lbs.	lbs.
1	$45\frac{1}{11}$	$4\frac{4}{11}$	$10\frac{6}{11}$	60
2	$47\frac{1}{5}$	$4\frac{3}{5}$	10	62
3	$49\frac{5}{7}$	$3\frac{3}{7}$	$8\frac{3}{7}$	$62\frac{6}{7}$
4	$46\frac{23}{59}$	$4\frac{35}{59}$	$8\frac{56}{59}$	$62\frac{23}{59}$
5	$43\frac{1}{7}$	$6\frac{4}{7}$	$9\frac{3}{7}$	$59\frac{5}{7}$

The same data furnish us with the quantities, per cent., of flour, pollard, and bran yielded by each parcel;—thus, 100 lbs. of grain without waste—

	Flour.	Pollard.	Bran.
	lbs.	lbs.	lbs.
No. 1 gives	$75\frac{5}{33}$	$7\frac{9}{33}$	$17\frac{19}{33}$
2 ,,	$76\frac{48}{77}$	$7\frac{11}{77}$	$16\frac{18}{77}$
3 ,,	$80\frac{40}{43}$	$5\frac{18}{43}$	$13\frac{21}{43}$
4 ,,	$77\frac{833}{2211}$	$7\frac{153}{221}$	$14\frac{208}{2211}$
5 ,,	$72\frac{196}{207}$	$11\frac{23}{207}$	$15\frac{195}{207}$

From this it appears, that had not the very green failed in quantity, it is superior to the ripe in quality —making more flour by 2 per cent.; while the raw, No. 3, is superior to all the other varieties. Thus, the bushel of No. 3 gives more flour than the bushel of No. 5 by 6¾ lbs., showing a gain of 15½ per cent. in weight of flour upon equal measures of grain. We also find that 100 lbs. of wheat, No. 3, make $80\frac{42}{43}$ lbs. of flour, while 100 lbs. of No. 5 yields $72\frac{186}{207}$ lbs. —showing an advantage of 7·984, or nearly 8 per cent., in favour of No. 3 upon equal weights of wheat. To those who are acquainted with Mr. Hardcastle it will be unnecessary to say, that neither ignorance nor design produced these results. And, when I state that he devoted his attention for several hours, and a portion of his machinery, to the exclusive trial of these wheats, it will be of little use to add, (though such was the fact) that every operation was conducted under my own eye, and that each parcel underwent an exactly similar process. Indeed, I must say that Mr. H. entered into the investigation with a spirit fully equal to my own, and conducted it with a skill that left me nothing to do but to thank him. And surprising as the results of this investigation may appear—surprising as they appeared to me—I must give Mr. Hardcastle credit for anticipating them in some degree; for, before the operation of grinding was concluded, he expressed to me his pleasure at being chosen to carry out an experiment of such interest; 'as a mark of which interest,' added he, 'I have no hesitation in saying, (and my opinion is confirmed by the senses of a practical miller—the sight, hearing, and touch)—that No. 5, the ripest wheat, grinds the worst—worse even than the greenest; a fact which few would believe unless they saw.' The results, as we have seen, fully confirmed Mr. H.'s opinion; and further examination explained the whole matter. In No. 5 we found a much greater quantity of flinty particles, which would not pass through the flour-sieve, than in any other, —a fact which clearly explained why it should, in millers' parlance, 'grind worst.' The deficiency of No. 5, in yield of flour, when compared with No. 3, was accounted for by the difference in the quantity of the pollard (or sharps), and in the quality of the brans; the bran from No. 5 being coarse and heavy, while that from No. 3 was thin as a bee's wing. 'Should a practical miller examine these brans, and be informed that they were from one sort of wheat,' remarked Mr. Hardcastle at the time, 'he would call No. 5 a very common specimen of grinding, and censure the miller; the other he would term a beautiful piece of workmanship, and say that the man who ground it knew how to prepare his machinery; yet the fact is, one miller and one mill have ground and dressed both.' The flour from the various wheats Mr. Hardcastle declared to be worth, at that time, 2s. 6d. per stone wholesale. The pollard he valued at 1s. 3d.; and the bran at 10d. per stone. Taking the straw at 2d. per stone, the real value of the respective cuttings will stand thus:—

No. 1.

	£	s	d
8st. 12 lbs. of flour, at 2s. 6d. per stone,	1	2	1½
12 lbs. of pollard, at 1s. 3d.	0	1	0¾
2 st. 1 lb. of bran, at 10d.	0	1	8½
22½ st. of straw, at 2d.	0	3	9
Total value of the produce of 20 perches,	1	8	7¾

No. 2.

	£	s	d
8 st. 6 lbs. of flour, at 2s. 6d. per stone,	1	1	0¾
11 lbs. of pollard, at 1s. 3d.	0	0	11¼
1 st. 11 lbs. of bran, at 10d.	0	1	5½
21 st. 3 lbs. of straw, at 2d.	0	3	6¼
Total	1	7	0½

No. 3.

	£	s	d
12 st. 6 lbs. of flour, at 2s. 6d. per stone,	1	11	0¾
12 lbs. of pollard, at 1s. 3d.	0	1	0¾
2 st. 1 lb. of bran, at 10d.	0	1	8½
20 st. 8 lbs. of straw, at 2d.	0	3	5
Total	1	17	3

No. 4.

	£	s	d
12 st. 3 lbs. of flour, at 2s. 6d. per stone,	1	10	6¾
1 st. 3 lbs. of pollard, at 1s. 3d.	0	1	6
2 st. 5 lbs. of bran, at 10d.	0	1	11½
19 st. 2 lbs. of straw, at 2d.	8	3	2¼
Total	1	17	2

No. 5.

	£	s	d
10 st. 11 lbs. of flour, at 2s. 6d. per stone,	1	6	11½
1 st. 9 lbs. of pollard, at 1s. 3d.	0	2	0½
2 st. 5 lbs. of bran, at 10d.	0	1	11½
18 st. of straw, at 2d.	0	3	0
Total	1	13	11½

Giving for the value of an acre of

	£	s	d
No. 1.—cut a month before fully ripe,	11	9	2
No. 2.—do. three weeks,	10	16	4
No. 3.—do. a fortnight,	14	18	0
No. 4.—do. ten days	14	17	0
No. 5.—do. ripe,	13	11	8

The loss, therefore, upon the green plots is respectively £2 : 2 : 6 and £2 : 15 : 4 per acre; and the gain upon the plots (3 and 4) cut raw respectively £1 : 6 : 4 and £1 : 5 : 8 per acre, when compared with the ripe. It will be observed here, that the loss upon No. 2 is greater than upon No. 1, which arises from the former being less in quantity than the latter. But the grain of No. 2 was bolder, and a better sample than No. 1. We have seen from the foregoing tables that it also made more flour to the bushel than No. 1; it will therefore appear strange that the produce should not be equal, at least, to that of the other. In reply to this I would say, that it is scarcely possible to select two plots of ground, the produce from which will be equal in all respects; and therefore a slight variation in the produce may, in any case, be accounted for. In this case, however, another cause operated, I have no doubt, in producing the apparently anomalous result. Thus, owing to the plots of ground being reaped before any other in the neighbourhood, they were, in spite of all precaution, robbed to some extent by the birds. Indeed, I have no doubt but that the loss upon the two cuttings 1 and 2 (especially upon the latter), would have been much less but for this circumstance; for though the desiccation or shrinking of the grain, from being cut too early, undoubtedly caused the quantity by measure of each to be less than that of the later cut samples, it could not, in my opinion, cause a difference of a bushel in 20 perches; nor could it have caused the measure of No. 2 to be less than that of No. 1—a far smaller sample. In order, therefore, to see how much of the deficiency in measure was to be attributed to the shrinking of the grain by drying, and how much to the other accidental circumstances, I took a long glass tube—sealed at the bottom—of ½-inch diameter, and partially filled it with water. Having made a mark on the glass at the point where the water reached, I made another some distance upwards. After this I poured grains of wheat from the sample No. 1 until the water's edge touched the top mark. The tube was then emptied, and a similar operation performed with all the samples. From this I found that it required 1110 grains of No. 1, 1005 of No. 2, and 910 of No. 5, to fill the tube so far that the water rose to the top mark. Between Nos. 3, 4, and 5, I could not, after several trials, find any real difference—the variation scarcely ever exceeding 1 per cent., and that in favour first of one sample and then another. From the foregoing test, however, we learn that, supposing the number of grains upon each portion to be originally the same, $\frac{1}{1110}$, $\frac{1}{1005}$, and $\frac{1}{910}$, will represent the comparative measures or spaces occupied by the produce of Nos. 1, 2, and 5 respectively; whence—

	Bushels.	Bushels.
$\frac{1}{910} : \frac{1}{1110}$ :: $3\frac{1}{2}$:	2·86, the produce of No. 1.	
And		
$\frac{1}{910} : \frac{1}{1005}$ :: $3\frac{1}{2}$:	3·16, the produce of No. 2.	

Now, the value of the flour, bran, and pollard, of 2¾ bushels of No. 1 was found to be £1 : 4 : 10¾; therefore, 2·86 bushels give a value of £1 : 5 : 10½. Similarly, the value of the flour, pollard, and bran of No. 2 was £1 : 3 : 6¼; whence the worth of 3·16 bushels is £1 : 9 : 8¾. To these values of Nos. 1 and 2, add respectively 3s. 9d. and 3s. 6¼d., the value of the straw from each, and we have for estimated produce of 20 perches of No. 1, £1 : 9 : 7½; and of No. 2, £1 : 13 : 3. The following will therefore be as correct an approximation of the values of the acre cut at the times stated, as it is possible to come at:—

No. 1, quite green,	£11	17	0
No. 2, green,	13	6	0
No. 3, raw,	14	18	0
No. 4, not quite so raw,	14	17	4
No. 5, ripe,	13	11	8

Showing a loss of £1 : 14 : 8 per acre upon No. 1, as compared with No. 5; a loss of 5s. 8d. per acre upon No. 2, do. do.; and a gain of £1 : 6 : 4 per acre upon No. 3, as compared with the ripe, and of £3 : 1s. per acre, as compared with the green cut No. 1. Let me here observe, that much as the advantage is on the side of the raw (No. 3) wheat, it would, I have no doubt, have been somewhat more, had not the sheaves been subject, in a slighter degree than Nos. 1 and 2, to the pillage of the birds. For although No. 3 produced as much in measure as No. 5, it is reasonable to suppose that it should have produced more, as the waste caused by reaping and stacking the ripe was much greater than that made in harvesting the raw cut wheat. And in so small a number of shocks, a very few visits from the winged legions were sufficient to carry away more than was wasted of No. 5. But this is of no import: with the yield alike, the advantage of No. 3 over the ripe is striking enough. It is an advantage gained not in any point open to variation or uncertainty: it is not a superiority merely in gross quantity of produce, which many things might have tended to produce; but a superiority in the quality of the article produced,—a better adaptation of the grain to make flour, and that to an extent by no means trifling. Thus, from data already given, we can clearly show that, by wheat being cut raw, we have a gain of 15½ per cent. compared with ripe, of flour, upon equal measures, and a gain in the weight of straw of 14 per cent.,—advantages which afford us a clear gain of 52¾ lbs. of flour upon every quarter of wheat,—a gain of 7s. 4¼d. in the value of every quarter of wheat,—a gain of 7s. 6¼d. in the value of every quarter of wheat, and the straw producing it,—a gain of £1 : 6 : 4 upon every acre producing 28 bushels, and of £1 : 8 : 2½ upon every acre producing 30 bushels, the quantity assumed as the basis of my calculations in my former experiment.

"But there are other advantages arising from the early reaping, which, though they cannot be estimated by pounds, shillings, and pence, are not the less valuable. For the sake of brevity, these advantages may be thus epitomised:—with an additional quantity of flour and straw, already considered, we have a better quality of both, a better chance of securing them, and a saving in securing them.

"The quality of flour as an article of food, and its power of affording nutrition to the body, are universally allowed to depend upon the quantity of gluten it contains; indeed, 'it seems pretty well ascertained,' says Professor Johnston, 'that those varieties of grain which contain the largest amount of gluten yield also the greatest return of flour.' Now, No. 3 here yields a greater return of flour than No. 5; it ought, therefore, to contain the greater proportion of gluten. And such is the case. My own analysis of the flours, in their dry state, gave to the raw sample an advantage of 1¼ per cent. in weight of gluten. In order to test the matter further, I forwarded the samples to Professor Johnston, who favoured me with an analysis. In their ordinary state of moisture, he found them to contain respectively—

No. 3,	19·15 per cent. of gluten
No. 5,	8·9 „ „

Thus proving the statement that the wheats which give the most flour give the best flour. And, although the farmer may not think much of this slight advantage in point of nutritive quality, it is no less a benefit both to the consumer and the producer,—affording to the former more nutritive matter for the same money, and enabling the latter to enjoy the profit of quantity and quality combined.

"That the straw of early cut wheat is of a better quality than that of the ripe, may be clearly seen from the researches of every analyst on the subject, and particularly from the following statement by Professor Johnston. 'The period,' says he, 'at which hay is cut, or corn reaped, materially affects the quantity (by weight) and quality of the produce. It is commonly known that when radishes are left too long in the ground, they become hard and woody—that the soft stem of the young cabbage undergoes a similar change as the plant grows old—and that the artichoke becomes tough and uneatable if left too long uncut. The same natural change goes on in the grasses which are cut for hay. In the blades and stems of the young grasses there is much sugar, which, as they grow up, is gradually changed, first into starch, and then into woody fibre. The more completely the latter change is effected—that is, the riper the plant becomes, the less sugar and starch, both soluble substances, they contain. And though it has been ascertained that the woody fibre is not wholly indigestible, but that the cow, for example, can appropriate a portion of it for food as it passes through her stomach; yet the reader will readily imagine that those parts of the food which dissolve most easily are also likely—other things being equal—to be most nourishing to the animal. It is ascertained, also, that the weight of hay or straw reaped is actually less when allowed to become fully ripe; and therefore, by cutting soon after the plant has attained its greatest height, a larger quantity as well as a better quality of hay will be obtained, while the land also will be less exhausted. The same remarks apply to crops of corn,—both to the straw and to the grain they yield. The rawer the crop is cut, the heavier and the more nourishing the straw. Within three weeks of being fully ripe, the straw begins to diminish in weight; and the longer it remains uncut after that time the lighter it becomes and the less nourishing. On the other hand, the ear, which is sweet and milky a month before it is ripe, gradually consolidates, the sugar changing into starch, and the milk thickening into the gluten and albumen of the flour. As soon as this change is nearly completed, or about a fortnight before ripening, the grain contains the largest proportion of starch and gluten; if reaped at this time, the bushel will be heavier, and will yield the largest quantity of fine flour and the least bran. At this period the grain has a thin skin, and hence the small quantity of bran. But if the crop be still left uncut, the next natural step in the ripening process is to cover the grain with a better protection, a thicker skin. A portion of the starch of the grain is changed into woody fibre, precisely as in the ripening of hay, of the soft shoots of the dog-rose, and of the roots of the common radish. By this change, therefore, the quantity of starch is lessened and the weight of husk increased; hence the diminished yield of flour, and the increased produce of bran. Theory and experience therefore indicate about a fortnight before full ripening as the

most proper time for cutting corn. The skin is then thinner, the grain fuller, the bushel heavier, the yield of flour greater, the quantity of bran less; while at the same time the straw is heavier, and contains more soluble matter than when it is left uncut until it is considered to be fully ripe.'

As a manure too, the straw cut 'raw' is equally superior to the ripe; for, as it is an agricultural axiom that the better the food of an animal is, the better the manure from it, the manure from a stock consuming this straw, containing a fair proportion of nutritive matter, must be more valuable than that from stock consuming the ripe with scarcely any in it. But a great proportion of the farmer's straw is converted into manure without undergoing the process of mastication and digestion. For this purpose the unripe straw is equally preferable, as all unripe vegetables are manures without preparation,—the soluble and nutritive extracts which they contain being the principal agents in forming vegetable manure, —as they not only combine to render the process of decomposition the more rapid, by breaking down the woody fibres, &c. in the manure heap, but are also in their pure and separate states stimulants to vegetation. It may be urged that the increased value of the straw is more in favour of that cut very green (No. 1) than that cut a fortnight later (No. 2.) This is true; but, to produce this increase of value, if we cut our wheat so early as No. 1, we have a desiccation of the grain to such an extent as to diminish the measured produce above 12 per cent.; while, by reaping with No. 2, we are, so far from injuring either sample or measure, actually improving both, and at the same time gaining above 5 per cent. in the weight, and at least as much in the quality of the straw. For the increase of weight in the latter is not produced by a greater produce, but by the presence of a greater portion of those soluble substances which are alike necessary to animal and vegetable life—are alike the nutritive part of food and the quickening principle of manure.

"We come now to the second advantage, the better chance of securing the crop. This is self-evident. We gain a fortnight at the commencement of harvest. If the weather be good, we can secure a great portion of our wheat before we should scarcely have begun upon the old system. If not, we can wait; so, under any circumstances, our chances of securing the grain must be greater. Moreover, if we take a retrospect of the harvests for a number of years, we shall find that nearly all the early harvests have been what we term good ones, *i. e.* good as regards weather and the condition in which the grain was secured. When the peculiarities of our climate, its general fickleness, and its still greater liability to change as the autumn advances, are considered, this will require no explanation. If we look, too, at the later harvests, we shall, I venture to say, find that, in nine cases out of ten, the grain which was cut first was secured in the best condition. As an example of this, the crop of 1839 will suffice. The crops were late, the beginning of reaping the same, and the result was, that in the North of England full 75 per cent. of the whole wheat crop was damaged. And full 75 per cent. of that which was uninjured, I will also venture to say, was that which was cut the first. In Yorkshire this was especially seen; for the earliest wheat was with the greatest difficulty secured. In this village (North Deighton) not a sheaf was in stack till the day before, and on some farms, the very day on which the rainy weather set in. The frequent recurrence of such years as this, will teach the value of even a fortnight better than any thing that can be said here. And that they will recur is beyond a doubt. What has happened once may happen again, but what has frequently happened (as this sort of harvest has,) with the same causes in operation, we are warranted in saying will happen again and often.

"The saving in securing the crop is a double one. In the first place, there is less waste in moving or reaping, and no danger of 'shaking' or 'necking' in strong winds. In the second place, there is an absolute economy in the expense of reaping the crop, which may be thus illustrated:—The busy period of harvest with the farmer generally extends over four or five weeks. In this month a certain portion of his work is done by his own hands, *i. e.* by the regular labourers and servants of the farm; therefore, by beginning a fortnight sooner, and extending the season of harvest over six weeks instead of four, it is evident that these regular servants would cut a much greater proportion of his crop—in fact one-half more. By this he is rendered less dependent on those extraneous 'helps' or 'takers' who, in the seasons of hurry and anxiety, fix their own terms. How often do we, especially in the north, behold a force of reapers in almost every field. The reason is this: the wheat, oats, and barley, are often ripe at one time; and aware as the farmer is of the injury which strong winds and showers would do them, he has to hunt up labourers at any price. And, after all this extra expense, it is extremely probable that, having the whole of his harvest upon his hands at once, he is compelled to let some part of his grain have too little or some too much weather. By commencing his wheat harvest a fortnight earlier, these evils would have been prevented; by the time that his barley and oats were ready, most or all of his wheat would have been cut, and some of it fit for the stack, and that, too, by the exertions of his regular workmen only. And being neither pressed for time nor labourers, his harvest would have been finished at a less expense, and his grain secured very probably in a much better condition. To assign a value for these advantages is, as has been said before, for the farmer himself; and it will not be an insignificant one. For if beginning harvest a fortnight earlier enables him to save a crop from spoiling once in a lifetime,—if the improved quality of his straw as food for his stock allows him to plough out an acre more, or to pasture another acre of clover with feeding stock, instead of mowing it for his lean stock, every grain saved, every extra bushel of corn produced, and every extra head of stock fed, is a benefit to the whole community as well as to himself—is so much added to the gross produce and wealth of the country; there being, in fact, an increased return without an increased outlay.

"I have now but one observation to make on the subject, and though it comes last, it is far from being least worthy of attention; it is, that however little, or however much, we may think of the gain to ourselves accruing from the adoption of any system, it is our duty, as members of society, to avail ourselves of every means of applying the resources the Almighty has given to the use of his creatures, and of developing still further those resources for the benefit of the community at large. When, then, we consider that there are in England and Scotland about 4,000,000 acres of wheat grown annually, producing 12,000,000 quarters of grain, of which three-fourths are allowed to become too ripe—when we consider, that, by cutting this sooner, we should produce an increase of 15½ per cent. of flour, and realize an increased value of 7s. 6¼d. upon each quarter produced, and that we should produce food for 1,362,857 persons over and above what we now produce, and an extra annual income of £512,491,—and when we consider that this income would be so much added to the wealth of the country, that it is equal to the proceeds (at 3 per cent.) of an estate worth £17,083,033, and that the increase of our population demands an increased supply of food, I would

ask, what is our duty in this case? The answer I leave."

All matters connected with the cutting of wheat are fully discussed in the article Reaping and in the other articles there referred to; and most other matters connected with the harvesting of wheat are so nearly the same as in the case of barley, oats, and rye that they need not be again described. Wheat reaped early in the morning with a strong dew, should not be bound up in sheaves till the dew is entirely dried out. When the weather is dry, and the crop is free from succulent weeds or from rank growing clover, wheat may be carted to the rick-yard in a comparatively short time after it is cut down; and if, according to the old practice, it has been allowed to stand uncut till the whole plant has become yellow and exsiccated, it may be stacked almost immediately from the reaping. In consequence of its comparatively great length and firmness of straw, wheat remains opener in the sheaves, both in the shock and in the rick, and therefore dries better in both, and may be carried in correspondingly earlier, than either barley or oats. The best criterion to judge of the fitness either of wheat or of any of the other culmiferous crops for being carried in, is to examine what are called the corn-knots or joints of the straw. If these are succulent and full of sap, it would be dangerous to carry the crop; but when these are dried and dead, it may be carried in with great safety, even although it may be at the time a little wetted by rain. If, however, the crop, or any part of it, is meant to be thrashed early, as for seed or otherwise, it is necessary to allow it to remain in the field till pretty thoroughly dried. When the straw happens to be mixed with succulent weeds, or with rank growing clover and rye-grass, the farmer's patience must be exercised till these are decayed and dried; for if allowed to remain succulent, they would be exceedingly apt to heat the whole rick, and materially damage the quality of the grain. A good practice is to have the shocks thrown down a short time before the sheaves are pitched into the waggon, in order that their butts may dry if damp, and that mice, which may have crept into the sheaves, may escape from them.

The Diseases and Accidents of Wheat.—The injuries to which wheat crops are subject, in the various stages of their growth, are numerous, great, and complicated. And the chief which arise from the weather, are noticed in the articles Accidents and Blight; from animals preying upon the young crop, in the articles Grub and Slug; from fungi in the maturing culms and ears, in the articles Mildew and Smut; from insects in the growing ears or grain, in the article Wheat-Fly; from animals in the yard or barn, in the article Vermin; and from insects preying upon the thrashed grain, in the articles Calandra and Corn-Moth.

The Produce and Composition of Wheat.—The produce of wheat grain varies exceedingly according to soil, manure, tillage, culture, rotation, variety, season, comparative healthiness, and other circumstances. About 35 years ago, when British agriculture was in a much less improved condition than in the present day, 18 bushels per English acre were considered a very poor crop, from 24 to 30 bushels were considered a fair average on farms of medium good soils under good management, 40 bushels were esteemed a large produce on good soils in high order, and from 38 to 55 bushels were occasionally obtained from prime soils under prime management in favourable years; and now, when soils have been much ameliorated by subsoil draining and other arts of georgy,—when manures have received the addition of bones, guano, nitrates, and many special preparations, and can be discriminatingly applied in the new lights of agricultural chemistry,—when tillage, from the breaking up and cleaning of the soil on to the completion of after-culture in spring rolling, may be so much better effected than before by means of recently invented or highly improved implements,—when the rotation of crops is so much more clearly understood in its principles, and may be so much more efficiently carried out by means of recently introduced hybrids and varieties of green-fallow plants,—when the peculiar capacities of particular soils can be brought into play, and the fullest energies of all soils called forth, by means of the minute adaptations to them which are found to exist in the many recently introduced varieties of wheat,—and when the diseases and accidents which affect wheat crops are so much better understood than before, and may, in many instances, be so readily prevented or diminished by recently discovered or recently invented appliances, we might fairly expect that a correspondingly great increase in wheat produce is obtained, if not throughout the whole kingdom, at least throughout all its well-improved districts or on all its enlightenedly conducted farms. But this we fear is far from being the case. Professor Low, in 1834, held "a fair good crop" to be 30 bushels per acre, and estimated the average produce of England at not more than 22 bushels, and that of Scotland at not more than 25; and Messrs. Way and Ogston, the Chemists of the Royal Agricultural College at Cirencester, found the mean produce of more than 40 specimens, grown in favourable circumstances of soil and culture in 1846, to be 28 bushels of the mean weight of 61 lbs. per bushel. The extensive abolition of the good old practice of summer fallowing has possibly acted as diminishingly upon wheat produce as the whole aggregate of improvements has acted augmentingly; and even these improvements themselves have by no means been carried out with the spirit and discrimination which general onlookers are ready to believe.

The weight of the straw of wheat crops is usually estimated at about double that of the grain; but as straw in the rick is commonly somewhat moist, and is usually weighed in a somewhat erroneous manner, this estimate seems to be a good deal above the truth. Messrs. Way and Ogston, by methods of the nicest care, ascertained the proportions between the straw, the chaff, and the grain of nearly 50 specimens in 1846, and at the same time determined the specific gravity of the grain, ascertained the quantity of constitutional water and of ash, resolved the ash into its constituents, and demonstrated the kinds and proportions of mineral matter which must be restored to the soil in order to compensate for what the wheat takes away; and, in all these respects, their report, both in its aggregate bearing upon the average of wheat crops, and in its individual details respecting the particular varieties of the wheats which were experimented on, and respecting the soils on which the several specimens grew, is so valuable that we should be inexcusable if we did not present a large abstract of it to our readers.

"The following table exhibits the weight of straw and chaff in reference to grain, in 11 specimens of wheat from the farm of Cirencester College, the grain being reckoned as 1000:—

No. of Specimen.	Variety of Specimen.	Soil.	Length of Straw.	Weight of Straw.	Weight of Chaff.	Weight of Straw and Chaff
			Inches.			
1	Hopeton,	Stonebrash and clay,	36	1107·2	204·3	1311·5
2	Hopeton,	Stonebrash,	38	986·8	206·1	1192·9
3	April Wheat,	Stonebrash,	28	996·8	278·5	1275·3
4	Spring Wheat,	Calcareous clay,	34	962·9	219·0	1181·9
5	Bristol Red,	Brash and clay,	38	955·8	216·0	1171·0
6	Clover's Red,	Stonebrash,	40	978·1	208·4	1186·5
7	Red-Chaff Dantzic,	Brash and clay,	38	1013·2	184·6	1197·8
8	Piper's Thickset,	Ditto,	29	928·0	173·0	1101·0
9	White Chaff,	Ditto,	36	827·3	154·7	982·0
10	Hopeton,	Ditto,	40	1163·3	194·3	1355·0
11	Spalding,	Stonebrash,	38	988·5	222·6	1211·0

With the exception of two specimens, we do not observe any very great dissimilarity in the numbers here given—we allude to April wheat (No. 3) and white-chaff wheat (No. 9). In the first, which is a bearded wheat, the chaff, including the awn, is necessarily high; in the white-chaff wheat, the straw and chaff are both very low. In taking the mean of the 11 wheats, the deviation in these two specimens is of little importance, as it occurs in opposite senses, the one destroying the effect of the other. The mean weight referred to grain as 1000 is—

For the straw,	991·3
,, chaff,	205·6
Straw and chaff,	1196·9

Mean length of the straw, 36 inches.

"We may next collect in a table the results of an estimation on five specimens of Hopeton wheat from Mr. Morton, of Whitfield Example Farm:—

No. of Specimen.	Variety.	Soil.	Length of Straw.	Weight of Straw.	Weight of Chaff.	Weight of Straw and Chaff.
			Inches.			
38	Hopeton,	Gritty silicious sand,	38	926·9	148·3	1075·2
39	Ditto,	Stiff clay,	43	1009·0	156·1	1165·1
40	Ditto,	Sandy,	42	1066·0	154·1	1220·
41	Ditto,	Clay,	45	1246·0	174·6	1420·6
42	Ditto,	Silicious sand,	44	1167·0	185·3	1352·3

The mean of these results will be found to be—

For the straw,	1083·
,, chaff,	163·6
For the straw and chaff,	1246·6

Mean length of the straw, 42·4 inches.

In these specimens the mean length of the straw and its weight in proportion to the grain are both greater than in those of the other series from the College farm: this is evidently due in a great measure to the method of collecting the crops, Mr. Morton's all being mown, and the others, with two exceptions, reaped.

The next table shows the proportion of grain, straw, and chaff, in 7 specimens of red-straw white wheat from Mr. Morton.

No. of Specimen.	Variety.	Soil.	Length of Straw.	Weight of Straw.	Weight of Chaff.	Weight of Straw and Chaff.
			Inches.			
43	Red-Straw White,	Silicious sandy loam,	47	1050·0	178·3	1228·3
44	Ditto,	Ditto,	45	1327·0	203·2	1530·2
45	Ditto,	Calcareous, brashy, and shallow,	42	852·5	192·2	1044·7
46	Ditto,	Clay loam,	46	1123·0	205·4	1328·4
47	Ditto,	Calcareous and silicious sand with clay,	42	1313·0	197·0	1510·0
48	Ditto,	Calcareous clay,	36	981·6	180·4	1162·0
49	Ditto,	Adhesive loam,	52	1165·0	240·5	1405·5

The specimens give a mean—

For the straw,	1116·
,, chaff,	199·6
Straw and chaff,	1315·6

Mean length of straw, 44·3 inches.

It will be seen that the highest number in the series does not much exceed 1,500 of straw and chaff to 1,000 of grain. The chaff of the red-straw white wheat, it will be observed, is larger in quantity than that of the Hopeton. This is probably a peculiarity of the variety. How far may this variation in the chaff affect the ripening of the two varieties?

"We next give a table of the same kind, embracing 15 specimens of different kinds of wheat received from Sir J. Johnstone. These were all bagged, and therefore the quantities represent very nearly the total straw; indeed in six cases the entire plant, including the root, was sent to us, and the estimation of straw effected after removing the latter at the distance of an inch and a half from the extremity.

No. of Specimen.	Variety.	Soil.	Length of Straw.	Weight of Straw.	Weight of Chaff.	Weight of Straw and Chaff.
			Inches.			
13	Creeping wheat,	Clay and grit,	39	957·7	188·0	1145·7
14	Talavera,	Ditto,	44	1175·0	164·9	1339·9
15	White Wheat,	Ditto,	40	1184·0	161·4	1345·4
16	Talavera,	Calcareous loam,	38	1155·0	174·9	1329·9
17	Creeping wheat,	Ditto,	39	1071·0	116·3	1187·3
18	Ditto,	"Hazle loam,"	42	1143·0	198·8	1341·8
19	Ditto,	Heavy tough clay,	42	1032·0	165·8	1197·8
20	Talavera,	Tough clay,	43	1068·0	176·1	1244·1
21	Hammond's wheat,	Free clay loam,	40	932·4	191·2	1123·6
23	Red wheat,	Weak clay loam,	38	919·3	242·9	1162·2
24	White wheat,	Weak sandy clay,	41	1009·0	178·2	1187·2
25	Creeping wheat,	Red clay,	40	981·0	179·5	1160·9
26	Ditto,	Clay and sand,	44	1272·0	179·0	1451·0
27	Ditto,	Ditto,	45	1279·0	185·6	1464·6
28	Ditto,	Calcareous rubble,	45	1192·0	181·1	1373·1

Of the 15 specimens here given, only in one instance does the united weights of straw and chaff reach 1,400; and the greater number of specimens fall far short of this amount. The mean of the whole is—

For the straw,	1091·4
,, chaff,	178·9
Straw and chaff,	1270·3

Mean length of straw, 41·3 inches.

"Let us compare the mean of all these specimens from different localities.

	Length of Straw.	Straw.	Chaff.	Straw and Chaff.
	Inches.			
11 Specimens from College Farm	36·0	991·3	205·6	1196·9
12 Specimens from Mr. Morton	43·3	1099·5	181·6	1281·1
15 Specimens from Sir J. Johnstone	41·3	1091·4	178·9	1270·3

Taking the mean of all these, we shall obtain the following numbers:—

For the straw,	1060·7
,, chaff,	188·7
For the straw and chaff,	1249·4

Mean length of the straw, 40·2 inches.

It would thus appear, from a careful examination of 38 specimens collected promiscuously, that the straw and chaff together never exceed 1,500, the grain being taken as 1,000—or, in other words, that the former are, at the highest computation, one and a half times the weight of the latter; and in these particular cases the length of the straw is very considerable, and certainly beyond the average of this, if not of most other seasons. As, however, in by far the greater number of cases the proportion of straw, including the chaff, falls very far short of this, we have every reason to believe that the mean which we have obtained rightly represents the relation of straw and chaff to grain this year. The number 1,250 of course gives one-fourth part more in weight, or about 17 cwt. of straw and 3 cwt. of chaff to 30 bushels of wheat at 61 lbs. On a farm of 400 acres of ordinary fertility, and cultivated on the four-course system, we might fairly consider that the average produce would amount to 28 bushels an acre of 61 lbs. to the bushel. On the calculation of the proportion of straw and chaff already deduced from our experiments, their united weight from the 100 acres (the grain being in weight $75\frac{3}{4}$ tons) would amount to rather more than $95\frac{1}{4}$ tons, including $14\frac{3}{4}$ tons of chaff. At the same time we must in fairness remark, that all observers agree in ascribing to the character of the season the most marked influence on the quantity of straw in relation to grain. Boussingault mentions crops grown at Bechelbron in two consecutive years, which differed most extraordinarily in this respect. In the first year (1840-41) the season was very wet; the second (1841-42) was remarkable for extreme drought. In these opposite conditions the weight of straw to grain was—

In 1840-41,	as 100 to 40
In 1841-42,	as 100 to 90

Converting these numbers into others which may be compared with our own, we have

	Grain.	Straw.
In 1840-41,	1000	to 4160·2
In 1841-42,	1000	to 1116·0

The latter number very nearly approaches our own mean for this year (1,250); the other instance exhibits a most extraordinary deviation. Boussingault states the ordinary relation of straw to grain at Bechelbron to be as 100 to 38 (or as 2,631, grain being taken at 1,000), and quotes in support of this being a probable average the following results of other continental observers:—

For 100 of straw—			Or grain as 1000.
Thaer	gives	50 of grain	2000 straw.
Podewils	...	35 ...	2857 ...
Berger	...	41 ...	2292 ...
Block	...	33 ...	3030 ...
Dierexen	...	39 ...	2564 ...
Schwertz	...	44 ...	2272 ..

It is not stated whether the chaff is included in the calculation, but we suppose that it is. In the Journal of the Royal Agricultural Society of England will be found many accounts of the estimation of straw and grain of wheat, in which the proportion of straw and chaff to grain is generally found to be between $1\frac{1}{2}$ and $2\frac{1}{2}$ that of the grain. If, then, our results merit confidence, they would plainly prove either that the straw of this year is exceedingly small

in quantity, or if (as we believe) its quantity does not fall far short of average years, that the proportion of straw to grain is usually very much overstated.

"The quantity of chaff in wheat does not, as far as we can discover, depend upon the amount of straw, but bears a general though perceptible relation to the grain. To the latter it stands in the proportion of 1 to 5½ on an average of 1 cwt. of chaff to every 10 bushels of wheat. Both straw and chaff are found in some cases to present singular deviations from the usually observed proportions: this is peculiarly the case in Piper's thickset wheat, Spec. 32, where the straw does not much exceed the half of the weight of the grain—the chaff, however, remaining constant. We do not observe that the soil has exercised much influence on the quantities of straw and chaff—the average of clays, of sandy and calcareous soils, being in our experiments very similar.

"We desire now to point out the connexion which exists between the specific gravity of the grain and the value of different specimens of wheat. The specific gravity of wheat is its true weight, with which no peculiarity of shape or size of the grains, no dampness or roughness of the skin, can interfere. Every farmer knows that the weight per bushel is most materially influenced by these circumstances, and, making allowances for them, is accustomed to consider it as a sure criterion of the value of the sample. It is known that the strength of flour and its fitness for making good bread is due to the gluten contained in it, and corresponds to a considerable extent with the weight per bushel—the greater the weight per bushel the better the flour; but setting aside the accidental differences of skin which are the result of thrashing in damp weather, &c., and taking two wheats as nearly alike as possible in this respect, the question to decide will be—Is the wheat of most pounds to the bushel necessarily the heavier?—in other words, Does it contain more gluten? Is it the best for the baker, the most nutritive for the consumer? We are prepared to show that it is not. The subject of specific gravity is rather difficult for parties unaccustomed to these matters to conceive, and it is particularly so in the case of a body consisting of individual grains like wheat. It is easy to understand and express the relation in weight existing between a cubic foot of water, of marble, and of iron. We should find, if we weighed this quantity of the three substances named, that the marble would weigh nearly three times and the iron seven times as much as the water. But the weight of a given bulk of any substance can only be compared with that of another (for the sake of determining the relative weights of the matter composing them) when there are no interstices or hollows in it. Wood is considered to be lighter than water because it floats upon it, but this is due to the air contained in its pores. Wood is really much heavier than water, and in consequence sawdust will be found very shortly to fall to the bottom of a vessel of water into which it is thrown. Now this reasoning applies equally to wheat. Were the grains of wheat solid bodies of large dimensions, so that they could readily be measured by the rule, or indeed were the grains all exactly of one size, the relative weight of two specimens could easily be made out; but this is not the case. A bushel of wheat is in the same predicament as a mass of wood; we cannot tell the true weight of the matter composing one or the other by weighing a certain measure of it, because the interstices between the grains of two specimens of wheat may differ in the same way as the pores or hollows of two kinds of wood. The weight, then, of any measure of two different grains will not correspond with their relative weight, supposing them solid, and therefore the weight per bushel may differ, the real weight remaining the same, or *vice versa*. This will be better seen if we collect in a table the specific gravities and the weights per bushel of those specimens which we have examined.

No.	Variety.	Soil.	Specific gravity.	Weight per bushel. lbs.	Ash per cent.

46	Ditto,	Clay loam,	1·413	63	1·60
47	Ditto,	Calcareous and silicious sand,	1·377	63	1·90
48	Ditto,	Calcareous clay,	1·388	62½	1·73
49	Ditto,	Adhesive loam,	1·386	61	1·71

In this table we cannot fail to observe a certain degree of connection between the specific gravity and the weight per bushel in many cases. Thus specimens 2, 9, 21, 23, and 31 correspond in having low specific gravities and low weights per bushel, whilst several specimens of high specific gravity give also a good weight per bushel, as specimens 28, 38, and 46. But on the other hand, in the greater number of instances the relation existing between these two circumstances is anything but clear: thus in several samples of the same weight per bushel, the specific gravity is widely different; we need only instance specimens 21 and 30. A glance at the table will supply many other such examples.

"The quantity of water in the different parts of the wheat plant next requires notice. A certain amount of water appears to be natural to the grain, straw, and chaff of wheat. If, when damp, they are exposed in a moderately warm and dry atmosphere, they soon lose their superabundant moisture, becoming to all appearance dry, but still retaining a certain and very considerable portion of water. This water is not, however, essential, although natural to them: for either of the three may by a heat under that of boiling water be perfectly dried without apparent injury or alteration of structure. The water in the grain varies between the limits of 9·5 and 13·5 per cent.: in the greater number of instances it is, however, between 10 and 12 per cent. The mean of all the specimens examined (62 in number) is found to be 11·69 per cent. In the straw the quantity of water ranges between 10·5 and 14·00 per cent.; the mean on 40 specimens being 11·96. The

chaff, when dried, loses from 11 to 14 per cent. of water; in one case (spec. 21) it amounted to 16 per cent., the crop having been injured by floods. The mean proportion of water in the chaff of wheat taken on 40 specimens is 12·21 per cent. It would thus appear that nearly one-eighth part of the whole wheat crop consists of water—about 20 tons of which are therefore removed by it from a farm of 400 acres.

"We now come to consider the mineral matter in the different parts of wheat, and first as to its quantity. The following tables give the amount of variation in the ash of all the specimens before described:—

No. of spec.	Name of Specimen.	Clay Soils.			Sandy (Silicious) Soils.			Calcareous Soils.		
		Ash of Grain.	Ash of Straw.	Ash of Chaff.	Ash of Grain.	Ash of Straw.	Ash of Chaff.	Ash of Grain.	Ash of Straw.	Ash of Chaff.

It will be convenient to consider in the first place the quantity of ash in the straw and chaff, in order that the mineral matter of the grain, both as regards its quantity and quality, may come under our notice at one time. The quantity of ash of wheat straw is usually comprised within the limits of 3·5 and 5 per cent. of its weight. There are, as will be seen by the table, deviations from this proportion—one specimen (No. 45) giving only 2·74 per cent., whilst in Piper's thickset (spec. 32) the per centage is as high as 11. There is no very evident connection between the quantity of ash and the soil upon which the specimen has grown; but if we may judge from the mean of the instances in the tables, it would appear that straw from clays contains the most ash—that from calcareous soils containing less, but more than the produce of sandy (silicious) soils. The variety of wheat would seem to control the proportion of ash of the straw; and the relative strength of different specimens is certainly to some extent dependent upon its amount. Thus in Piper's thickset (spec. 32), which possesses a straw of unusual strength, the proportion of ash is very great, more than doubling the usual average. This peculiarity is not observable in another specimen of straw of the same wheat (spec. No. 8); but the singular lowness of ash in this instance is due in some way to the soil. The mean of 40 specimens of straw given in the table will be found to be 4·50, or about 100 lbs. of ash for every ton of straw. The greatest quantity of ash removed from an acre by the straw of any crop which we have examined is 243 lbs. (spec. 47); in this case the per centage of ash is very high. The amount of mineral matter removed from the soil by the straw will of course be dependent on the quantity of straw itself, and therefore on the season. The proportion of ash in the chaff varies between the limits of 7 and 16 per cent.; more frequently, however, being found between 12 and 15 per cent.; as in the case of the straw, the silicious soils give chaff containing the least ash, and clays the most, the calcareous soils being interme-

diate in this respect. The ash in the chaff, indeed, in many instances corresponds with that of the straw. Thus in specimens 1, 2, 3, 4, 6, 11, we have a very low per centage of ash both in the straw and chaff; and this might be expected, as the chaff is only a prolongation of the straw. The 40 specimens of chaff give a mean ash of 12·25 per cent.; so that one-eighth part of the chaff of wheat is mineral matter. We have already shown that chaff contains on an average 12·25 per cent. of water. No less than one-fourth, then, of its whole weight consists of matter incapable of affording nourishment to animals; this should be taken into account in estimating the feeding properties of wheat-chaff—every ton of it being equivalent to 15 cwt. only of solid vegetable food. According to the calculation just given, a ton of chaff would contain 274 lbs. (about 2½ cwt.) of mineral matter. The largest amount removed from an acre by the chaff in any of the crops described, is seen in specimens 32 and 33, where it reaches 85 lbs.

"Of the ash in the grain:—From the last table it will be seen that the quantity of ash for a given weight of grain is not by any means constant, though confined within more narrow limits than that of the straw and chaff. The extreme points, high and low, are found to be 1·36 (spec. 7) and 1·97 (spec. 35); but the greater number of specimens have afforded from 1·5 to 1·7 per cent. of mineral matter. The analysis of 62 specimens of the grain has afforded us a mean of 1·67 per cent. This quantity of ash appears of very trifling importance, but will be seen, when we speak of its composition, to be by no means so insignificant as it would at first sight appear. Neither is it small when taken on a large amount of crop. A bushel (of 61 lbs.) of grain will upon the average contain exactly 1 lb. of mineral matter. The crop of an acre (28 bushels) will carry off ¼ cwt.; and therefore from a farm of 400 acres, on our former calculation, no less than one ton and a quarter of mineral matter will be removed by the grain alone.

"We naturally ask, what circumstances influence the quantity of ash in the grain of wheat? We have given the lists of soils and varieties in the table, in order to answer this question as far as the data before us will allow. The influence of variety on the quantity of ash is not very evident, for we have five specimens of Hopeton, and 7 of red-straw white wheat, which, with one exception, give nearly the same per centage of ash. Piper's thickset and red Britannia wheat (specimens 8, 22, 32), although very peculiar in some respects, do not exhibit any marked deviation with regard to the quantity of ash in the grain. On the other hand, the character of the soil would seem to have but little to do with the matter; in the list of specimens grown on clay, the same differences are observed as in those from silicious or calcareous soils, whilst the mean of the three affords very little deviation. Again, Mr. Morton's specimens of red-straw white and Hopeton wheat, although grown on different soils, possess very little latitude in the quantity of ash. In specimens 38 and 39, 40 and 41, we have very strong evidence against the belief that the soil alone affects the quantity of the ash in the grain of wheat. The two former of these are from the same field, half of which is sand, the other half clay; the two latter, from another field, half sand, half clay.

		Per cent. of ash.
Spec. 38,	Hopeton wheat—silicious sand,	1·61
„ 39,	„ clay,	1·63
„ 40,	„ sand,	1·71
„ 41,	„ clay,	1·69

It is clear that in these instances no alteration in the quantity of mineral matter of the grain is produced by the very opposite description of soil on which the crops were grown. Again, does climate exercise any influence on the quantity of ash of wheat? So far as the differences of locality afforded by Sir John Johnstone's specimens in Yorkshire, Mr. Huxtable's in Dorsetshire, Mr. Morton's in the vale of Gloucester, and our own on the Cotswolds, can afford an answer to this question, it is already given. Climate does not exert any marked influence on the quantity of ash in the grain. We have, however, better instances than these, in the result of the estimation of ash in several specimens of foreign grain:—

French wheat,	1·55	Rostock wheat,	1·61
Egyptian wheat,	1·97	Spanish wheat,	1.65
Odessa wheat,	1·50	Dantzic wheat,	1·71
Marianople wheat,	1·70	Ditto,	1·46
Rostock wheat,	1·46	Ditto,	1·47

Here we observe differences which are as great, though not greater than in specimens from the soils of our own country. Warm climates cannot be said to favour the abstraction (by the grain) of mineral matter from the soil, for in Spanish wheat we have a low per centage of ash; and although the Egyptian grain gives more ash than any other specimen we have examined, the excess is hardly worth notice.

Spec. —.	Egyptian wheat gives	1·97
„ 21.	From Yorkshire	1·94
„ 53.	April wheat from Worcester	1·92
„ 47.	From Mr. Morton	1·90

We cannot then give to the climate credit for creating differences in respect to the quantity of ash in the grain. If climate create no difference, aspect and locality are equally insufficient to account for the observed discrepancies. But though the character of the soil (that is, whether it be light or heavy, silicious or calcareous), though the variety of the crop, the climate, aspect, and locality, do not seem materially or uniformly to influence the quantity of ash, there is still another circumstance which may in part affect the question;—this is, the mineral constitution of the soil, irrespective of texture—the quantity and condition of mineral food at the command of the crop; and although we cannot speak positively on the point, there is evidence in favour of the view, which does not exist for any of the others. * * * It is curious that the larger the crop in any instance, the smaller in general is the per centage of ash in the grain. Twenty-eight bushels has been shown to be the mean crop per acre of the specimens we have examined, and 1·67 per cent. the amount of ash. If we collect, on the one hand, all those specimens which exceed, and, on the other, those which fall short of this per centage, taking the mean of their quantities and of the per centage of ash, we shall obtain the following result:—
The mean of specimens affording less than 1·67 per cent. of ash, is

30 bushels of grain to the acre,
And 1·56 per cent. of ash.

Of those affording more than 1·67 per cent. of ash, the mean is

27 bushels of grain to the acre,
And 1·76 per cent. of ash.

Now

	Bushels.	Ash.		Bushels.	Ash.
As	30	1·76	: :	27	1·58:

very nearly the amount which our results indicate. The quantity of ash then would appear to be inversely as the crop—that is, the quantity of mineral matter does not increase with the amount of crop, but is less in proportion to the vegetable matter in the large than in the smaller produce. This would seem to lead to the inference that the quantity of mineral matter present in plants is to a certain extent regulated by the abundance of the supply.

"Of the chemical composition of the ash of wheat grain:—The following table shows the amount of each of the mineral ingredients in 26 specimens of the ash of wheat:—

It will be seen that the first named, silica, constitutes only a very small proportion of the whole ash; it probably exists only in the skin as a mechanical protection to the grain; in quantity it varies between the limits of 1·30 and 6·00 per cent.; in one instance however the ash contains as much as 9·71 per cent. of this substance, Spec. 29. The specimen in which this unusually large quantity of silica occurs, is also remarkable for the very large proportion of oxide of iron present in its ash; it was grown on the 'green-sand,' and hence in all probability the peculiarity referred to. The green-sand owes its colour to the large quantity of silicate of protoxide of iron existing in it. When decomposed by liming, or water containing carbonic acid, it would furnish an abundant supply of both these substances, which would pass into the plant. The average proportion of silica in the ash of wheat upon the 28 specimens in the table is 3·66 per cent. Phosphoric acid, the next body in the table, is certainly the most important of all the mineral ingredients of wheat, both on account of the large proportion of it which exists in the ash, and the very small extent to which it is present in soils. The ash of wheat contains a quantity of this substance, varying between 40 and 50 per cent. of its weight. In one specimen however (No. 37) the phosphoric acid does not exceed 35 per cent.; but this result does not accord with any other we have obtained. The specimen alluded to is from Marianople; it is in peculiarly small and thin grains, almost approaching in appearance those of rye; it is of interest also in containing a large proportion of soda, not in the place of potash, but in addition to the usual amount of the latter alkali. Specimens 41 and 43 exhibit the highest amount of phosphoric acid in any of the ashes. The mean of phosphoric acid in all the specimens is 45·00 per cent. of the ash. A bushel of wheat of 61 lbs., containing 1·67 per cent. of mineral matter, would require $7\frac{3}{10}$ oz., or taking 28 bushels an acre as an average, we should remove from the soil in the grain of every acre of wheat 12 lbs. 3 oz. The largest amount removed in any crop examined is seen in specimen 47, where it reaches 22 lbs. 5 oz. This sample has been before noticed, from the large amount of ash taken off in the straw; it is in all respects an extreme case, the ash of the grain, the straw, and the chaff, being all unusually high. The large amount of crop with these high percentages renders the specimen the most exhausting of all those which have fallen under our notice. Sulphuric acid is generally present in the ash of wheat, though in small proportion; it does not exceed in any instance 2·00 per cent., and is usually much less than this. The mean quantity of this acid in the ash is 0·34 per cent., and the largest amount removed by an acre of wheat (in this grain) 8 oz. Carbonic acid is an ingredient of many ashes; but in the grain of wheat it is seldom met with. The presence of carbonic acid in an ash indicates the existence of organic acids combined with lime, &c., in the plant. The grain of wheat, however, would appear in its matured state never to possess any such organic salts; and consequently the column appropriated for this acid in the table is almost void. Lime is another ingredient in the ash of wheat: in quantity it varies between 1·5 and 8·00 per cent., being more frequently near the former than the latter number. The mean quantity is 3·61. The largest amount removed from an acre is seen in Spec. 42, where it is 3 lbs. 9 oz. Magnesia is a highly important constituent of plant ashes: in wheat it varies between 9·00 and 14·00 per cent. of the ash—more often however being found to constitute 11 or 12 per cent. of the mineral matter. Our analyses give us as a mean 12·36 per cent. A bushel of 61 lbs. contains 2 oz., and an acre of 28 bushels will remove 3 lbs. 8 oz. The largest quantity of magnesia removed in any crop examined by us was 6 lbs. 13 oz. (Spec. 47). Peroxide of iron exists to a small extent in the ash of wheat: its quantity varies between 0·25 and 3·5, the smaller number being nearer the ordinary quantity. It is remarkable that those specimens which contain most iron are from the chalk districts, or analogous soils. The average proportion of peroxide of iron is 0·81, and the largest amount removed from an acre (Spec. 29) 1 lb. 6 oz. Potash is, next to phosphoric acid, the most considerable and important of all the substances which exist in wheat ash: in quantity it varies between 27 and 37 per cent., having about the same latitude as phosphoric acid. The mean of 26 specimens is 31·37. A bushel of wheat (61 lbs.) will contain 5 oz., and an acre of 28 bushels will carry off 8 lbs. 15 oz. The largest quantity described in the Report as removed from an acre is 14 lbs. Soda is an alkali scarcely ever entirely absent from wheat, but present only in small quantity. When compared with potash, it varies between 1 and 5 per cent. of the ash. In one instance, that of the Marianople wheat before mentioned, its quantity is comparatively large, reaching 9 per cent.; but we have as yet met with nothing to induce us to adopt the opinion of Liebig, of the substitution of one alkali for another. At all events

this does not appear a usual occurrence. We have not certainly examined any specimens grown in soils where the total absence of the other alkali would necessitate a plant to assimilate soda; but were this possible without great injury to the health of the plant, or defect in quality and quantity of the produce, why do we not find it more frequently the case? If it be indifferent to the plant whether the alkali furnished it be potash or soda, why should the quantity of the latter seldom exceed a sixth part of the former? Again, in guano we have always abundance of common salt and other salts of soda, and yet in Spec. 26, where guano was applied, the proportion of soda does not exceed the mean, which is 2·72. Chlorine in combination with sodium as common salt, will be seen to be present in some two or three specimens of wheat, but only in very minute quantity; and it is singular that in two of the three instances where it occurs, an unusually large proportion of oxide of iron is also present, as if the same circumstances had led to the peculiarity in both cases. Possibly in these instances the wheat was not fully matured, and these bodies would come under the title of 'accidental ingredients.' The absence of soda in any quantity, either as soda or as common salt, from both the grain and straw, would seem incompatible with the statement to which much attention has lately been drawn, that common salt is a manure for wheat; or rather perhaps we should say, that it is an argument in favour of the theory which supposes the existence of two distinct classes of manures—one serving as food for plants, the other assisting in preparing that food, or in effecting some other desirable object in the amelioration of the soil. In the first of these ways, common salt certainly can have no influence on wheat: it cannot serve as food for the wheat crop, because it is not required, and the little soda existing in the ash, if essential, is always abundantly supplied by the soil. Common salt probably owes its efficacy in part to the power which it possesses of absorbing and retaining moisture—a tendency which would insure a certain though small supply of moisture to the roots in the driest seasons: it is also poisonous to the wire-worm and other depredators on this crop. We find, then, that in the ash of different specimens of wheat deviations in the proportions of its several ingredients occur, which, although they do not destroy the principle of uniformity of composition upon which the whole interest of the subject depends, yet tend very materially to interfere with its simplicity.

"It will be seen that we have only in one instance analyzed the ash of straw and chaff separately (spec. 46). In the other instances the straw was burnt with the quantity of chaff belonging to it—very perfect and unbroken specimens of average length being selected. It will be manifest that, however desirable a separate analysis in each case might be, the time involved by it will not admit of such a proceeding. The agricultural distribution of the crop is divided into grain, and straw, and chaff, the ash of the former being entirely removed, that of the latter being returned to the soil from the manure heap. The following table exhibits the analyses of nine specimens of wheat straw, with the proportion of chaff belonging to it:—

No. of spec.	Variety.	Soil.	Silica.	Phosph. Acid.	Sulph. Acid.	Carb. Acid.	Lime.	Magnesia.	Perox. Iron.	Potash.	Soda.	Chlor. Sodium.	Ash of Chaff.	Ash of Straw.

The variation in the composition of the mixed ash of the several specimens in the table is not very great. Sulphuric acid and lime are present in considerable quantity in the straw, but the specimen of chaff which we have examined did not contain the former, and the latter only in small quantity. We give here a table of the quantity of the different mineral matters contained in a ton of straw and of chaff; and also, for comparison, a calculation of the average quantity of these substances removed by the grain, straw, and chaff of an acre, calculated as before at 28 bushels of 61 lbs.

	Mineral matters in 100 parts of Straw Ash.	Mineral matters in 100 parts of Chaff Ash.	In a ton of Straw.	In a ton of Chaff.	Removed from an Acre.	
					In 28 bushels of Grain, at 61 lbs. (1792 lbs.)	In 2109 lbs. of Straw and Chaff (18 cwt. 91 lbs.)
			lbs. oz.	lbs. oz.	lbs. oz.	lbs. oz.

	99·99	99·98	93 14	212 0	28 $6\frac{6}{10}$	119 11

From this table we may learn that the straw and chaff of a given amount of crop (on the average of this year) remove from the soil together very little more than half the phosphoric acid contained in the grain—at the same time, however, requiring twice as much potash. The quantity of silica removed in the whole produce is very considerable, ¾ cwt. of this substance being required for a very moderate crop. The addition of silicate of potash to the land must be tolerably liberal if it is wished to supply by its means the silica required for the wheat crop. A comparison of columns 3 and 4 will show us that, weight for weight, wheat chaff contains three times as much silica and phosphoric acid as the straw; and although, from the quantity of mineral matter it contains, and the woody nature of its vegetable substance, it may not be so nutritious a food for animals as the straw, the manure into which it is converted must be regarded as much more valuable than that produced from the latter.

"We may fairly conclude that, in round numbers, an average crop of wheat would remove from the soil in the grain, straw, and chaff per acre,

84 lbs. of silica.
20 lbs. of phosphoric acid.
4 lbs. of sulphuric acid.
8 lbs. of lime.
6 lbs. of magnesia.
1 lb. peroxide of iron.
23 lbs. of potash.
1½ lb. of soda.

Of these substances three may be considered as non-essentials: these are, the lime, the peroxide of iron, and the soda, all of which, if the plant requires them, it may readily obtain from almost any soil. To supply the other ingredients in the form of manure of mineral composition alone, we must employ an alkaline silicate, phosphate of lime, and a salt of magnesia. The silicates of potash and of soda, as they are manufactured for agricultural purposes, are compounds of very varying constitution. Of silicate of potash, the average amount required for the supply of 84 lbs. of silica would probably be about 2 or 2½ cwts. It is plain that the quantity of potash required by the crop is small when compared with that which would be added in the requisite dose of silicate of potash. We would therefore recommend silicate of soda as a more economical method of supplying this mineral ingredient of plants. The potash must then be applied in another form. The total phosphoric acid of the wheat crop would be furnished in ¾ cwt. or 1 cwt. of unburnt bones; the magnesia by 40 lbs. of sulphate of magnesia (Epsom salts;) and the potash by about 35 lbs. of carbonate (pearl-ash,) or 50 lbs. of nitrate (saltpetre;) but this last addition will be unnecessary if silicate of potash be employed: the necessary top-dressings will then be—

2½ cwt. silicate of potash,
1 cwt. of crushed bones,
40 lbs. sulphate of magnesia.

Taking into consideration, however, the very gradual solution of the phosphate of lime of bones, it would no doubt be better to adopt another form of top-dressing for wheat. The following would perhaps be a better application:—

2 cwt. of silicate of soda,
1 cwt. of bones dissolved in
½ cwt. of oil of vitriol,
40 lbs. of sulphate of magnesia, and
35 lbs. of carbonate of potash.

The bones should be dissolved in the acid previously diluted with an equal measure of water: when they become thoroughly broken down, the sulphate of magnesia and carbonate of potash should be added, and the whole well stirred and left at rest for twenty-four hours. At the end of this time the mixture would in all probability be found sufficiently dry, when broken up, to be distributed by the hand; it might otherwise be mixed with ashes or mould, in order to attain the proper condition. We have already remarked, that of the total silica required by the wheat, three-fourths belong to the straw, the remainder being found in the chaff and grain. On the other hand, by far the largest proportion of phosphoric acid is appropriated by the grain. Reasoning upon these facts, we should endeavour, as far as possible, to supply the several ingredients at the time when they are wanted. Two-thirds of the silicate of soda and one-third of the prepared top-dressing might be applied to the young plant very early in the spring; the remainder of both should be reserved and applied as late as practicable, in order that they may be at the command of the plant as the ear fills and the straw and chaff strengthen. In many soils, such as stiff clays, and in all localities where the soil is formed from granitic or other primary rocks, the addition of silicates will be an unnecessary outlay of money; but the other mixture is comparatively inexpensive, and would always more than remunerate the farmer, if not in the wheat, at least at some other period of the rotation. The advantage of the method of application here proposed mainly consists in the use of soluble phosphates, such as those of potash and magnesia, which are produced when the materials before mentioned are mixed together; for this purpose, however, the employment of sulphuric acid to dissolve the bones is indispensable. It is quite probable that such a top-dressing, from its solubility and tendency to absorb moisture, would take effect when the season is too dry to allow of other applications being made with advantage. But the same solubility will cause its earlier removal from the land by rains and drainage, unless the precaution be taken of applying it at intervals, as we have suggested." See the articles FLOUR, STARCH, BREAD, GLUTEN, GRAIN, and STRAW.

WHEAT-FLY. Any one of several insects which feed on wheat. The chief is the *Cecidomyia tritici*, popularly called the wheat-fly par excellence, or the wheat-midge; another of some interest is the *Cecidomyia destructor*, popularly called the Hessian fly or the American wheat-midge; and a third is the *Chlorops pumilionis*,

which has never obtained any distinctive popular name. All these are dipterous insects or true flies; and the first and second belong to the tipula family, and the third to the musca family.

The genus *Cecidomyia* is an extensive group, and comprises nearly 30 British species. Their antennæ are slender, granose, as long as the head or longer, more or less necklace-shaped, comprising in the female 13 subovate joints, and furnished with short verticillated hairs; their eyes are entire, and either oval or round; their forehead is narrowed and prolonged in the manner of a rostrum; their wings are membranous, ciliated, pubescent, and incumbent on the body, and present each but three nervures; their palpi are long and four-jointed; and the extremity of their tibiæ is spinous. But though forming a perfectly natural and quite distinct group as to their structural character, they differ very widely from one another in habit and economy; for while two, as we have hinted, live upon the ears of wheat, some live on rotting tulip and hyacinth bulbs and on half-decayed cow-dung, others inhabit the leaves of the Scotch pine, the buds of the sallow, and the flower-buds of the common hedge-mustard; and many form downy excrescences, somewhat similar to galls, upon ground-ivy, field wormwood, common campion, and some other plants.

The wheat-midge, or British wheat-midge, or chief wheat-fly, *Cecidomyia tritici*, is very minute, scarcely exceeding the twelfth part of an inch in length, and resembling a small gnat or midge. The female has a pale ochreous colour and is pubescent. Her eyes are intensely black, and coarsely granulated, meeting on the crown, and covering nearly the whole head. No part of the mouth is visible, except a short bilobed pilose lip, and two incurved palpi or feelers, which are four-jointed and slightly pilose. The antennæ are stretched forward or curved upward, and inserted close together in front of the face; they are as long as the body, pale brown, and clothed with longish hairs; and they comprise thirteen sub-elliptical joints, contracted round the middle and connected at the ends by a single thread, like a string of beads. The thorax is ovate and of a deep reddish ochre colour. The scutellum is transverse-oval. The abdomen is rather short and tapering to the apex, which is furnished with an ovipositor nearly thrice as long as the body, the sheaths at the base stout, the oviduct exceedingly slender. The wings are incumbent in repose, longer than the body, yellowish-white, and beautifully iridescent, pubescent, and ciliated; the costal nervure surrounding the wing, the subcostal short, the second extending to the margin, the third shorter, the apex forked. The two halteres or poisers are large and capitate. The six legs are long, slender, and nearly of equal length. The thighs and shanks are equally long. The tarsi or feet are five-jointed, the basal-joint minute in all, the second as long as the tibiæ, the remainder decreasing in length. The claws are very minute. The male is seldom seen; and his antennæ are believed to be usually composed of twenty fine globose and somewhat remotely strung joints. The ovipositor of the female, notwithstanding its great length, is not seen, and would not be suspected by a stranger to exist in the ordinary condition of the fly; but is readily discovered by pressing the anus, or at the season of oviposition. It can be unsheathed by the insect at pleasure; and it comprises a long retractile tube or vagina, together with an aculeus, or pointed instrument like a sting, as fine as hair.

The wheat-midge makes its appearance in wheat-fields just about the time when the ear is beginning to emerge from its leafy envelope, most commonly in the early part of June. It readily escapes the observation of persons ignorant of its character, or not looking out for it; but, to an intelligent observer, it may be seen on calm evenings, most frequently about eight o'clock, swarming about in small undulating clouds, in the manner of winter gnats and other kindred species, and it is occasionally seen also in the mornings and during the day. Each female usually chooses as the receptacle of her eggs an ear just emerging from the sheath; and she introduces them by means of her ovipositor into the floret,—and while doing so, keeps her anus nearly at right angles with the margin of the floret's glume. She is so engrossed with her occupation that she is not easily disturbed, and may even go on with her proceedings though a magnifying glass should be held close to her by an observer; and she slowly introduces her ovipositor, and slowly parts with her eggs, and then cautiously and deliberately withdraws the instrument. So many as thirty-five flies may sometimes be seen at one time upon one ear; and some one or more of them may become almost exhausted in the effort to withdraw the ovipositor, or even may entirely fail to withdraw it, and remain fastened to the spot till devoured by some enemy. Mr. Kirby, after some vain attempts to see the eggs pass through the long retractile tube, eventually witnessed that curious phenomenon. "I gathered an ear upon which some of the insects were busy," says he, "and held it so as to let a sunbeam fall upon one of them, examining its operation under the three glasses of a pocket microscope. I could then very distinctly perceive the eggs passing one after another, like minute air-bubbles, through the vagina, the aculeus being wholly inserted into the floret. I examined the process for full ten minutes before the patient little animal disengaged itself; and at last it was through my violence that she discontinued her employment and flew away." The eggs, in passing through the oviduct, receive a coating of glutinous matter which causes them to adhere firmly to the glumes; and they are deposited in small clusters, varying in number from two to upwards

of twenty; and they amount in the aggregate to so vast a multitude as might seem to threaten terrible desolation or even utter destruction to wheat crops. They are oblong, transparent, and of a pale buff colour; and are hatched in the course of ten or fourteen days. The minute maggots which proceed from them have the same general form as other dipterous larvæ; and are at first transparent and colourless, but soon begin to assume hues of straw-colour, yellow, saffron, and orange, according to their age. They are thought by some persons to feed on the pollen, and by others to live on the juices of the ovary; and they not improbably devour the reproductive substances of both the anthers and the germen, both before and after the shedding of the pollen; but at all events they so completely destroy the reproductiveness of the particular florets in which they are lodged that the seed never forms and the parts of fructification lose all their virus and shrivel and decay. So many as forty-seven have been counted in one floret; and even the smallest number ever present seem to be perfectly competent to do the work of destruction. Nearly all become full-grown about the beginning of August; and they may then or a little earlier be easily found on examining an infested ear; and they afterwards either remain among the heads of the wheat, and continue ensconced there till they become transformed into pupæ, or leave the ear, and pass down to the ground, and bury themselves in the soil or about the roots of the stubble, there to await their transformation; and when the corn is thrashed, either the larvæ themselves enveloped in a singular kind of membrane, or the pupæ which have been formed from them, may be discovered in the chaff-dust, and if abundant and conspicuous, will readily be mistaken by unsuspecting farmers and farm-servants for the seeds of weeds. "Naturalists who have given their attention to these insects," says Mr. Sidney, "are of opinion that the chrysalis state is not reached till the spring, and that the thin membranous covering is a protection against cold till that condition is attained. It is true that there has been one instance of a fly hatched from a chrysalis in September, but this was an exception. There have been many attempts made to breed these flies from the larvæ covered with the membrane, or the supposed chrysalides found in the chaff; but all have failed. It was tried in vain by the writer; but he thought others might have obtained them by reason of more skilful methods, till on inquiry he found they were equally unsuccessful. Conjectures have, as usual, been sufficiently abundant; and a question has been raised, whether the larvæ do not enter the earth to become pupæ or chrysalides. Certain it is that the membranous cases of the larvæ are found left adhering to the sound grains and to the chaff-scales; and Professor Henslow and others assert, that some larvæ have been known to leave the ears and bury themselves in the earth. Any entomologist who decides the question whether these larvæ certainly enter the ground to turn into pupæ, will do great service to science in general, besides affording information to the farmer respecting the habits of one of the most fatal enemies to his produce when the season is suitable to them."

The ravages of the wheat-midge are somewhat fitful,—insignificant in one season and excessive in another,—inconsiderable on some farms or crops and very considerable in others; but, in the aggregate of years, they are much greater than most farmers are aware of or would readily believe. Mr. Kirby estimated the loss in a field of 15 acres which he particularly examined at about one-twentieth of the whole produce, or at an average of about two grains in each ear. Mr. Markwick, who in the first instance did not suppose the wheat-midge did any serious mischief, became eventually convinced that Mr. Kirby's estimate was not too high if applied to infested wheat-crops in general; for of the ears which he examined, scarcely any contained fewer than two injured grains, most contained more, and some contained so many as six. Mr. Gorrie estimated the loss in the late sown crops in Perthshire, in 1828, at one-third of the whole produce. Mr. Bell of Mid Lioch, writing in June 1830, expresses apprehensions respecting the crops of Scotland fully in accordance with Mr. Gorrie's estimate, and says, "Another year or two of the wheat-fly will make two-thirds of the farmers here bankrupts." Mr. Sidney says, "The author can assert that in the autumn of 1845, he found great quantities of the larvæ not only in a first-rate wheat district in Norfolk, but in other parts of the country. Ear after ear was gathered by him, examined, and the contents shown to farmers who never before had even heard of such things, and who were perfectly astonished when they saw them. Often has he also entered a barn and taken up a handful of dust from the floor where wheat has been winnowed, turned out the little orange-coloured devourers, now in their membranous cases, one after another, but scarcely ever met with any person who had previously noticed them. If they had seen them, they took them for the seeds of some kind of weed. There seems also to be good reason to suppose that the wheat-midge is to be found on the continent of Europe, and that it attacks the corn-crops in France, causing the same sterility in the grains that has been shown to be the result of its ravages in England."

The wheat-midge is known to subsist on common couch grass, *Triticum repens* or *Agropyrum repens*, in the same manner in which it subsists on wheat; and it might therefore be supposed to attack with equal readiness all plants more nearly allied to wheat, and particularly all the species and varieties of wheat itself; yet it is generally believed to have strong preferences and dislikes in refer-

ence to the commonly cultivated wheats, and has been supposed or observed to do prime injury to some, secondary injury to others, and little injury or none to others. One reason why some wheats are little affected by it may be that they are generally sown at a time which, conjointly with their habits, occasions their coming into ear at a period when the midge is not in a condition to attack them; and another reason why the same or other varieties enjoy comparative safety may be that they have too hard an envelope to be readily pierced by the midge's ovipositor. "The species of woolly-eared, Lammas red, and Rivet wheats," says Mr. Shirreff, "have been stated in East Lothian to resist the attack of the fly. The two first mentioned kinds come into ear about a week sooner, the last about a week later, than those commonly cultivated, and to these peculiarities owe their occasional escape, earing either before or after the general depositing of eggs takes place. The fly, however, does not always appear in strict conformity with the growth of the wheat plant, and the earing of different species is late or early, compared with the general crop, according to the time at which they are sown. The eggs of the wheat-fly are generally deposited when the ear is escaping from the sheath,—and when delayed beyond this period, the grains either become diminutive, or the maggots perish; and therefore a species of wheat in some measure impervious to the ovipositor of the fly at this stage of the plant's growth must tend to mitigate the ravages of the fly. There is such a species cultivated in many countries, the name of which is the Polish wheat, *Triticum polonicum*. It is characterized by a large exterior chaff, which closely envelopes the cups when the ear is escaping from the sheath, and at this time defends the flower in a great measure from the fly's ovipositor. I have grown the polonicum, on a small scale, amongst other kinds; and although it did not altogether escape the attack of the fly, it was much less injured than any of those which came into ear at the same time." The *Triticum polonicum*, however, is very far from being eminent in other good agricultural properties; and, if really proof against the midge, it probably could not render better service to farmers than by being made to communicate its large exterior chaff to some of the best cultivated varieties through the process of hybridizement. A variety called in some parts of England cone wheat, and known in some parts of Scotland as antifly or cone Rivet or German thickset wheat, belonging to the species *Triticum turgidum*, and somewhat nearly akin to the common Rivet and Pole Rivet wheats, possessing a tall vigorous stem, and yielding a very large produce, though the grains are coarse and of inferior quality to those of the common winter wheat, was found by Mr. Gorrie, in the course of comparative experiments during the prevalence of the wheat-midge in 1829, to be completely proof against the midge. "I had a fall of it," says he, "growing in the centre of a field of common wheat, which came in the ear on the 22d June, exactly at the same time with the common variety. At that period, I visited the field every evening for a week, and although the flies were numerously and busily employed on every ear of the common wheat, the half of which they destroyed, I, and my friends, who went frequently with me, could only detect one solitary fly at work on the new variety; and although the ear was marked, no maggots could therein be afterwards observed." The field of 15 acres examined by Mr. Kirby was planted partly with common white wheat and partly with common red; and the result of his examination was that in thirty ears of the white, seventy-three grains were destroyed by the fly, being at the rate of not quite $2\frac{1}{2}$ grains per ear, while in twenty ears of the red twenty-nine grains were destroyed, being at the rate of not quite $1\frac{1}{2}$ grain per ear. But all these instances, as well as some others which have been recorded, are probably more or less deceptive; and the different results may have been in an appreciable measure due either to the accidental circumstance of one crop being more exactly in the stage of fitness for the insect's use than another, or to the influence of the gregarious habits of the midge, whose swarms usually assemble and remain in the neighbourhood of the spot where it first finds a nidus or is induced to make a settlement; and even in periods and districts which have become signalized by great and recent ravages of the midge, many an intelligent farmer may perhaps think himself less safe in trusting to the reputed antifly properties of any particular variety, than in aiming to bring wheat crops of the best common agricultural varieties into developement a little before or after the time when the fly is likely to be most active in the work of depositing its eggs. Yet though this device might seem to be obvious and efficient, and though it has been recommended as a preventive by very distinguished practical agriculturists, it may often be baffled either by the retarding or accelerating of unusual weather upon the crops, or by the sustaining and modifying influence of unusual circumstances upon the fly. "The designs of Nature," remarks Mr. Duncan, "are not to be thus easily frustrated. There is a plastic and accommodating principle in the nature of insects, conferred upon them by that Benevolence which careth for all its creatures, apparently for the express purpose of enabling them to maintain their existence among the numerous hostile influences to which they are continually exposed. In such a case as that here supposed—the female being ready to deposit her eggs before the appropriate plant is ready to receive them—it usually happens that the life of the insect is purposely prolonged until a suitable opportunity occur for continuing the species. A whole season is in this way sometimes added to the ordinary duration of insect

life; and it is unlikely, unless in rare cases, that the brood is ever lost in consequence of a want of synchronism in the maturity of the insect and the plant which is to form the nursery for its young." Still, though the whole brood may never be cut off by anachronism between the plant and the insect, the numbers of it may thereby be very materially diminished; and though a farmer, in any infested district, or after any disastrous season, ought never to rely solely or mainly upon the producing of such an anachronism as a preventive, he may at least regard it as an auxiliary of sufficient possible consequence to be worthy of his attention.

Remedies or preventives directed immediately against the life or operations of the perfect fly were recommended by Kirby as most likely to prove successful. "By a set of experiments first made upon a small scale," says he, "the intelligent farmer may possibly find out some method that will prevent this insect from laying its eggs in his wheat. These should commence as soon as the ear begins to quit the *folium vaginans* or hose; and they ought to be continued till the germen is impregnated, or, to use the rural phrase, the wheat is off the blossom. Perhaps fumigations of tobacco or sulphur, if made when the wind is favourable, might render the ear disagreeable to this insect." But either fumigations of any such kind, or medicated aspersions, or any other applications which might be suggested, in order to be made on a sufficiently extensive scale to produce decided effect, would probably cost almost as much trouble and expense as they could be worth, and might also deteriorate the market value of the wheat or even impart to it deleterious properties. Remedies or preventives directed against the matured larvæ or the pupæ have been suggested by some distinguished savans on the assumption that they burrow in the ground, and by others on the assumption that they principally or wholly continue attached to the harvested corn. "It is possible," says Mr. Duncan, "that Mr. Gorrie's plan of ploughing the wheat stubbles, and having what is called a skim-coulter attached, of such a construction as would cut and lay about an inch of the surface at the bottom of the furrow, would bury many of the pupæ at such a depth as to render their resurrection improbable. But grass and clover seeds are so often sown with wheat, that this method can seldom be practised, even if there was more inducement to follow it than there really is, without deviating from the ordinary rotation. The same objection will apply to Mr. Poppy's suggestion of burning the wheat stubble on the land; but when this can be done, it promises to be a highly useful expedient. When the stubble is short and scanty, the conflagration may be assisted by straw, or other inflammable matters, (such as dry furze,) brought for the purpose. If it is rank, as is usually the case in Suffolk and some other southern counties where the reapers scarcely bend their backs in cutting the crop, the fire will be sufficient to heat the whole surface of the ground, and in all probability will destroy the greater part if not the whole of the pupæ, heat being speedily fatal to them." But the probability is that a large proportion of the larvæ which live to become pupæ remain attached to the harvested corn till separated from it by the process of thrashing, and that they are afterwards conveyed, in mixture with the chaff-dust, either directly or indirectly to the ground, and there pass in spring or in early summer into their pupa state; so that a method of prevention recommended by Professor Henslow, for separating the chaff-dust and afterwards carefully collecting and burning it, may be by far the most efficient of all the methods hitherto proposed, and certainly is the cheapest and easiest. He says, "It occurred to me that, if a wire-gauze sieve were placed before the winnowing-machine in a sloping position, so as to allow the chaff to fall upon it and then roll from it, the pupæ would pass through, and might be caught with the dust in a tray placed below the sieve. I have put this to the test of experiment, and find it answer perfectly. Two pieces of wire-gauze were placed together at an angle, sloping like the roof of a house, and the chaff readily fell off on each side to the floor, while dust and pupæ passed through. If a simple contrivance of this kind formed an appendage to every winnowing-machine in the country, what myriads on myriads of the pupæ might be collected and destroyed!"

Some natural enemies of the wheat-midge, however, keep it powerfully in check; and, in particular, three species of ichneumons, "minute benefactors of our race, sent in mercy by Heaven, know how to introduce their eggs into its larvæ, thus preventing the mischief they would otherwise occasion, and saving mankind from the horrors of famine." One of these ichneumons, *Encyrtus inserens*, is black and shining, and about half the length of the wheat-midge; another, *Eurytoma penetrans*, is black, with a brassy lustre, the abdomen glossed with blue, compressed, and truncated behind; and the third and most important, *Platygaster tipulæ*, is a minute black midge-like fly, with the legs and the base of the antennæ red,—the male quite black, and rarely seen,—the female of a pitchy colour, with a sharp ovipositorial point at her tail, exceedingly abundant and active in all infested fields in the months of July and August. "Superficial observers who have noticed the larvæ of the wheat-midge in the ears," remarks Mr. Sidney with particular reference to the *Platygaster tipulæ*, "have mistaken the ichneumon, which they have observed amongst them, for the parent of these larvæ, and have consequently condemned it as the origin of the very ills it is destined to diminish. This affords another instance of the folly of hasty conclusions, and of the false

reasoning relative to the inferences people deduce without accurate investigation, when they merely see two things together. Just in the same way some farmers have concluded that the little ichneumon flies we are now noticing must lay the eggs producing the larvæ of the midge, because they have themselves seen them amongst the corn containing these larvæ. It is time for all observers to arrive at a better state of knowledge, lest we destroy, as authors of mischiefs, the friendly antidotes to their increase. Prejudice and hasty judgment lead to perpetual misconstructions as to things both moral and natural. But to return to the ichneumon. This little platygaster may be readily found on the glumes of the wheat-plants, in the months of July and August. It runs rapidly over the ears, and seems to know well which are those occupied by the larvæ of the midge. The author found numbers of them in various wheat-fields in August, 1845; and almost invariably, on examining the ears on which they appeared, discovered that they contained the objects of their search. The ichneumon hunts for them with the utmost eagerness, and by the aid of a sharp tail places a single egg in each of their bodies. The sight has been witnessed by the following experiment: a number of larvæ of the wheat-midge were put upon a piece of white paper, pretty near each other, and an ichneumon was dropped into the midst of the group. The energy of her manner, the rapid vibrations of her antennæ, and the whole of her attitudes, were most amusing. On approaching one of the larvæ, her agitation quickened to the utmost intensity; she soon bent her body in a slanting direction beneath her breast, applied her tail to the larvæ, and, becoming still as death, sent forth her curious sheath and deposited her egg in the victim, which writhed considerably under the operation. If she came to one that had previously an egg in it, she left it in an instant and sought another; for the platygaster lays but one in each. This, however, often repeated, destroys a great many of these little devastators of the grain. The observations of Professor Henslow confirm those which have been already made. He says, 'When these eggs are hatched, the young maggots which they produce, and which are the caterpillars of the ichneumons, feed upon the fleshy or muscular parts of the caterpillar they are attacking, carefully avoiding the vital parts. At length the caterpillar they have been thus devouring alive dies; or, as frequently happens, it changes to the state of a chrysalis before it is destroyed. The ichneumon caterpillars also pass to the chrysalis state, and either remain within the body of the dead caterpillar, or come out before they assume the fly state. Each species of ichneumon is restricted in its attacks to one or at most to a few particular species of caterpillar; and the females instinctively proportion the number of eggs they deposit in each individual to the relative size of their own offspring and that of the insect on which they are destined to prey.' It is impossible to contemplate these habits of the minute insects thus brought before our notice, without being deeply impressed with the omnipresence of the great Being to whom all things owe their existence. The same hand that spread the north over the empty space, and suspended the earth upon nothing, and keeps the stars in their courses, regulates the numbers, instincts, and uses of the smallest living things, appearing equally perfect in all:

> 'What less than wonders from the Wonderful,
> What less than miracles from God can flow?'"

The American wheat-midge or Hessian fly, *Cecidomyia destructor*, works great havoc in America, and has of late years become known in various parts of Continental Europe, but does not seem to have ever been detected in Britain. Yet it deserves somewhat particular notice, at once as an object of general curiosity to agriculturists, and on account of its congenership to the British wheat-midge, and for sake of the possibility of its yet becoming practically and painfully known to the British farmer. "The Americans," says Mr. Curtis, "entertain an idea that this fly was first introduced into their country in straw which accompanied the Hessian troops; whence they have given it the appellation of Hessian fly. It has been occasionally a dreadful scourge in North America, for the larvæ have committed such ravages on the wheat-crops as to cause even famine in the land. It was not until the autumn of 1833 that this destructive insect, or a species closely allied to it, was observed in Hungary; whether, from its previous rarity, it had been overlooked, or had not found its way into the Austrian dominions, is not known. Kollar states that it appears, from a report transmitted to the Archduke Charles, that in the beginning of June the ears of wheat were observed to droop and the straw to bend, on his estates at Altenburgh, although the crop was previously in fine condition: in a few days, patches on the poorest soil in different parts became entangled, as if matted together by heavy rains or high winds, which were supposed at first actually to have been the cause. This soon proved to be unfounded; for the mischief gradually spread from the poor to the best lands, until the whole was blighted. Two-thirds of the straw at least was laid in less than a week, and the work of devastation was completed by the heavy fall of rain which took place during the latter part of June. The straw thus prostrated produced only small abortive ears; the few grains they contained were shrivelled, and would scarcely ripen, and the straw was of a very bad quality. On examining the roots of those plants which had died off, the soft straw where the larvæ had stationed themselves in families, within the sheath of the leaf, ap-

peared withered, tough, and brown, yet not wounded: at this period the larvæ were transformed into pupæ, which were found in clusters inside of each leaf-sheath, at the first joint next to the crown of the root. On the estates of the Duke of Saxe Coburg, at Weikendorf and in other parts of that neighbourhood, whole fields were destroyed. The larvæ were found to live in society, forming a sort of nest between the straw and the sheath. They are said to penetrate into the tube of the straw: however that may be, they deprive the stem of the sap, and it consequently withers and dies. The larvæ are of a pale green colour, with a minute black dot above; they do not exceed two lines in length; and they live from about three weeks to a month: the pupa is brown, and enclosed in a case. It was several weeks before the fly hatched; it is extremely small and delicate, scarcely so large as a common gnat; the body is clothed with short black hairs; the thorax is very convex, smooth, and shining; the scutellum projects, and is rounded behind; the breast being sometimes of a golden yellow colour, the abdomen brownish; the wings are blackish; the deep yellow of the base sometimes extends to the nervures, where it is gradually softened off: the poisers are yellowish white; the base of the thighs is golden yellow. The female has a black streak on the abdomen. The above descriptions do not agree with Say's; and I see, by a paragraph in the Entymological Transactions, Mr. Herrick, of New Haven, North America, had informed Mr. Spence that the accounts hitherto published concerning the natural history of the Hessian fly were very erroneous: he considered it to be referable to Meigen's genus *Lasioptera;* and it is attacked by five parasites, two of which belonged to the genera *Eurytoma* and *Platygaster*. Mr. Spence also observed, at a previous meeting of the Entomological Society, that Dr. Hammerschmidt's *Cecidomyia*, which is the Hungarian one, is specifically distinct from Mr. Kirby's *C. tritici;* and that Say's *C. destructor*, called the Hessian fly, is different from either. The female of the American species lays in the autumn not more than eight eggs, which are introduced by her ovipositor between the sheath and the stem, close to the base, where the larvæ feed as soon as they hatch, and are said to live through the winter with their heads downward; but the mischief they cause is not discoverable until the wheat is more advanced. A parasite, called by Mr. Say *Ceraphron destructor*, but which may possibly be a *Pteromelas* in the opinion of Mr. Westwood, though smaller than the *Cecidomyia*, proves so formidable an enemy, by depositing its eggs in the larvæ, that few of them become pupæ; otherwise, Mr. Say believes that their wheat-crops would be totally annihilated. Kollar also found the majority of his pupæ so full of a similar parasite that he felt convinced the crops would not be attacked by the wheat-midge the following year; which prediction was completely verified."

The *Chlorops pumilionis* injures the young stem or central shoot of the wheat plant after it has risen a considerable way above the ground. The genus to which it belongs comprises upwards of twenty British species, which may often be observed in great numbers on umbelliferous plants, and not rarely in houses, during the months of autumn; and it is characterised by the face being naked, the forehead tomentose, the seta of the antennæ distinctly two-jointed, the abdomen oval, the feet naked, the costal nerve of the wing extending to the tip of the submarginal, and the prevailing colour, in most cases, being brown with various stripes and spots of bright yellow. The wheat-fly species bears the name of *pumilionis* or 'dwarfish,' in consequence of its dwarfing the wheat-plants which it attacks, destroying their proper stems, and causing them to throw out many lateral shoots which seldom attain any considerable height. Its predominant colour is black; the under side of the head and two longitudinal lines on the thorax are yellow; the under side of the body is pale yellow, with two black spots on the mesosternum; the halteres are white; the legs are ash-grey with black tips. The maggot is small and white, the body composed of eleven well-defined rings, the head pointed at the end, black at the tip, and resembling the letter V in shape. The pupa is yellow, smooth, and shining, and rather more than the twelfth part of an inch in length. The *Chlorops pumilionis* caused great alarm in Britain about 50 or 60 years ago, in consequence of being mistaken for the American wheat-midge; and it was first noticed in a scientific way, about that time, by Bjercander in Sweden and by Mr. Markwick in Britain. It attacks rye much more frequently than wheat in Sweden and other northern countries. Bjercander did not succeed in observing it deposit its eggs; but he found its larvæ in great plenty from the 23d of April till nearly the end of May, when they became for the most part fully grown. He could not discover any holes in the stems of the plants; and he thence inferred that the eggs or larvæ must enter at the top of the leaves, and that the fly when matured forces its way upwards and escapes. Mr. Markwick found the larvæ lodged in the centre of the stem of wheat plants just above the root; and he observed that, by the end of March, many of them were full grown and passing into the state of pupæ. He did not see the deposition of the eggs any more than Bjercander; and he indulges in some conjectures as to the manner in which they had been introduced into the field, concluding that it could not well be by means of the manure, as that consisted entirely of lime. What we know of the proceedings of other insects, in similar cases, leaves little room to doubt that the eggs were placed on the plant by the fly itself. "The larva and chry-

salis," says Mr. Markwick, "were always found deposited on the principal stem, just above the root. This stem it invariably destroyed, which gave the crop a most disastrous appearance, so that there was scarcely a hope of any produce; but after the larva had changed into a chrysalis state, the mischief ceased, and the root was not so materially injured as to prevent its throwing out fresh shoots on each side, and stocking itself, as the farmers term it, as I experienced by those I planted in my garden." Bjercander recommends that the infested stems should be pulled up and burned while the insect is yet in the larva or pupa state; but as the plant makes such vigorous efforts to recover itself, and even at times succeeds in bringing ears to maturity, it seems preferable, as Mr. Markwick advises, to pinch the central leaves just above the crown of the root, which would probably destroy the insect without materially affecting the vitality of the plant. It was found that it was only the early sown wheat that was attacked, such fields as were sown later than the middle of October escaping without injury.

WHEEL-CARRIAGE. The principal wheel-carriages used in British agriculture are noticed in the articles CART, WAGGON, and LIQUID MANURE CART; and some important topics connected with them are discussed in the articles FRICTION, SPRING, DRAUGHT, ROAD, and HORSE. We shall, in this place, make ample extracts, with some slight alterations, from an able essay on agricultural wheel-carriages by the distinguished mathematician William Galbraith, in the 2d and 4th Volumes of the Quarterly Journal of Agriculture.

Wheel-carriages are generally divided into two kinds or classes—one having two wheels, and the other four; and both these have their peculiar advantages. For lighter purposes, those having two wheels are generally employed. They are more readily managed, quicker in their movements, and relatively perform a greater quantity of work with the same number of horses than the larger machines; while for the transportation of the more bulky and ponderous objects, those having four wheels are most convenient, and often absolutely necessary. The bodies of the carriages which are intended to contain the load supported upon the wheels, are, or ought to be, formed according to the species of loads they are likely to carry. When the loads are specifically light, the body should be large and full, so as to bring the centre of gravity as low as possible, to prevent the cart from overturning on an inclined road, when highly loaded with comparatively light materials, as hay, straw, and similar substances. For loads of great specific gravity in particular, that is, loads of considerable weight within a small bulk, the body of the carriage should be strong and compact, and every advantage taken of the materials of which it is constructed, to render it sufficiently strong, with the least possible weight, by means of a proper arrangement of its parts to resist pressure without derangement or fracture. This can only be accomplished by possessing an accurate knowledge of the relative strains in different parts, and then applying the iron, wood, and other materials, in the best possible manner, founded upon scientific principles. In the common cart, for example, with two wheels, since the shafts must support generally the most considerable strain in a vertical direction, they should therefore be stronger that way than in a horizontal direction; or a section of each shaft somewhat rounded in an elliptical or parabolic shape, should have its greatest diameter in a vertical position. This is obvious from the well known property of beams demonstrated by Galileo, that their strength is proportional to the breadth multiplied by the square of the depth. Whence the relative strength of two beams of the elliptical or parabolic form, supposing the area of the section to be the same, is as the longer diameter to the shorter. This shows the great importance of giving every part not only its proper size, but also its true position. No doubt sometimes in turning a cart, there is an additional strain on the shafts in a horizontal direction, though far from being sufficient to justify such a deviation from sound principles.

The axle ought to be properly and securely fixed to the body of the carriage, by bolts, hoops, or such other means as may seem most convenient. To give the wheel the best position for easy motion, and as little friction as possible, the general shape of the axle should be straight. Its arms should be rounded, slightly tapering, in the form of a frustrum of a cone, and smallest at the extremities, that it may not wear loose; and at the same time that it may allow the wheel to be readily removed and replaced without being too tight, or having too much play, though sufficient to admit the usual compositions of tar, grease, &c., to lubricate the axle and diminish friction. As every body is liable to bend by pressure, it is obvious that the axle, whether made of wood or iron, will be liable to flexure in a slight degree, in a vertical direction. Since the force of the power applied to move the carriage forward will be opposed by the friction of the wheels upon the irregularities of the road, there will also be a slight tendency of the axle to bend backwards at the extremities. These two flexures, however, from the nature and construction of the machine, must be very slight: and therefore a very small bend downwards and forwards given to the extremities of the axle, will be sufficient to counteract these effects, and render the lower surface of the arms of the axle nearly horizontal within the naves of the wheels.

Great care should be taken not to give the axle at its entrance into the nave of the wheel too great a bend, as is sometimes customary, particularly in England. The bad effects of this are, to cause the wheels to be formed somewhat of the shape of the frustrum of a cone, of which the vertex is at some distance from the carriage, nearly in the direction of the axle, whereby the wheel, instead of proceeding forward, naturally has a tendency to move round the imaginary vertex of the cone just alluded to, as a centre, revolving obliquely, producing an irregular and unfavourable action of the parts in contact, and increasing friction. It is likely, indeed, that the axle in the rude machines of early ages was at first straight, but as improvements were introduced, it would in time receive such modifications as the judgment or caprice of the constructor might suggest. Still, however, there seems to be no just objection to the axle being nearly straight, in order to insure the best and easiest motion to the wheels, provided the part within the nave be truly cylindrical and of equal diameter throughout, though

there may be some other advantages attending a deviation from this form, which will be afterwards examined. Thus A B, *Fig.* 1, would likely be among the more early modes of constructing the axle, having shoulders at C and D, and iron bars called *linch-pins* at E and F, to keep the wheels G H and I K (having their planes perpendicular to their axis, and rendering their motion of rotation by that means the easiest possible), steady in their proper position; the parts E C and D F, round which they revolve, being equal cylinders of the same diameter. In this mode, however, it would be found from experience, that the wheels would with difficulty, or at least less easily, be removed and replaced, more especially before the invention of a machine for raising the wheel from the ground, as is now usual, at least for gentlemen's carriages. This would suggest the propriety of giving the axle a slight taper towards its axis at the extremities, in order to remove the inconvenience. At the same time, the wheel may be prevented from becoming loose by wearing, by pressing the nave towards the shoulder, and tightening it by the linch-pin. The axle would then have the shape of *a b*, *Fig.* 2, tapering all around regularly from *c* to *a*, and from *d* to *b*, and the planes of the wheels *gh*, *ik*, would still be at right angles to the axis, rendering their circular motion the most favourable for ease and simplicity. One bad property would result from this structure, namely a tendency of the wheels to slide off at the end of each axle, thus producing a considerable pressure on the linch-pins, at *e* and *f*, which would be both inconvenient and injurious, from the severe friction of the bushes in the naves against them. The upper parts of the wheels would, in both the preceding methods, be liable to rub or chafe the carriage, or the load when it projected over the sides of the cart; while in wet weather the mud carried up by them would partly be thrown into the cart, and would partly fall upon the axle and nave, and work in between the axle and bush, causing a considerable wear in both in a short time.

Fig. 1.

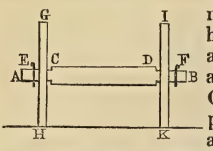

Fig. 2.

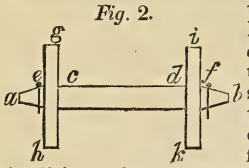
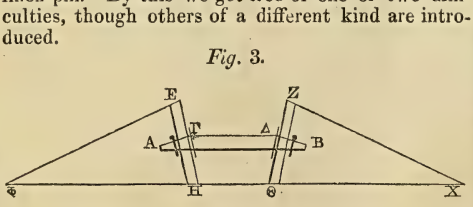


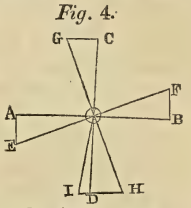
To obviate these inconveniences, it would next be requisite to render the lower surface of the tapering and working part of the axle called the arm perfectly, or at least nearly, horizontal, so that the pressure on it should have no tendency to force off the wheel, and make it press unnecessarily on the linch-pins, while the upper parts of the wheels by this means would be thrown outwards from the load, and would move quite free of it. Indeed, it seems to be sanctioned by experience, that the axle should be slightly bent at the shoulder, in order to give the wheel a tendency to press upon the axle rather than on the linch-pin. By this we get free of one or two difficulties, though others of a different kind are introduced.

Fig. 3.



Let AB, *Fig.* 3, be the axle, having its under side nearly a straight line, the extremities ΓA, ΔB, tapering within the naves; then the planes of the wheels become oblique to the horizon: the exterior surface of the felloes must be bevelled so as to become a small frustrum of a cone, the vertices of which are about Φ and X, thus introducing oblique action in motion, and an unfavourable position of the spokes of the wheels, with regard to strength, since they must be strongest when perpendicular to the level plane ΦHΘX. This last evil may be corrected by *dishing* the wheels, as it is called, while the oblique motion of the wheels arising from their necessarily conical shape, produces less injury in ordinary circumstances than that derived from the pressure of the nave against the linch-pins in equally tapering axles. Hence, if the under surface of the axle be straight, the quantity or amount of the dishing ought to depend upon the angle of taper of the axle, the one being exactly equal to the other. For let AB, *Fig.* 4, be a horizontal line, and CD a vertical line at right angles to it. Also, let EF be a part of the axis, or central line of the tapering axle, and GH a perpendicular to it, passing through O as before. Then the angles AOD, EOH are right angles. From each take away the common angle EOD, and there remains the angle AOE equal to DOH; that is, to bring the under part OH of the oblique wheel GH into the vertical position OD, it must decline from the plane of the oblique wheel GH at an angle of *dishing* HOD, equal to AOE, which the oblique central line of the axle makes with the horizontal line AB. If this principle be attended to, the spokes will, on a road nearly level, be truly vertical, or in the strongest position, as in this situation they ought to be.

Fig. 4.



In the case of iron axles, the taper is in general small, and perhaps would not, in many cases, be sufficient for the required quantity of dishing, which should be about one-twelfth of the diameter of the wheel; whence this easy practical rule,—the diameter of the wheel in feet gives the dishing in inches. Then a moderate bend in the axle will be requisite to bring them nearly to an equality, though the dishing should be properly a little more, not exceeding an inch or two, taking the direction OI; so that, when the carriage is inclined in a small degree, the under spokes are truly vertical. On these principles, let $\alpha\varrho$, *Fig.* 5, be the central line or axis of the cylindrical portion of the axle within the naves, to which $\varkappa\lambda$ is perpendicular, similarly to EH, *Fig.* 3, and $\varrho\eta$ perpendicular to the under surface of the axle; then, as has just been demonstrated in last article,

Fig. 5.

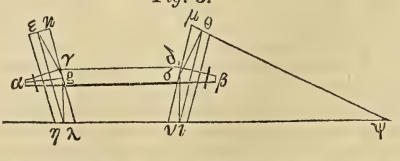


Fig. 4, it is obvious, that the angle $\eta\varrho\lambda$ is equal to the inclination of $\alpha\varrho$ to the sole of the axle. The taper consequently ought to regulate the amount of the dishing when properly executed, so that the spokes, in ordinary circumstances, may be nearly perpendicular to the plane of the road. Whence $\varepsilon\varrho\eta$ and $\theta\sigma\iota$ give the dished shape of the wheels; and, to make the dishing moderate, the taper of the extremities of the axle, combined with the bend, should not, taken together, be great. Hence also the stability of the carriage is not injured by this mode of dishing, because the centre of gravity is in as favourable a situation as if the wheels were actually vertical, since the spokes in the under part of the wheels are nearly vertical, however different the distance between the

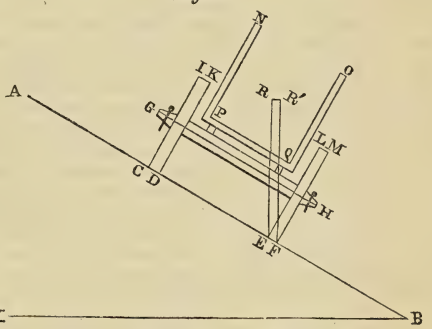
felloes of the wheels may be at top and bottom, while the greater distance at the top gives additional room for both carriage and load. In fact, it is to the want of a proper attention to the nature and true properties of the axle, that most, if not all, the faults said to attend well constructed dished wheels may be attributed. Undoubtedly the oblique action of conical wheels is unfavourable for easy motion; but, if the spokes in the under side of the wheels be at right angles to the truly horizontal under surface of the axle within the nave, the easy motion of the wheel would not be much injured by such a shape, if it were possible that the exterior surface of the iron-hoop could touch the rod at the lower point only. Now as this, though not perfectly true in bad roads, is nearly so in good ones, there seems to be little cause for the vituperation of dished wheels properly made, which has been generally cast upon them by many popular writers, who have not investigated their properties upon scientific principles. Indeed they offer several advantages which the other wheels do not, and a careful consideration of their properties can alone show their qualities. Any custom very generally adopted, frequently results from some valid reason of the inventor, which is often lost sight of by his successors, who continue, as they think, to follow the original plan, sometimes with improvements; but having become ignorant of the motives and principles of the first constructors which should have guided them, they fall frequently into extremes, which are really injurious. In addition to the taper of the axle, a considerable bend, much more than is requisite for the purposes already pointed out, and consequently injudicious, is often given to it at the shoulder where it enters the nave, thus producing a very injurious action in the wheel, placing the spokes, or rather the plane of the spokes, too much in an inclined position towards each other at the bottom, unfavourable to strength, and diminishing the stability when the carriage is inclined on a bad road. All these ought to be particularly guarded against, although perhaps a slight degree of dishing more than the taper of the axle, depending on the amount of bend, may be given, especially when the wheels are narrow, as a slight inclination of the spokes *outwards* appears to be of use in keeping them more steady on their axles than if they were exactly vertical. By an inclination of the carriage, too, a greater proportion of the weight of the load is thrown on the lower wheel, and then its spokes, being in a vertical position, are able to exert all their strength with advantage. The dished form will be found on experience to render the wheels more lasting, because, from their slightly conical shape, the effect of the felloes, supported by the iron hoop, tends to bind them together, and prevents the spokes from working loose in the mortises of the naves. But when the spokes, as sometimes recommended, are at right angles to the axis, this property is lost, and the spokes are then chiefly prevented from working in the direction of the axis by the support of the nave only, and in time acquire a slight dishing in the opposite direction, or toward the cart, at the same time the tops of the wheels become closer than the bottom, which makes them look very unseemly. In some wheels each alternate spoke is made to have a different inclination, producing by that means greater stiffness and mutual support, by bearing against each other, and acting as braces in the direction of the axis, than when they have all the same degree of dishing.

The next property to be considered is the stability of wheel carriages, or their tendency to resist oversetting when on an inclined road, and moving at a considerable velocity. This depends upon the position of the centre of gravity of the carriage and load together. The lower it is, so much the more stable will the carriage be. A proper proportion between the height and breadth regulates this point. When carriages are narrow and high, the centre of gravity rises; and, on the contrary, when they are broad and low, under the same capacity, it descends; and a just proportion between these serves to assign its true and safe position, so as to fall within the wheels, even when the carriage is moderately inclined. It is obvious, then, that it depends in part on the proper position of the under part of the wheels, when the distance of their centres is given. By increasing the distance between the felloes at the bottom, the stability may be increased; and, by diminishing it, the stability will be lessened. But it is clear that a certain latitude only can be given to this variation of the inclination of the planes of the wheels, otherwise their strength and efficiency will be injured; and we shall now endeavour to place the different varieties in one point of view, so that the relative properties with regard to stability also may become known. Let *Fig.* 6 be a

Fig. 6.



carriage supported on wheels, of which the spokes are perpendicular to the axis of the nave, as in *Figs.* 1 and 4, formerly given, and moving on the inclined plane AB. *Fig.* 7, also corresponding to *Fig.* 5, and *Fig.* 8 to *Fig.* 3, already explained, and moving on

Fig. 7.

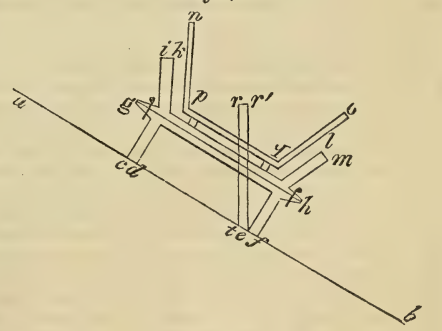


Fig. 8.

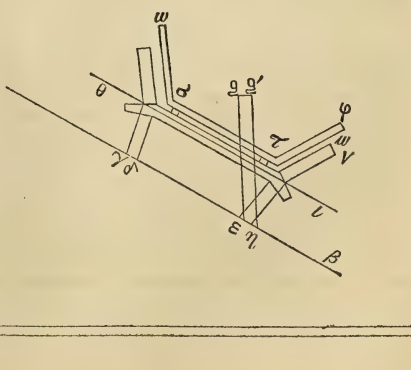

planes *a b*, *α β*, equally inclined to the horizontal or level line as AB to BX, *Fig.* 6. Also let the points marking the centres of gravity of these carriages be respectively R, *r*, *ϱ*, of which R is the highest above the road, from the smaller breadth of the body of the cart NPQO, which, from the shape of the wheels, cannot be wider at NO than at PQ. It is clear, from *Fig.* 6, that when the carriage is at rest, or moving straight forward, it is just stable, though very little more inclination would overset it, either by the wheel DI moving over any slightly higher obstacle, or by the wheel EM falling into a hollow. On account of the greater breadth at the top of the cart *n p q o*, *Fig.* 7, than that of NPQO, *Fig.* 6, the centre of gravity falls lower than R, and consequently the vertical line *rt*, passing through the centre of gravity *r*, falls nearer the middle between the wheels than RE. By reason of the bend in the axle of the cart, *Fig.* 8, which is, in this instance, too great, the soles of the wheels approach each other much more closely than either of the other two; and the vertical line ϱ^2, passing through the centre of gravity ϱ, falls nearly upon the bottom of the wheel, though, on account of the shape of the body of the cart, it is lower than either of the other two. Upon the whole, then, the construction of the cart or waggon, *Fig.* 7, with properly dished wheels on the plan formerly proposed, has still the advantage.—In addition to these, other means have been resorted to for the purpose of keeping the centre of gravity down. One of them consists in having the luggage placed as low as possible in travelling coaches, by carrying it in a box slung under the carriage, so as just to clear the road sufficiently. Such are the plans of some of our best coachmakers and agricultural implement makers.

It has as yet been supposed that the carriages were either at rest or moving forward in a straight line. It frequently happens, however, that, in the old roads in particular, a rapid turn, or quick bend, is met with in the road, where the carriage must turn smartly, producing what is called a centrifugal force, which has a tendency to throw the carriage over in the opposite direction, or towards the convex side of the turn. The amount of this force depends upon the radius of the curve in the road, combined with the velocity, which, in the case of the mail coaches, and travelling carriages, may sometimes be considerable. If this concur to augment the danger from the inclination of the road and a badly constructed carriage, on entering a bridge, or approaching a precipice in particular, the consequences may be fatal. Indeed, it is generally under these circumstances that the greatest accidents happen; whence a due attention to the proper formation of our roads is as indispensable for the safety of travellers, as an eligible construction of our carriages. To illustrate this to persons not very conversant with mathematical and philosophical inquiries, a few results, stated in a table, with conclusions drawn from them, will, it is hoped, be sufficient. The formulæ for obtaining the amount of centrifugal force are,

$$F = \frac{v^2}{r} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

which gives the effects in feet, supposing the force of gravity, generally denoted by *g*, to be 32 feet; *v* the velocity of the moving body, or the number of feet which it passes over in one second of time; *r* the radius of the circle in which the body is moving, which, in this case, is the radius of the curve in the road; and F the centrifugal force. If the centrifugal force be required in terms of the weight of the moving body, then

$$f = \frac{v^2}{gr} = \frac{v^2}{32r} \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

f being the value of the force, *v* the velocity, and *r* the radius of curvature, as before. Suppose the radius, or *r*, to be 100 feet, which is not an uncommon case, then will the following table, drawn up for the purpose, give the effects to different velocities:—

Velocity in English miles per hour.	Velocity in ft. in one second.	F in feet.	*f* in parts of the weight.
5	7·3	0·54	0·017
10	14·6	2·15	0·070
15	22·0	4·84	0·151
20	29·3	8·60	0·270
40	58·6	34·42	1·080
60	88·0	77·44	2·420
100	146·6	215·11	6·722

From an examination of the formulæ, it is evident that the centrifugal forces vary inversely as the radius of curvature, the velocity being the same: that is, as the radius of the curvature or bend in the road *increases*, the centrifugal force *decreases;* and, on the contrary, when the radius of the turn decreases, the centrifugal force increases. Therefore, as any other assumed radius is to 100 feet, that adopted in computing the foregoing table, so is the centrifugal force stated in the table to that for the radius required. Hence the effects of centrifugal force may, by this means, be estimated for any other curvature wanted. Thus, let the radius be 50 feet, one-half of 100, and F and *f* will be doubled, &c. From the principles of centrifugal forces, the centre of gravity is virtually thrown aside from R, *Fig.* 6, where it would be if the carriage were at rest, or moving forward in a straight line to R′; so that when the velocity is about ten English miles an hour, and the radius of curvature 100 feet, if the vertical line RE, passing through the centre of gravity R, were 32 feet in length, then RR′ would be by the table 2 feet nearly; that is, RR′ is $\frac{1}{16}$th of RE, or of the height of the centre of gravity above the road nearer the wheel EM, if the carriage turn rapidly at the rate of ten miles an hour, or $14\frac{1}{2}$ feet in a second of time round A as a centre, at the distance AE of 100 feet. It would be twice $\frac{1}{16}$th, or $\frac{1}{8}$th, if AE were 50 feet, which is not an uncommon case. In ordinary circumstances, the centre of gravity is less than 4 feet above the road, and therefore it might generally be about $\frac{1}{4}$th of 4 feet, or $\frac{1}{2}$ foot thrown aside from E to F, which would render the carriage, on such an inclined plane, just ready to overset. At twenty miles an hour, the centrifugal force, compared with gravity, is, from column 3d, 9 feet nearly, or $\frac{9}{32}$ of the height of the centre of gravity, or say, for the sake of simplicity, one-third of that height; so that, if the centre of gravity be 4 feet above the plane of the road, as formerly supposed, it would in effect be thrown aside by this means, nearly $\frac{1}{3}$ of 4, or $\frac{4}{3}$ foot, equal to $1\frac{1}{3}$ foot, or 1 foot 4 inches. Supposing the distance between the bottoms of the wheels to be 5 feet, then this effect of centrifugal force would be the same as if the carriage were moving on an inclined plane having a rise of 1 foot 4 inches in 5 feet, or at an angle of 15°. In like manner, the investigation might be carried to higher velocities; but enough, it appears, has been said to prove the danger of high velocities at rapid turns or curves in a road. On account of the good shape of the wheels, axle, and body of the carriage in *Fig.* 7, it is clear it would be just stable, since *rr′* would be less than RR′, on account of the centre of gravity being lower than that of *Fig.* 6, which is just ready to overset. Consequently *r′ e*, the vertical passing through the centre of gravity, would be just within the wheels, and the carriage would possess some degree of stability; while ϱ ε, (*Fig.* 8,) the vertical passing through its centre of gravity, just meets the

outer side of the wheel, though the centre of gravity ϱ itself, from the capacity of the carriage, derived from its peculiar shape, is the lowest of all the three forms, and therefore most favourable for stability. But the evil in this last case arises from the bad shape of the axle, which is considerably bent at the shoulder, and brings the bottoms of the wheels too close; therefore the centrifugal force throws the centre of gravity into the vertical line $\rho' n$ without the base, and overturns the carriage as easily as that shown by *Fig.* 6.

The proper size of the wheels is also a very important object in a well-constructed carriage. They ought not to be made too high, otherwise the horse draws disadvantageously, nor too low, since the friction would then be greater than necessary or expedient. Many vehicles are at the present time very improperly carried on remarkably small wheels, which causes great additional exhaustion to the horse, from the effects of friction, unless the roads be very smooth and well made. It is perhaps difficult to say what ought, in every case, to be the precise height of the wheels. It may generally be remarked, that they may vary between $3\frac{1}{2}$ and $5\frac{1}{2}$ feet in diameter, but cannot properly fall short of the one, nor exceed the other, without disadvantage. The fore-wheels in four-wheeled carriages are, in general, smaller than those behind, for the purpose of turning more easily, and giving a better position to the line of draught. otherwise they would be better if they were all of the same size. A great deal has been written on the relative qualities of wheels which have broad or narrow felloes; and opinions are generally given in favour of the former. The reasons assigned are, that the narrow wheels have a tendency to cut up and materially injure the roads; whereas, on the contrary, the broad wheels, acting like a roller, smooth down, consolidate, and harden them. This, as a general principle, is undoubtedly true; but the question still remains, What is the most advantageous breadth? It is not very easy to answer this question satisfactorily. By giving a considerable breadth to the wheels, they no doubt act as a roller, and are advantageous to the roads; but, at the same time, they become heavier by the additional wood and iron, supposing the hoops nearly of the same thickness, and they cannot well be reduced in thickness inversely as their breadth, otherwise they would be too thin to afford proper support to the felloes, and would require a frequent changing of the iron, which would be both troublesome and expensive. This would, in some degree, counterbalance the advantage to the roads, by the disadvantage of trouble, expense, and the additional load upon the cattle employed as a moving power. The difficulty appears, then, to be to combine the greatest advantage with the least disadvantage; and this will be accomplished by making them neither extravagantly broad nor too narrow, according to the size and nature of the cart or carriage, and the roads on which it will generally be employed. From $2\frac{1}{2}$ to 5 inches may be the limits within which they ought to be kept, except in extraordinary cases.

We now proceed to consider the agent generally employed in wheel-carriages as a moving power. A horse, when treading in a mill-path, at the rate of $2\frac{1}{2}$ miles an hour, will, on an average, raise about 150 lbs. by a cord hanging or passing over a pulley capable of easy motion, which is equivalent to 33,000 lbs. 1 foot high in a minute. This serves as a scale to measure the effective exertion of a horse, and is generally denominated a horse-power. Messrs. Boulton and Watt adopt a result somewhat less, or 32,000 lbs., in estimating the effect of their steam-engines, and Tredgold only 27,500. In different varieties of the horse, the power is doubtless different, and perhaps 30,000 lbs. may be a fair approximate value, in round numbers; and, when compared with the strength of a man, the effect of a horse will be, in ordinary circumstances, nearly equivalent to that of five or six men. A horse generally works with advantage about eight hours a-day only, while a man commonly can work, without injury, at least ten. The action of a horse is indeed greatly reduced by the length of time during which he works, though the rate of decrease is not perhaps well known. Writers on this subject have advanced different hypotheses, and given formulæ to ascertain the effects under various circumstances of load and velocity, and some of them are at least tolerably good, by affording approximations somewhat useful. Thus, according to Euler, if f be the force which an animal exerts, measured by the weight with which it is actually loaded, in the manner just mentioned, F the utmost effort which the animal can exert, or the resistance which, at a dead pull, it is just able to overcome, v the velocity with which the same animal is moving with a given load, V the velocity with which the power of drawing or carrying a load entirely ceases, then

$$f = \mathrm{F}\left(1 - \frac{v}{\mathrm{V}}\right)^2 \quad \text{.....(A)}$$

This formula, originally proposed by Euler, from theoretical considerations, has been shown by M. Schulze to be pretty near the truth, by direct experiments. The effect of animal strength, or quantity of work done in a given time, will be proportional to $f \times v$, or as the product of the force employed multiplied by the velocity of the animal's motion. It is also measured by E, the effect, which will be

$$\mathrm{E} = \mathrm{F}v\left(1 - \frac{v}{\mathrm{V}}\right)^2 \quad \text{.....(B)}$$

This, by the principles of the differential calculus, becomes a maximum when $v = \frac{\mathrm{V}}{3}$, and $f = \frac{4\mathrm{F}}{9}$; that is, the effect will be greatest when the animal moves with one-third of the speed with which, at its greatest velocity it is only able to move itself, without carrying any load, and at the same time is loaded with four-ninths of the load it is capable of moving. It also appears that the greatest effect produced will be represented by the product of the two last, or

$$f \times v = \frac{4}{27} \times \mathrm{F} \times \mathrm{V} \quad \text{.....(C)};$$

that is, multiply the greatest weight which a horse can move at a *dead pull*, by the greatest velocity with which he can travel without being able to move any weight, then $\frac{4}{27}$ths of this product will be the greatest effect; or the product of the weight which he ought to exert to move a load, and the velocity at which he ought to travel.

Desaguliers, one of the more early writers on this subject, states that a horse drawing a weight out of a deep well, by a rope passing over a pulley having little friction, will raise 200 lbs. for eight hours together, at the rate of $2\frac{1}{2}$ miles an hour. Supposing the horse in this case to work to the greatest advantage, which is known to be nearly true, there would be obtained for the horse the value of F in formula (A), equal to 450 lbs. $\mathrm{V} = 7\frac{1}{2}$ miles an hour, v the known velocity, being $2\frac{1}{2}$ miles an hour.

Hence $f = 450\left(\frac{7.5}{7.5 - 2.5}\right) = 8\,(7.5 - v)^2 = 200$ lb. (D)

This result seems to be rather too great, when compared with some late experiments. In the eighth volume, new series, of the London Philosophical Magazine, p. 22, Mr. B. Bevan, civil engineer, has given the results of eight series of experiments on the power of horses working in the plough, which, at a mean for 144 horses, gives 163 lbs. for the constant force of each horse exerted in drawing the plough. If the third experiment be rejected, as it is so much under all the others, the mean would be 168 lbs. for

each horse walking at the rate of $2\frac{1}{2}$ miles an hour, whence as before,

$$f = 378\left(\frac{7.5-v}{7.5}\right) = 6.72\,(7.5-v)^2 = 168 \text{ lb.}\ldots.(E)$$

When the work of a horse is estimated by the load which he draws in a cart or waggon, it generally bears some relation to that load, according to the good or bad construction of the cart, and the more or less easy motion of the wheels. Though accurate experiments on the friction of wheel carriages have never been made with due care on a sufficiently extensive scale, yet no great error can be committed in supposing the friction on the road with a carriage of the ordinary construction, on the usual roads, to be between $\frac{1}{8}$ and $\frac{1}{12}$ of the load. If, then, a horse draw a ton in a cart, which a strong horse will continue to do for several hours together, his action may be supposed the same as if he raised the twelfth part of a ton, or 186 lbs., perpendicularly against the force of gravity, as in the case formerly mentioned. To raise a weight of 186 lbs., at the rate of $2\frac{1}{2}$ miles an hour, may, from the consideration of the action of a horse in a cart, be taken as nearly the average work of a strong draught horse in good condition. This is somewhat less than the estimate of Desaguliers, and a little more than that of Mr. Bevan, and it would give—

$$f = 7{\cdot}44\,(7{\cdot}5-v)^2 = 186 \text{ lbs.}\ldots\ldots(F)$$

The mean of all these co-efficients, 8, 6·72, and 7·44, will be 7·17, or, for simplicity, about 7 in whole numbers nearly, which finally give—

$$f = 7\,(7{\cdot}5-v)^2 = 175 \text{ lbs.}\ldots\ldots\ldots(G);$$

where v is, as usual, one-third of the greatest velocity ($7\frac{1}{2}$), or $2\frac{1}{2}$ miles an hour for strong draught horses. Indeed $7\frac{1}{2}$ miles an hour will be nearly the greatest velocity of such horses as are generally used in waggons and heavy carts, though, for those breeds of horses which run in mail-coaches, it must be too small, since they generally go at the rate of 10 miles an hour for one stage of 10 or 12 miles twice a-day, when they receive a good rest between them. From this circumstance, it is evident that V, or the greatest velocity, must vary according to the quality of the horse, in relation to the manner in which the animal may be crossed with the finer breeds, while F must likewise change its value somewhat indirectly as V, as it is well known that slow heavy horses, at a moderate pace, can exert greater force, while light horses, at a considerable velocity, exert less. It is not too much to estimate V at 15 miles an hour for the latter kind of horses, and F at 180 lbs. or 200 lbs., about one-half the former, for strong draught horses, and consequently

$$f = 180\left(\frac{15-v}{15}\right)^2 = \tfrac{4}{5}\,(15-v)^2 = 80 \text{ lbs.}\ldots(H)$$

supposing v to be $\frac{1}{3}$ of V (15) or 5 miles. By this means, the relative effects at their maximum value will be easily found from formula (B) or

$$f \times v = 175 \times 2\tfrac{1}{2} = 437\tfrac{1}{2} \text{ for cart-horses.}$$
$$f \times v = 80 \times 5 = 400 \text{ for coach-horses.}$$

So that the greatest effects by these different kinds of horses, when the most favourable velocity is combined with the best weight, are very nearly equal; and the greater strength of the draught horse is, in a great degree, counterbalanced by the greater velocity of the coach-horse.

To point out clearly the relative effects produced by these two kinds of horses at different velocities, the following table is given. Part I. for cart-horses, and Part II. for coach-horses.

TABLE I.

I. Cart-Horses.			II. Coach-Horses.	
v	f Form. (H).	E or $f \times v$	f Form. (I).	E or $f \times v$
Miles.	Pounds.	Effect.	Pounds.	Effect.
0	394	0	180	0
1	296	296	157	157
2	212	424	135	270
$2\frac{1}{2}$	175	437	125	312
3	142	426	115	345
4	86	344	97	388
5	44	220	80	400
6	16	96	65	390
7	2	14	51	357
$7\frac{1}{2}$	0	0	44	337
8	...	...	39	312
9	...	...	29	261
10	...	...	20	200
11	...	...	13	143
12	...	...	7	84
13	...	...	3	39
14	...	...	1	14
15	...	...	0	0

In this table, the first column contains the velocity of the horse in miles an hour; the second contains the force which a cart-horse is capable of exerting, in pounds avoirdupois, at the different velocities marked in the first column; the third, the effect or product of the velocity multiplied by the force in pounds which the animal can exert at that velocity. The second part, for coach-horses, contains two columns corresponding to those in Part I. for cart-horses. By inspecting this table, it will be found, by columns first and second, that a cart-horse works most advantageously when moving at a rate of between two and three miles an hour, and exerting a force in pulling of between 150 lbs. and 200 lbs., since the numbers in the third column are then greatest, and they decrease at both a greater and smaller velocity, and consequently the labour becomes less effectual. Comparing column first with the two columns in part second, it appears that the most effective rate of a coach-horse is five or six miles an hour, when exerting a force of traction of between 60 lbs. and 100 lbs.; consequently, there is a loss of effect when coach-horses move either faster or slower than this rate. No doubt the mail-coaches move faster than this rate (almost double indeed), but then the horses can exert little force if they do not injure themselves, or, if they are compelled to exert considerable force, they are worn out in a few years if they run two stages exceeding eight or ten miles a-day.

In order to illustrate this subject more fully, it will be necessary to have recourse to investigation Let f be the force exerted by the muscles of the animal, which is continued for a day, b the weight of the animal itself, s the space described in a given time, and v the velocity; then, by the principles of dynamics, v will vary as $\sqrt{\frac{fs}{b}}$. (Hutton's Course of Mathematics, vol. ii. § 133.) Now, the space s will be inversely as the duration of a day's work, denoted by d, or s is as $\frac{1}{d}$, and, consequently, v is as $\sqrt{\frac{fs}{bd}}$. For a horse of average strength, $f = 250$ lbs. nearly, and b about 1000 lbs., or, in general, the force exerted by the muscles will be about one-fourth of the weight of the animal's body; and as f, s, and b are all constant, it follows that

$$v \text{ is as } \sqrt{\frac{1}{d}} \ldots\ldots\ldots(I);$$

or, in words, the velocity varies inversely as the square root of the length of the day estimated in hours of working. It has already been shown, that the maximum velocity of a strong cart-horse is about 7·5 miles an hour, and that of ordinary coach-horses about 15 miles an hour, and that they cannot keep up that speed without injury for more than one hour. On these principles, the following table shows the duration of labour, and greatest velocity of a horse of each kind, in miles per hour, which, by interpolation, may serve for any other velocity required.

TABLE II.

Duration of Labour,	H. 1	H. 2	H. 3	H. 4	H. 5	H. 6	H. 7	H. 8	H. 9	H. 10
Greatest velocity. Cart-Horse,	M. 7·5	M. 5·3	M. 4·3	M. 3·7	M. 3·4	M. 3·0	M. 2·8	M. 2·6	M. 2·5	M. 2·4
Greatest velocity. Coach-Horse,	M. 15·0	M. 10·6	M. 8·6	M. 7·5	M. 6·7	M. 6·1	M. 5·7	M. 5·2	M. 5·0	M. 4·8

This table will represent very nearly the rate of decrease of velocity by an increase of the duration of the time of labour on a level road. But if the road be inclined the velocity of ascent will be diminished in the ratio of the sine of the angle of elevation, or it will be increased in descent in the same ratio; that is, if the road rise or fall one foot in a hundred, the velocity will be diminished or increased by about one-hundredth of that stated in the table. The results in the table are those corresponding to a horse loaded very slightly, so as to continue to do so day after day without being injured, and must therefore be the utmost limits of velocity, though the work done must be little or nothing. It is also obvious, that if the load be so great that the horse can just move it, the work done in this case will also be nothing; but between these limits of velocity and power there must be a ratio at a certain point, which will produce the greatest quantity of useful effect, and must therefore be the most advantageous for the application of horse-power. To obtain this quantity, let V be the maximum velocity when unloaded, v the actual velocity, as in formula (B), or $E = F v \left(1 - \frac{v}{V}\right)$. Let $V - v = u$, then $F \frac{v}{V^2} (V - v)^2 = F \frac{v}{V^2} \times u^2 = F \frac{u^2}{V^2} (V - u)$. Omitting the constant quantities, and making $u^2 (V - u)$ a maximum, by putting its fluxion equal to nothing, that is, $2 V u\,du - 3^2 u\,du = o$. Whence $u = \frac{2}{3} V$, and therefore $v = V - u = V - \frac{2}{3} V$, or

$$v = \frac{1}{3} V \quad . \quad . \quad . \quad . \quad (L).$$

Hence the velocity required to produce the maximum effect is one-third of the greatest velocity at which the animal is capable of moving. This gives about two and a-half miles an hour for cart-horses, and five miles an hour for coach-horses, when working eight or nine hours a-day. The time thus obtained seems to answer very well for draught-horses, but it is too long for mail-horses, where less effect but greater speed is required. It is easy to regulate this by the table. Thus, if a set of coach-horses have to run two stages of an hour each, or two hours on the whole in a day, then under 2 h., and opposite coach-horses, will be found 10·6 m., or about ten and a-half miles, the rate at which they may run without much injury, when slightly loaded, during one day of twenty-four hours, when well fed, and receive a good rest between the times of their running their prescribed stage. Since, by formula (A) $f = F \left(\frac{V - v}{V}\right)^2 = F \frac{v^2}{V^2}$, and $u = \frac{2}{3} V$, we have

$$f = F \frac{\frac{4}{9} V^2}{V^2} = \frac{4}{9} F \quad . \quad . \quad . \quad . \quad (l),$$

as already remarked, or the power at the maximum is four-ninths of the force exerted by the muscles at their greatest capability. This conclusion ought therefore to be attended to, when the greatest quantity of work is required from strong sound horses.

It will now be useful to show the addition of expense for a variation of velocity from the maximum of useful effect. Since the expense must be inversely as the effect produced, if the maximum, Table I., be taken for unity, then will be obtained

TABLE III.

Velocity.	Proportional Expense.	
Miles per hour.	Cart-Horses.	Coach-Horses.
0	Infinite.	Infinite.
1	1·48	2·55
2	1·03	1·48
2½	1·00	1·28
3	1·03	1·16
4	1·27	1·03
5	1·99	1·00
6	4·55	1·03
7	31·21	1·12
7½	Infinite.	1·19
8	...	1·28
9	...	1·53
10	...	2·00
11	...	2·80
12	...	4·76
13	...	10·26
14	...	25·57
15	...	Infinite.

From this table it will appear that, if a cart-horse walk at the rate of two and a-half miles an hour, the expense will be the least; but if slower or faster than this, the expense will be increased. Thus, at 5 miles an hour the expense will be doubled for a heavy cart-horse, while it will be the least for lighter coach-horses. The latter would be doubled at ten miles an hour, the usual rate of mail-coaches, consequently our mails are accelerated at great expense.

By comparing the three tables just given, a fair estimate of useful effect may be obtained, involving the velocity, duration of labour per day, and relative expense; and the proper value of each may be so chosen as to suit the object most particularly in view. Thus, a draught horse moving on a railway will produce the greatest effect at least expense, when moving at the rate of 2½ miles an hour, exerting a force of traction of nearly 175 lbs. (Table I.), and will work eight or nine hours a day (Table II.), on an expense denoted by 1 (Table III.), or the least possible expense. If the velocity be increased to 4 miles an hour, the animal will be able to exert a force of 86 lbs. only, work about three and a-half hours, at an expense of 1·27, or an increase of 27 per cent. In like manner, similar consequences may be drawn for other velocities and for other kinds of horses. Thus a coach-horse running at the rate of 10 miles an hour, can exert safely a force of traction of about 20 lbs. (Table I.), can work two hours a-

day only (Table II.), and that at an expense denoted by 2 (Table III.), that is, this velocity is obtained at an expense of cent. per cent., and so on of others. It is not affirmed that the conclusions derived in this manner are strictly accurate in every case that may occur, but that they are approximations, which will be found useful in making estimates of animal performance, not far from the truth.

WHEEL-DRAG. See Drag.

WHEEL-PLOUGH. See Plough.

WHEEZER. See Broken Wind.

WHEY. The liquid of milk which remains after the abstraction of the curd for sweet-milk cheese, or after the separation in any other way of the main portion of the milk's caseous and butyraceous principles. It is properly identical with the serum of the milk, but it also comprises small and variable unseparated portions of the caseum and the butyrine; and it varies widely in constitution according to the different species of the milk, or according to the different conditions of the same species, and according also to the manner in which the main bulk of the caseum and the butyrine are separated. Its chief constituent as to bulk is water; and its other proper constituents are lactic acid, sugar of milk, and several salts. See the articles Milk and Lactic Acid. The sugar of milk gives it its sweetish taste, and may readily be separated from it by evaporation, and is manufactured on a large scale in Switzerland, and applied to pharmaceutical purposes, and in particular is the vehicle of all the granulated medicines of the homœopathists. It has not a strong saccharine taste; but it yields by distillation every product obtainable by that process from vegetable sugar; and if it be dissolved in water, clarified with the white of egg, and evaporated in the usual manner, it will form delicate white crystals. The odour of its empyreuma resembles that of benzoic acid. The mucic acid found in all gums occurs in sugar of milk, and formerly took from it the name of saccholactic acid. This acid, when pure, is obtained in the form of a white powder; it decomposes the chlorides of barium and calcium, combining with the bases after they have absorbed oxygen; and it forms two sets of salts with soda and potash, and nearly insoluble salts with the metallic oxides.

Whey is used in the families of many farmers as a beverage; it is also used, on many farmeries in Scotland, for making a very palatable and wholesome variety of oatmeal porridge; and it is commonly given as both food and drink to cows, horses, and hogs. The whey obtained from the milk of three or at most four cows will, with a very small supply of other food, raise a young pig, from April till December, to a weight of from 12 to 25 stones; and, if the creature belong to any ordinarily good breed, will render its pork of very fine quality. In some slovenly dairies, whose business is currently managed in an ignorant or unskilful manner, butter is extracted from whey. If the curd is set and the whey taken off at the proper temperature, the butter that can be extracted from the whey will not indemnify the labour in collecting it. But if the milk is too hot when it is coagulated, or the curd too roughly handled, such a portion of the butyraceous matter will go off with the whey as it may be proper to collect. This is bad economy in itself, and also does great injustice to the cheese, for whatever butter is found in the whey is robbed from the cheese.

WHIMBREL,—scientifically *Numenius Phæopus*. A British bird of the longirostrous family of Grallæ. It is a congener of the curlew, and very closely resembles that bird in at once plumage, haunts, and habits; but is considerably smaller, and very much less abundant. It is called in some districts the half-curlew and the jack-curlew. It is occasionally seen in many parts of our shores in winter; but is most plentiful in May and in autumn. The male measures 16 inches in length,—the beak 3 inches; and the female measures about 18 inches in length,—the beak 3½ inches. The flesh is of similar excellence to that of the curlew. Whimbrels feed on worms and insects; and utter a cry or note which resembles a quick repetition of the articulations "tetty, tetty, tetty, tet." The eggs are pear-shaped, 2 inches 5 lines long, 1 inch 8 lines broad, of a dark olive brown colour blotched with darker brown, and four in number.

WHIN. See Furze.

WHINCHAT,—scientifically *Rubicola rubetra*. A British bird of the warbler group of Passerinæ. It is a congener of the stonechat, and very much resembles that bird in at once appearance, haunts, and habits; and it takes its popular name of whinchat from its partiality for the furze. It darts with undulating flight from bush to bush of furze in a thicket or on a moorland pasture, and always perches on the uppermost twigs of a bush; and pours out its song either from that position, or while hovering in the air over it. It appears about the middle or end of April; and it becomes fat, and a desirable object for the gourmand, in August. It feeds on worms, insects, molluscs, and berries. Its total length is rather less than 5 inches; its neck, back, smaller wing-coverts, and the top of its head are a mixture of pale brown and very dark brown; over its eye and ear-coverts is an elongated streak of white; its throat and breast are delicate fawn colour; and its belly is pale buff. The nest is generally built on the ground; and is formed of mosses and bents, and lined with fine bents and other grasses. The eggs amount to five or six, and have an uniform bluish green colour, with some minute specks of dull reddish brown, and measure 9 lines in length and about 6½ in breadth.

WHINSTONE. Any crystalline or unstratified rock except the quartzose and the granitic. The name is a popular one, and very loosely used, and has different latitudes of meaning among different persons and in different districts. It

most commonly designates the harder kinds of traps, — particularly basalts, greenstones, and compact porphyries; but it is sometimes made to include all greyish or bluish stratified rocks,— particularly the harder sorts of greywacke.

WHIRL-BONE. The joint, in the horse, between the thigh-bone and the pelvis. It is very strong, and very little liable to dislocation; yet it sometimes suffers extension of its ligaments,— and then the horse is said to be lame in the whirl-bone.

WHISKEY. See Alcohol.

WHISTLER. See Broken Wind.

WHITE BEAM TREE. See Aria.

WHITE BIRCH. See Birch.

WHITE BLIGHT. See Aphis.

WHITE CEDAR. See Cypress.

WHITE CLOVER. See Clover.

WHITE COPPER. An alloy consisting of 40·4 per cent. of copper, 25·4 of zinc, 31·6 of nickel, and 2·6 of iron.

WHITE FIORIN. The white bent grass,— *Agrostis alba*. See the articles Agrostis and Fiorin.

WHITE LAND. Land with a chalky soil.

WHITE LEAD. See Lead.

WHITE POPLAR. See Poplar and Abele.

WHITE-ROT. See Pennywort.

WHITE SPRUCE. See Fir.

WHITE-THORN. See Hawthorn.

WHITETHROAT,—scientifically *Curruca*. A genus of British birds of the warbler family of Passerinæ.

The common whitethroat, *Curruca cinerea*, bears many provincial names, having reference to its note or appearance or habits,—such as whurr, wheetie-why, muff, maggy cut-throat, and Peggy nettle-creeper. Its total length is 5½ inches; its general plumage displays various shades of brown colour; its chin and its throat are white; and the lower part of its neck, its breast, its belly, and its flanks are pale brownish white tinged with rose colour. It is readily distinguished from the babillard by its general brown plumage and by its yellow legs, and from other small birds by the feathers being very full and bulging out around the throat. It makes its appearance about the third week of April; and is more generally diffused than any other of our immigrant summer warblers. It has a merry song, and often pours it out while mounting in the air like the titlark, or while flitting from hedge to hedge. It frequents thickets, the sides of woods, hedgerows with broad banks, and lanes abounding with low bushes, brambles, nettles, and rank herbage. It feeds on white caterpillars, on other larvæ, on some perfect insects, and on most of the small garden fruits and berries; and it ranks as only a partially destructive hedge-bird, and has generally been accused of doing much more mischief than it really perpetrates. Its nest is built in a low bush or in a tangled mass of rank vegetation; and is a neatly woven structure of grass and straws and hair. The eggs amount to four or five, and have a greenish white colour spotted and sprinkled with ash-brown and with two shades of ash-green, and measure 9 lines in length and 6½ in breadth.

The lesser whitethroat, *Curruca garrula*, is rather shorter and more slender than the common species. Its total length is 5¼ inches; its head, neck, and back have a smoke-grey colour; its chin, throat, and breast are almost pure white; and its belly also is white, but tinged with red as far as the vent. Its habits and food are very similar to those of the common whitethroat. Its eggs measure each 8 lines in length and 6 in breadth.

WHITE-TREE. See Cajeput.

WHITE VINE. See Clematis.

WHITE VITRIOL. The sulphate of zinc. It is commonly prepared in England by direct combination of zinc and sulphuric acid, but in Germany by a process commencing in the exposure of roasted blende to the air and humidity. It crystallizes in transparent, colourless, right rhombic prisms, terminated by quadrangular summits; it slightly effloresces in the air, and is soluble in 2½ times its own weight of water at 60° Fahrenheit; and it is inodorous, and has a slightly acidulous, styptic, metallic taste. It is used in both human and veterinary medicine; but in large doses is a poison. It serves as a human tonic in dyspepsy, fluor albus, and some convulsive affections; as a human emetic in cases which require almost instantaneous emetic action; and as a lotion in some kinds of superficial inflammations. It serves in farriery as a good general caustic, as a lotion in the after-stages of inflammation of the eye, as a good application to indolent ulcers and in the latter stages of grease, and, under discriminating conditions, as a tonic for the horse but not for the cow. "It has been recommended as a tonic remedy for the horse," says White, "in doses of from half an ounce to six drachms; but I have seen it given to the extent of eight ounces at one dose to a glandered horse by way of experiment, without producing much inconvenience. The only effect produced, was upon the urinary organs, occasioning a frequency and a little difficulty in staling."

WHITE WATER. Tepid water containing bran or oatmeal, and given as a drink to a horse. Many horses who are bad feeders, and who become incapable of eating after very fatiguing labour or exercise, are refreshed and sustained by a drink of this kind, containing from a pint to a quart of oatmeal.

WHITFIELDIA. A recently discovered genus of ornamental exotic plants, of the acanthus family. The brick-coloured species, *W. lateritia* was introduced to Britain from the interior of Sierra Leone, a few years ago, by the gentleman in honour of whom the genus is named. It is a small, bushy, evergreen, stove shrub; and thrives best in a light open loamy compost. Its branches

are spreading and rather tortuous; its leaves are petiolate, opposite, oblong-ovate, entire, and somewhat leathery; and its flowers come out in racemes at the terminations of the branches. The racemes are disposed opposite to each other, like the leaves, and are drooping, and furnished with coloured bracteas; the calyx or outer covering proceeds from between the bracteas, and is composed of four segments, funnel-shaped, and of a brick-red colour; and within this is situated the corolla, projecting about half of its length beyond the calyx, a figure between bell-shaped and funnel-shaped, and divided into two portions, called the upper and the lower lips; and the former of these is again separated into two segments, and the latter into three.

WHITLOW-GRASS. Plants of the draba genus, and also the pepperwort draba. See the article DRABA.

WHOLE SCHŒNUS. See ISOLEPIS.

WHORL GRASS. See CATABROSA.

WHORTLEBERRY. Fruiting and ornamental plants of the vaccinium genus and heath family. The name is sometimes given loosely to all the vacciniums; but it more properly belongs only to the indigenous fruiting species,—the chief two of which are noticed in the articles COWBERRY and MYRTLE BILBERRY. See also the article VACCINIUM.

The bog whortleberry, bog bleaberry, or great bilberry, *Vaccinium uliginosum*, grows on boggy mountains in many parts of Britain, and is particularly abundant in the Scottish Highlands. It is a deciduous shrub; and has commonly a height of about two feet. Its branches are cylindrical; its leaves are obovate, entire, and smooth; its flowers grow several together, and have a flesh or pink colour, and bloom in April and May; and its berries are comparatively large and of a bluish black colour, and are less acidulous and less wholesome than those of the myrtle bilberry.

WIDOW-WAIL. See CNEORUM.

WIGANDIA. A recently discovered genus of ornamental exotic plants, of the hydrolea family. The Caraccas species, *W. caracasana*, was introduced to Britain from Caraccas in 1836; and is a small evergreen shrub, carrying lilac-coloured flowers, and delighting in a soil of loamy peat.

WILD BASIL. See BASIL (WILD).

WILD BEET. See STATICE and BEET.

WILD BLITE. See BLITE.

WILD BUGLOSS. See BUGLOSS (WILD).

WILD CHAMOMILE. See MATRICARIA and CHAMOMILE.

WILD CUMIN. See CUMIN (BASTARD).

WILDFIRE. See ERYSIPELAS.

WILD LIQUORICE,—botanically *Abrus*. An ornamental, tropical, climbing plant, of the kidney-bean division of the leguminous order. It is a native of the West Indies; and was introduced to Britain in the latter part of the 17th century. It constitutes a genus of itself, and bears the specific name of *precatorius*. It commonly attains a height of about 12 feet, and carries pale purple flowers from March till May; and it loves a soil of sandy peat, and is propagated from seeds.

WILD OAT. See OAT.

WILD OLIVE. See OLIVE (WILD) and SUMACH.

WILD PURSLANE. See SPURGE.

WILD RADISH. See RADISH and WEED.

WILD SERVICE. See SERVICE.

WILD TAMARIND,—botanically *Codarium*. A small genus of ornamental, tropical, evergreen ligneous plants, of the leguminous order. Two species, the acute-leaved and the obtuse-leaved, the former about 20 feet high, the latter about 12 feet high, and both carrying pale red flowers in February, have been introduced to British gardens from Sierra Leone; and they love a soil of loamy peat, and are propagated from cuttings.

WILD TANSY or GOOSE TANSY. See POTENTILLA.

WILD THYME. See THYME.

WILD VINE. See VINE.

WILDERNESS. A grove traversed by meandering or labyrinthine walks. It has long been a favourite feature of many a pleasure-ground and landscape garden. "Wildernesses," says Millar, "should always be proportioned to the extent of the gardens in which they are made; for it is very ridiculous to see a large wilderness planted with tall trees in a small spot of ground; and, on the other hand, nothing can be more absurd, than to see little paltry squares, or quarters of wilderness work, in a magnificent large garden. As to the situation of wildernesses, they should never be placed too near the habitation, nor so as to obstruct any distant prospect of the country,—there being nothing so agreeable as an unconfined prospect; but where from the situation of the place, the sight is confined within the limits of the garden, nothing can so agreeably terminate the prospect as a beautiful scene of the various kinds of trees judiciously planted; and if it is so contrived, that the termination is planted circularly, with the concave towards the sight, it will have a much better effect, than if it end in straight lines or angles. The plants should always be adapted to the size of the plantation; for it is very absurd for tall trees to be planted in the small squares of a little garden, and in large designs small shrubs will have a mean appearance. It should also be observed, never to plant evergreens amongst deciduous trees; but always to place the evergreens in a wilderness in a separate part by themselves, and that chiefly in sight." See the article LANDSCAPE GARDENING.

WILLOW,—botanically *Salix*. A large genus of ligneous plants, of the amentaceous order. They belong to the *Diœcia Diandria* of the Linnæan arrangement; and they group among the Amentaceæ with the poplars, and have all more

or less of an aquatic or sub-aquatic habit; but they comprise a wondrous diversity of size and form and character, and present to the botanist great difficulties and complexities of classification. About 75 species, besides a number of very distinct varieties, are natives of Britain; and about 160 have been introduced from other countries,—a very large proportion of them from Continental Europe, and particularly from Switzerland. A few are undershrubs, varying in height from a span or 6 inches to 2 feet; a considerable number are trees, varying in height from 25 to 70 feet; and the rest are shrubs, varying in height and character, at all stages, from undershrubs to trees. Three are tender evergreen tall shrubs and small trees; one is a hardy evergreen undershrub; a few are small, low, hardy, deciduous trailers or procumbents; a few are hardy deciduous undershrubs; and all the rest are hardy deciduous shrubs and trees. Many have villous leaves; many have smooth serrated leaves; and a few have smooth entire leaves. All may be propagated from cuttings; and most require a swampy situation; but a few thrive well on any common soil.

Many or most are ornamental; several are eminently medicinal; a few possess considerable value as timber-trees; and almost all are, in some way or other, useful. "The importance of the willow to man," says Loudon in his Arboretum Britannicum, "has been recognised from the earliest ages; and ropes and baskets made from willow twigs were probably among the very first of human manufactures in countries where these trees abound. The Romans used these twigs for binding their vines and tying their reeds in bundles, and making all sorts of baskets with them. A crop of willows was considered so valuable in the time of Cato, that he ranks the salictum, or willow field, next in value to the vineyard and the garden. In France, the leaves, whether in a green or dried state, are considered the very best food for cows and goats; and horses, in some places, are fed entirely on them, from the end of August till November. Horses, so fed, it is stated, will travel twenty leagues a-day without being fatigued. In the north of Sweden and Norway, and in Lapland, the inner bark is kiln-dried, and ground for the purpose of mixing with oatmeal in years of scarcity. The bark of the willow and also the leaves are astringent; and the bark of most sorts may be employed in tanning." "There is not a twig of the meanest willow," says Dr. Walker in his work on the Hebrides, "but what is turned to some useful purpose. The native willows supply the Hebrideans the use of ropes. A traveller there has rode during the day with a bridle made of them, and been at anchor in a vessel at night, where tackle and cable were made of twisted willows. In the islands of Colonsay, Coll, and Tiree, the people tan the hides of their black cattle with the bark of the grey willow. In Dumfries-shire, the bark of the apple-leaved willow is sold to the tanners, along with the oak bark, though at an inferior price. The barks of all the willows are of a very styptic nature; they are all capable of dyeing black, and therefore capable of being a tan." The foliage of the British willows, like that of the Continental ones, is greedily eaten by cattle; but, in consequence of its very astringent quality, it may be useful mainly in averting febrile attacks throughout morassy districts, or in situations much exposed to marshy vapours and miasmata, and may not be at all suitable or healthy to flocks who generally feed on dry pastures and breathe a pure dry air. The flowers of both male and female willows afford early and abundant food to bees. Most species of willows furnish an eminently effective fence against the encroachments of streams; for when planted on the banks, they spread their roots in all directions, and take deep and stubborn anchorage, and mat and consolidate the soil. The principal species expressly cultivated for the use of basket-makers are noticed in the article Osier; and the most abundant indigenous species of a rigid habit, forming rough bushes or large trees, and used in other departments of economy than basket-making, are, in many districts, popularly called sallows.

The common white willow, *Salix alba*, is a deciduous tree, and naturally abounds in moist situations, in woods and in the neighbourhood of towns and villages, in most parts of Britain and of Continental Europe. It usually attains a height of about 40 or 50 feet; and it grows quickly, and is an useful timber-tree when lightness of wood and cleanness of grain are required. Its bark is thick, full of cracks, and suitable for tanning, and is called by some writers *Cortex salignum* and *Cortex anglicanum;* its branches are numerous, and have a silky surface when young, and spread widely as they advance in age; its leaves are alternate, elliptico-lanceolate, pointed, silky on both surfaces, and glandular in the lowest serratures; and its flowers appear in April and May. This tree grows best in a deep rich soil by the side of water, and there attains a large size, and, if advantageously situated, has a very ornamental appearance, making a fine contrast in its slender silvery leaves to the dark foliage and dense masses of oaks and beeches on slopes and heights in its vicinity; but it rarely gets fair play or tolerable scope for developing itself as an ornamental plant, and is generally and most unworthily degraded to the condition of a pollard. A pretty well known variety of it, however, greatly excels the normal kind in at once handsomeness of appearance, rapidity of growth, and economical value of both bark and timber; and two other varieties, which might almost rank as distinct species, are the blue, *S. a. cærulea*, an indigen of moist meadows in some parts of England, —and the curled-leaved, *S. a. crispa*, found only on cultivated grounds, principally within parks and gardens. The bark of the white willow

abounds in salicin, and may be used as a substitute for Peruvian bark.

The golden willow, or yellow-branched willow, *Salix vitellina*, grows wild in the marshes of some parts of England, and of many parts of Continental Europe. It is a low deciduous tree, seldom attaining a height of more than from 15 to 20 feet; and it claims a place in ornamental plantations—not indeed for sake of any fine figure which it makes in summer—but on account of its smooth clear-yellow bark, which gives it a singular and striking effect among other trees in winter. Its leaves are smooth and serrated; and its flowers appear from March till May.

The sweet or sweet-scented or pentandrous willow, *Salix pentandra*, is a native of river banks in marshy and mountainous situations in many parts of Britain and of Continental Europe. It is a small deciduous tree; and commonly attains a similar height to the golden willow; but is capable of becoming a large timber-tree. It delights in a very wet situation; and commonly blooms from March till June; but has been observed throwing off its seeds and covered all over the top with its white seminal down in the beginning of December. Its bark is brown and smooth. Its leaves are far broader than those of any other willow, and have a general resemblance to those of the bay tree; they are smooth and of a shining green colour above, of a paler green below, and serrated on the edges; and they suffuse a delightful aromatic fragrance to a considerable distance after a shower, and plentifully emit it when bruised,—and for sake of this fragrance, the sweet willow deserves a place among ornamental plantations.

The triandrous willow, *Salix triandra*, inhabits river banks, wet woods, and similar situations in many parts of Britain, Switzerland, and Siberia. Its stem is erect, and, when not repressed or damaged, soars readily up to a height of 30 feet; its old bark peels off and falls toward autumn; its large branches are broad and solid, and crack angularly asunder like those of the plane tree; its young branches are erect, long, smooth, brownish, leafy, tough, and pliant, but are somewhat brittle at the insertion; its leaves are linear-oblong, serrated, smooth, and somewhat unequally sloping at the base; and its flowers bloom from May till August. This species is cultivated in England for white basket-work; and produces annual crops of tough, pliant, durable rods of 8 or 9 feet in length; but it comprises several varieties,—one of which, called the French willow, is cultivated in the eastern and south-eastern counties, and is more slender than the normal plant, and not near so tall.

The phylica-leaved willow, *Salix phylicifolia*, grows wild in a dwarfish state in the Scottish Highlands, and was long ago introduced to British collections with the habit of a small tree or tall shrub from the north of Sweden. It never at best attains so great a size as the triandrous willow. Its branches are numerous, flexible, tough, and serviceable for various purposes of the basket-makers; its leaves are lanceolate, smooth, serrated, and undulated; and its flowers grow in long catkins, and come out early in the spring from the sides of the branches, and soon afford a large quantity of down, which is wafted by the winds to a considerable distance. A variety of it occurs with broad leaves.

The almond-leaved willow, *Salix amygdalina*, is a native of the marshy grounds of Britain and of most parts of Continental Europe. It is a deciduous shrub, of commonly about 6 or 7 feet in height. Its branches are numerous, flexible, and tough, and are clothed with a light green bark; its leaves are lanceolate, pointed, serrated, smooth, eared at the base, and of a light green colour on both surfaces; and its flowers grow in oblong catkins, and appear in April and May, and turn to a light down in the summer. The branches or shoots of one year's growth are highly serviceable for basket-making; yet only those of what is called the old almond-leaved willow are well deserving of cultivation; for several varieties occur,—all of inferior value to the normal plant.

The crack willow, *Salix fragilis*, inhabits the banks of rivers in many parts of Britain and of the northern countries of Continental Europe. It is a small deciduous tree, and readily attains a height of 15 or 18 feet. Its branches are upright, and covered with a smooth brownish bark, but are very brittle and quite unfit for the uses of the basket-maker, and gave rise to both the popular and the botanic names of the species; its leaves stand on glandular footstalks, and are ovate-lanceolate, pointed, serrated, smooth, green on both surfaces, and from 3 to 5 inches long; and its flowers grow in long, slender catkins, with loosely disposed scales, and appear in April and May. The bark ranks with that of the common white willow as a good medicinal substitute for Peruvian bark. A variety called the almond-leaved crack willow has yellow-coloured bark, and casts it every year.

The goat willow, or great round-leaved willow, or common sallow, *Salix capria*, is a very abundant native of the woods of Britain and of most other parts of Europe. It delights in a dry rather than a moist soil. It is a deciduous tree of medium size, and readily or usually attains a height of about 30 or 35 feet. Its branches are cylindrical, smooth, shining, and of a dark green and brownish colour; its shoots are pubescent; its leaves are alternate, petiolate, oval, waved, rough, indented at the top, smooth and dark green above, and veined and densely woolly below; and its flowers grow in very large catkins, and have a yellow colour, and appear in April and May, and are much frequented by bees on their first coming out of their hives. The bark serves, like that of the white and the crack willows, as a good medicinal substitute for Peruvian bark; the

timber of old stems is admirably suited to many kinds of turnery; and the wood of the branches and of young stems is employed principally for hurdles and fuel. One variety of this species has long leaves ending in acute points; and another, called the striped sallow, has smooth leaves beautifully striped with white.

The Bedford, Dishley, Huntingdon, or Russel willow, *Salix Russelliana*, grows wild in the swampy grounds of some parts of England; and was first introduced to notice as a tree deserving of cultivation by the late Duke of Bedford; and has been found, on fair and ample trial, to be more profitable for at once its timber, its bark, and its rapid or economical habits of growth than any other tree-willow hitherto cultivated. It also possesses considerable claim to rank as an ornamental tree; and it has eminent adaptations for protecting the sides of streams, and defending their banks from encroachment. It has often been most injuriously confounded with the crack willow; though it exhibits almost a perfect contrast to that species in the aggregate of economical value, and can readily be distinguished from it by some of its most obvious characters. It is far handsomer, and has a lighter or brighter hue, and attains a far greater height and a far larger bulk; for it easily and commonly rises to the altitude of 40 feet, and is capable of acquiring the greatest girth. Its branches are long, straight, slender, cylindrical, flexible, very tough, smooth, and polished, and have none of the angularity in their insertion which those of the crack willow have, and may always be readily recognised from these when stripped of their foliage; its leaves are lanceolate, tapering at both ends, serrated all round, and very smooth,—and they have a much longer footstalk than those of the crack willow, as well as a different shape; and its flowers appear in April and May. The bark is very rich in both tannin and salicin; and therefore is eminently suitable for both the tanner and the physician. The timber possesses a high degree of at once lightness, toughness, and durability; and when newly cut is easily made to bend to any curvature; and when very old, in such situations as the cuppling of tolerably well constructed houses, is almost as hard as bone, very light, and still quite fresh; and it is well suited for boat-building and for many other uses. This valuable tree thrives best over a moist subsoil or near water.

The shining or hermaphrodite willow, *Salix hermaphroditica*, inhabits the banks of rivers in some parts of Britain, and in some parts of northern Europe. But it is a comparatively rare species; and is regarded by some botanists as merely a variety of the pentandrous willow. It commonly attains a height of 15 or 20 feet, and has a tree-like habit and an ornamental appearance. Its branches are numerous, erect, and flexible, and are clothed with a greyish bark; its leaves are ovate-lanceolate, acute, serrated, eared at the base, and green on both surfaces; and its flowers grow in long, narrow, loose catkins, and appear from March till June. This species is planted by the basket-makers to mix with other kinds for their different sorts of work.

The herbaceous willow, *Salix herbacea*, inhabits the mountains of various parts of Britain. It is a curious and striking contrast to the tree willows; for it is so small that six plants of it, roots, stem, leaves, and flower, may be placed between two leaves of a duodecimo volume. It commonly attains a height of about 5 or 6 inches, and blooms in June. But a variety of it found in Sunderland, or at least a plant possessing all its characters except size, commonly attains a height of about two feet. The species, however, both in its normal form and in this variety, is herbaceous principally in mere name and appearance, and has sufficient ligneousness to claim rank among undershrubs.

The brown willow, *Salix fusca*, inhabits moist heaths in various parts of Britain. It is a small, deciduous, ornamental shrub, commonly about 2 feet in height, having villous leaves, and blooming in May. Five varieties of it, all very distinct in character from the normal plant and from one another, and some of them remarkable for peculiarity of habitat, also grow wild in Britain. The prostrate, *S. f. prostrata*, is a creeper or procumbent of about a foot in height, inhabiting moist mountainous pastures; the stinking, *S. f. fœtida*, is a small-leaved creeper or procumbent of about 18 inches in height, inhabiting moist heaths; the creeping, *S. f. repens*, is a creeper of about 2 feet in height, inhabiting sandy heaths; the silvery, *S. f. argentea*, is a creeper or procumbent of about 4 feet in height, inhabiting sandy shores; and the trailing, *S. f. incubacea*, is a somewhat erect plant of about 4 feet in height, inhabiting sandy shores.

Hoffmann's willow, *S. Hoffmanniana*, is a timber tree of commonly about 30 feet in height, nearly allied to the triandrous willow, blooming in May, and inhabiting the river banks of Britain.—The lance-leaved willow, *S. lanceolata*, is a timber tree of about the same height as the preceding, blooming in April and May, and inhabiting the meadowy grounds of some parts of England.—The blackish broad-leaved willow, *S. nigricans*, is a large bushy plant, of commonly about 10 feet in height, blooming in April, and inhabiting the osier holts of England.—The shining willow, *S. nitens*, is a large shrub, commonly about 10 feet high, blooming in April, and inhabiting some of the mountains of Scotland.—The deceptive willow, *S. decipiens*, is a shrub of commonly about 8 feet high, blooming in May, and inhabiting the woods of some parts of England. —Bover's willow, *S. Boveriana*, is a bush of commonly about 8 feet in height, blooming in May, and inhabiting some of the mountains of Scotland.—Davall's willow, *S. Davalliana*, is a shrub of commonly about 6 feet in height, bloom-

ing in May, and inhabiting some of the mountains of Scotland.—The laurel-like willow, *S. laurina*, is a shrub of commonly about 8 feet in height, blooming in April and May, and inhabiting moist grounds in some parts of England.—The two-coloured willow, *S. bicolor*, is an undershrub, commonly about 2 feet high, blooming in May and June, and inhabiting stony hills in various parts of Britain.—The dark or petiolated willow, *S. petiolaris*, is a tall bushy plant, commonly about 10 feet high, blooming in April, and inhabiting some of the marshes of England.—Lambert's willow, *S. Lambertiana*, is a tall bushy plant, commonly about 10 feet high, blooming in March and April, cultivated for the use of basket-makers, and naturally inhabiting the banks of streams in some parts of England.—The apple-leaved willow, *S. malifolia*, is a small ornamental shrub, commonly about 3 feet high, blooming in April, and inhabiting some of the uplands of England.—The plum-leaved willow, *S. prunifolia*, is a small ornamental shrub, commonly about 3 feet high, blooming in April and May, and inhabiting some of the lofty mountains of Scotland.—The myrsine-like willow, *S. myrsinites*, is a small deciduous shrub, commonly about 3 feet high, blooming from April till June, and inhabiting some parts of the Scottish Highlands.—The veiny-leaved willow, *S. venulosa*, is an evergreen undershrub, commonly about 2 feet high, blooming in April and May, and inhabiting some parts of the Scottish Highlands.—The bilberry-leaved willow, *S. vacciniifolia*, is an ornamental undershrub, commonly about 2 feet high, blooming in April and May, and inhabiting some parts of the South of Scotland.—The keel-leaved willow, *S. carinata*, is a shrub of commonly about 3 feet in height, blooming in April and May, and inhabiting some of the lofty mountains of Scotland.—The little tree willow, *S. arbuscula*, is an ornamental undershrub, commonly about 2 feet high, blooming in April, and inhabiting some of the lofty mountains of Scotland.—The livid willow, *S. livida*, is an ornamental undershrub, commonly about 1 foot high, blooming in May, and inhabiting some of the heaths of England. All the species enumerated in this paragraph have smooth and serrated leaves.

The glaucous willow, *S. glauca*, is an ornamental undershrub, commonly about 2 feet high, blooming in May, and inhabiting some of the lofty mountains of Scotland.—The grey willow, *S. cinerea*, is a small tree, commonly about 15 or 18 feet high, blooming in May, and inhabiting the woods of Britain.—The hairy-branched willow, *S. hirta*, is a small tree, similar in height to the preceding, blooming in April and May, and inhabiting the woods of England.—The water willow, *S. aquatica*, is a tall shrub, commonly about 10 feet high, blooming in April, and inhabiting the wet thickets of Britain.—The acuminate willow, *S. acuminata*, is a small tree, commonly about 15 or 18 feet high, blooming in April, and inhabiting the moist woods of Britain.—Forster's willow, *S. Forsteriana*, is a tall shrub, commonly about 10 feet high, blooming in April and May, and inhabiting some of the woods of Scotland.—The woolly willow, *S. lanata*, is an ornamental undershrub, commonly about 2 feet high, blooming in May, and inhabiting some of the Scottish mountains.—The sand willow, *S. arenaria*, is a small shrub, commonly about 3 feet high, blooming in May and June, and inhabiting some of the lofty mountains of Scotland.—The silvery-sand willow, *S. argentia*, is a small ornamental shrub, commonly about 5 feet high, blooming in May, and inhabiting the sandy shores of Britain.—Dickson's willow, *S. Dicksoniana*, is an undershrub, commonly about 1 foot high, blooming in April, and inhabiting some of the lofty mountains of Scotland.—The small-leaved willow, *S. parvifolia*, is an ornamental undershrub, commonly about 2 feet high, blooming in April and May, and inhabiting the moist heaths of England.—The ascending willow, *S. ascendens*, is a curious minute undershrub, commonly about 5 or 6 inches high, blooming in April and May, and inhabiting the moist heaths of England.—Don's willow, *S. Doniana*, is a tall bush, commonly about 6 or 7 feet high, blooming in May, and inhabiting some of the Scottish mountains.—The rosemary-leaved willow, *S. rosmarinifolia*, is an undershrub, commonly about 2 feet high, blooming in April and May, and inhabiting sandy soils in various parts of Britain.—The marsh willow, *S. uliginosa*, is an undershrub, commonly about 2 feet high, blooming from April till June, and inhabiting the moist woods of Britain.—The cotinus-leaved willow, *S. cotinifolia*, is an undershrub, commonly about 2 feet high, blooming in April, and inhabiting some of the woods of Britain.—The olive-leaved willow, *S. oleifolia*, is an ornamental shrub, commonly about 4 feet high, blooming in March, and inhabiting some of the thickets of Britain.—The withered-pointed willow, *S. sphacelata*, is an undershrub, commonly about 2 feet high, blooming in April and May, and inhabiting some of the lofty mountains of Scotland.—Stuart's willow, *S. Stuartiana*, is a shrub of commonly about 4 feet in height, blooming in July and August, and inhabiting some parts of the Scottish Highlands.—The silky-rock willow, *S. rupestris*, is an ornamental shrub, commonly about 3 feet high, blooming in April, and inhabiting some parts of the Scottish Highlands.—Anderson's willow, *S. Andersoniana*, is a shrub, commonly about 3 feet high, blooming in April and May, and inhabiting some of the mountains of Scotland. All the species enumerated in this paragraph have villous leaves.

The netted willow, *S. reticulata*, is a similar curiosity to the herbaceous willow, having a height of only 5 or 6 inches, and having smooth entire leaves, blooming in June and July, and inhabiting some of the lofty mountains of Bri-

tain.—The slenderer willow, *S. tenuior*, is a small tree, commonly about 15 or 18 feet high, blooming in May, and inhabiting the banks of some of the Scottish rivers.—The rusty-leaved willow, *S. ferruginea*, is a tall shrub or small tree, commonly about 12 feet high, blooming in April, and inhabiting the hedge-rows and hedge-banks of various parts of Britain.—Woolgar's willow, *S. Woolgariana*, is a tall shrub or small tree of about the same height and blooming about the same period as the preceding, and inhabiting the banks of some of the English rivers.—The rock willow, *S. petræa*, is a tall shrub, commonly about 7 or 8 feet high, blooming in April and May, and inhabiting rocky grounds in various parts of Britain.—The phillyria-leaved willow, *S. phillyreæfolia*, is a curious shrub, commonly about 5 feet high, blooming in April, and inhabiting some glens and valleys in the Scottish Highlands.—The loose-flowered willow, *S. laxiflora*, is a tall shrub or small tree, commonly about 12 feet high, blooming in April, and inhabiting moist grounds in various parts of Britain.—The thin-leaved willow, *S. tenuifolia*, is a tall shrub or small tree, commonly about 12 feet high, blooming in April, and inhabiting some of the moist meadows of England.—The damson-leaved willow, *S. damascena*, is a tall shrub or small tree, similar in height and in the period of blooming to the preceding, and inhabiting some of the uplands of Britain.—And the ambiguous willow, *S. ambigua*, is a small ornamental shrub, blooming in April and May, inhabiting some of the grassy heaths of England, and comprising several varieties both indigenous and exotic.

The hastate or halbert-leaved willow, *Salix hastata*, is one of the best and longest known of the exotic kinds for both ornamental and economical purposes. It is a native of Lapland and Switzerland; and was introduced to Britain from the former of these countries in 1780. It commonly attains a height of about 15 feet; but is capable of becoming a middle-sized tree; and it also sends forth from its stools several long green shoots, which, though full of pith, are tough and serviceable to the basket-maker. Its leaves are nearly oval, acute, serrated, and smooth, and they sit close to the branches, and have broad appendages at their base; and its flowers grow in long yellow catkins, and come out in spring from the sides of the young shoots, almost their whole length.—An exotic species, called the serrulate willow, and the two indigenous species, called the apple-leaved and the little-tree willows, are regarded by some botanists as mere varieties of the hastate willow.

The Babylonian willow or weeping willow of Babylon, *Salix babylonica*, is by far the most ornamental kind of willow known, and, in certain situations, possesses more true elegance than any other plant whatever. It is a native of various oriental countries, and was introduced to Britain from the Levant in 1692; but it is sufficiently hardy to be successfully raised in any ordinary moist soil in a low or comparatively sheltered situation. It commonly attains a height of about 30 feet, and can easily be coaxed up to the bulk and altitude of a pretty large tree. It adorned the banks of the Euphrates in the days of the prophet Daniel, and has been rendered venerable by its association with the captivity of Judah, and with the language of one of the inspired psalms; and it is the most proper of all plants for any decorated spot by the side of a river, pond, or spring, which requires a combination of sadness and beauty; and when hanging over a rock, jutting from a promontory, or reclining over an urn, it is both pleasingly melancholy and inexpressibly beautiful. Its branches are slender, and very long and pendulous, and hang streaming in the air, and very easily admit of being twined and woven into garlands; its leaves also are long and narrow; and after a fall of mist or of rain, drops of water hang at the ends of the leaves, and combine with the pendulousness of the branches to give the plant a singularly weeping appearance.—Two plants somewhat nearly akin to the Babylonian willow are regarded by some botanists as varieties of it, and by others as separate species,—the one called the ring-leaved or curl-leaved willow, of doubtful origin, and occurring only in gardens,—and the other called Napoleon's weeping willow, a somewhat tender evergreen, introduced in 1823 from St. Helena.

WILLOW-HERB,—botanically *Epilobium*. A genus of plants of the order Onagrariæ. Nine species grow wild in Britain, upwards of a dozen have been introduced from other countries, and a few more are known. One of those in Britain is an annual, one is a very aquatic perennial, two are evergreen herbs, and the rest are perennial-rooted annual-stemmed herbs. One of the evergreens is tender, and all the other species are hardy. The leaves of all the indigens are simple, and those of most toothed; and the flowers of most of the species are either purple, pink, or red,—and those of most grow in terminal leafy clusters or in spikes. Some of the species have a weedy appearance; but others are decidedly ornamental,—and a few are highly beautiful. Most thrive well in any common soil, and are easily propagated by radical division; and indeed the best known and most common one in gardens, the narrow-leaved, is notorious for such a powerful habit of self-propagation by means of decurrent, subterranean, root-like stolons, that when it once gets fair possession of a few inches of ground, it cannot be exterminated without excessive care and labour.

The narrow-leaved or rose-bay willow-herb, *Epilobium angustifolium*, is a native of meadows and moist shady places, chiefly in the north of England. It is an annual-stemmed perennial of commonly between 3 and 6 feet high; and usually grows in fasicles, with a number of stems arising from congeries of roots or stolons. Its

root is fleshy, and rapidly decurrent, and powerfully stoloniferous; its stems are erect, cylindrical, reddish, smooth, leafy, and seldom branched; its leaves are numerous, scattered, almost sessile, linear-lanceolate, acute, veiny, smooth, and of various breadth; and its flowers grow in long terminal clusters, and have a crimson-purplish colour, and are numerous and very showy and handsome, and bloom in July and August. This plant is a great and general favourite in all sorts of flower-gardens, particularly in those of careless or slovenly cultivators; and it thrives, and takes care of itself, and freely propagates, in almost all sorts of soils and situations, even in the smoky air and choked flower-plots of the largest cities. A variety of it called the white, *E. a. album*, has white flowers, but occurs only in gardens.

The great hairy willow-herb, or codlings and cream, *E. hirsutum*, abounds in such watery places as ditches and the margins of rivers, among reeds, coarse aquatic grasses, and willows, in many parts of Britain. It is a true and even splashy aquatic, yet possesses an ornamental character, and thrives more or less on any common soil; and it is all over downy, soft, and clammy, and exhales a transitory, peculiar, acidulous odour, very similar to the flavour of boiled codlings and cream. Its root is extensively creeping; its stems are cylindrical, leafy, abundantly branched, bushy, and from 3 to 6 feet high; its leaves are half-clasping, ovate-lanceolate, and hairy; and its flowers grow in leafy corymbose clusters, and are large, and have a delicate purplish-pink colour, and bloom in July and August. A variety of it, *E. h. variegatum*, occurs wild with variegated leaves and rose-coloured flowers.

The small-flowered willow-herb, *E. parviflorum*, inhabits watery places in many parts of Britain, and has a highly ornamental character; and it commonly attains a height of about 3 feet, and carries purple-coloured flowers in July and August.—The square-stalked willow-herb, *E. tetragonum*, is a weedy-looking native of the marshes of Britain, and has a height of about 2 feet, and carries purple flowers in July.—The mountain willow-herb, or broad smooth-leaved willow-herb, *E. montanum*, is a weedy-looking native of the woods of Britain, and has a height of about 2 feet, and carries purple flowers in June and July.—The rose-coloured willow-herb, or pale smooth-leaved willow-herb, *E. roseum*, is a slightly ornamental inhabitant of the marshes of England, and has a height of about 18 inches, and carries pink flowers in July.—The marsh willow-herb, or round-stalked marsh willow-herb, *E. palustre*, is a weedy-looking inhabitant of the marshes of Britain, and has a height and appearance and time of blooming similar to the square-stalked species.—The alpine willow-herb, *E. alpinum*, is a small evergreen inhabitant of the margins of the lofty upland streams of Britain, and has a height of only 2 or 3 inches, and carries red flowers in June.—The chickweed-leaved willow-herb, *E. alsinifolium*, is a weedy-looking native of the Scottish Highlands, and has a height of about 6 inches, and carries pink flowers in July.

WILLOW-OAK. See Oak.

WILLOW-WEED,— botanically *Polygonum Lapathifolium*. An annual British weed, common on dunghills, rich loose deep soils, and some marshy lands in many parts of England, but scarcely or not at all known in clay districts or on turnip lands. Its stalks are tender, succulent, and pale, spotted, or reddish, and have very swollen joints, and commonly attain a height of about 12 or 18 inches; its leaves resemble those of the common willows, but are marked in the middle with dark spots; its flowers have a herbaceous colour, and bloom from June till September; and its seeds are very bright and heavy, and amount to vast numbers in favourable situations, and are highly nutritious, and are very grateful to partridges and other birds. This weed is one of the rankest, and most cumbersome, in the English fen districts, and is always a great robber of the soil wherever it grows, and makes a large contribution of seeds to infest samples of wheat, oats, and barley on corn lands; yet it serves well as a decoy for attracting wild ducks and some similar fowls, and might be made to contribute its seeds in a boiled state to the feeding of hogs. Other popular names for it than willow-weed are snake-weed, dockleaved knotgrass, and pale-flowered persicaria; though these names probably confound it with other native polygonums.

WIND. A sensible current in the atmosphere. The motions of the atmosphere are subject, in some degree, to the same laws as those of the denser fluids. If we remove a portion of water in a large reservoir, we see the surrounding water flow in to restore the equilibrium; and, if we impel in any direction a certain portion, an equal quantity moves in a contrary direction, from the same cause; or if a portion, being rarefied by heat, or condensed by cold, ascends in the one instance and descends in the other, a counter-current is the visible and natural result; and similar effects are found to follow the same causes in the atmospheric fluid: thus no wind can blow without a counter or opposite current; nor can any wind arise without a previous derangement of the general equilibrium, the general causes of which may be stated as follows: 1. The ascent of the air over certain tracts heated by the sun; 2. evaporation, causing an actual increase in the volume of the atmosphere; 3. rain, snow, &c., causing an actual decrease in its volume, by the destruction of the vapour. In the 'Philosophical Transactions of the Royal Society of London' (vol. 51st), there is a table of the different velocities and forces of winds, drawn from a considerable number of facts and experiments, which give the following results:—

Velocity of the Wind. Miles per Hour.	Feet per Second.	Perpendicular Force on one square Foot in Avoirdupois Pounds and Parts	
1	1.47	·005	Hardly perceptible.
2	2.93	.020	Just perceptible.
3	4.4	.044	
4	5.87	.079	Gently pleasant.
5	7.33	.123	
10	14.67	.492	Pleasant, brisk.
15	22.	1.107	
20	29.34	1.968	Very brisk.
25	36.67	3.075	
30	44.01	4.429	High wind.
35	51.34	6.027	
40	58.68	7.873	Very high wind.
45	66.01	9.963	
50	73.35	12.300	Storm or tempest.
60	88.02	17.715	Great storm.
80	117.36	31.490	Hurricane.
100	146.7	49.200	Hurricane that tears up trees, and carries buildings before it.

Currents thus produced may be permanent and general, extending over a large portion of the globe; periodical, as in the Indian ocean, or variable and occasional, or, at least, uncertain, as the winds in temperate climates. General or permanent winds blow always nearly in the same direction, and are called *trade-winds*. On the north of the equator, their direction is from the north-east (varying at times a point or two of the compass each way): on the south of the equator, they proceed from the south-east.—See Anemometer, Weather, and Calendar.

WIND. The breathing of any animal, particularly of the horse. The most effectual method of bringing a horse into the peculiarly healthy habit of breathing technically called good wind, is to give him regular exercise, to increase very gradually the amount of exercise, to give him oats and good hay in quantity proportioned to his exercise, to make his allowance of hay at all times moderate, to give him water in moderate quantity three times a-day, to keep his stable in a clean and well-ventilated condition, and to give him occasionally or when needed a dose or two of mild physic. The nature and varieties and proper treatment of morbidity in a horse's habit of breathing are treated in the articles Broken Wind, Thick Wind, and Pneumonia.

WIND-FLOWER. The marsh gentian and the anemone. See the articles Gentian and Anemone.

WIND-GALLS. Elastic tumours on each side of the back sinews of the horse, immediately above the fetlock joint. They are generally caused by hard work at too early an age; and they arise from excessive secretions of the synovial fluid, which lubricates the joints and bony prominences of the limbs. They are called *bursæ mucosæ* by scientific veterinarians; but both this name and the popular one are misnomers; for they contain neither mucus nor wind, but are simply enlarged capsules of synovia. They seldom occasion much suffering or inconvenience, and can scarcely be regarded as decided indications of unsoundness; but are commonly slow, chronic, painless enlargements. They may be partially subdued by means of blisters, stimulating liniments, firing, or appliances of any kind for promoting the absorption of their contents; but they are best dealt with by the mere pressure of bandage,—or at the utmost by the combination of this with an evaporating lotion; and never ought they, according to the practice of the old farriers, to be opened and surgically evacuated,—for the laying of them open occasions almost as much irritation and danger as if the joint itself were to be perforated.

WINDMILL. A mill whose moving power is the wind. It is fitted with arms, vanes, or sails, for catching the breeze, and may have them either vertically or horizontally, and admits of a considerable diversity of both structure and adaptation. Windmills with vertical sails are the best; but even they, no matter how well constructed or how advantageously situated, are far inferior, in aggregate value, to water-mills or steam-mills, and are not equal, in some cases, to even horse-mills or hand-mills. They suit tolerably well on only exposed spots, where every current in the air can be caught; and even there they have the incurable defect of being perfectly useless in calm weather, and sometimes therefore at a season when mill-work is most wanted, and cannot without loss and great inconvenience be postponed. Mr. Ferguson calculated the velocity of the sails of a windmill, in a moderate wind, to be 30 miles per hour.

As a horizontal windmill consists of vertical sails moving horizontally round a vertical arbour or windshaft, no motion would arise on exposing it to the action of the wind, as the effect of the wind upon the sails on one side would be counterbalanced by its action upon the corresponding sails on the opposite side. Hence it is necessary either to screen the sails on one side from the action of the wind, or to construct the sails in such a manner that, when they return against the wind, they present only their edge to its action. The method of screening the returning sails from the wind is adopted in Tartary and some provinces of Spain, and is the most simple that has been tried. When the screen is not used, the sails may be fixed like float-boards, with hinges, on the circumference of a large drum or cylinder, so that, when they are to receive the action of the wind, they stand at right angles to the drum, and when they turn against the wind, they fold down upon its circumference. Other ingenious methods have also been devised for bringing back the sails against the wind. In the vertical windmill, on the other hand, the arms which carry the sails revolve in a plane facing the wind. In this arrangement, if the sails were in the same plane with the arms, the wind would fall perpendicularly upon them, and merely press the arms against the building, perpendicular to the plane in which they are designed to move. If, on the other hand, the sails were perpendicular to the plane in which the arms move, their edges would be presented to the wind, and would, therefore, offer no resist-

ance, and there would be no motion. In order to make the arms revolve, the sails must, therefore, be placed in some direction intermediate between those of the wind and the plane in which the arms revolve. In determining the angle at which the planes of the sails should be inclined to the axis of motion, or the direction of the wind, it is necessary to consider the sail in motion; and the neglect of this element in the calculation has led to very great errors in theoretical calculations. The sail being in motion, the velocities of the sail and the wind must both be taken into account; for, if the sail moved before the wind with a speed equal to that of the wind itself, no effect would be produced. The effect will depend on the difference of the velocities, that being the velocity with which the wind strikes the sail. Now, as the obliquity of the sail to the wind should depend on the force with which the wind acts upon it, and as those parts of the sail which are nearer to the centre of motion move more slowly than those which are more remote, it follows that the position of the sail should vary at different distances from the centre of rotation. From the experiments of Mr. Smeaton on this subject (Philosophical Transactions, 1759), it appears that the following positions are the best. Suppose the radius to be divided into six equal parts, and call the first part, beginning from the centre, one, the second two, and so on, the extreme part being six:—

No.	Angle with the Axis.	Angle with the Plane of Motion, or Angle of Weather.
1	72°	18°
2	71	19
3	72	18
4	74	16
5	77½	12½
6	83	7

As it is necessary that a windmill should face the wind from whatever point it blows, the whole machine, or a part of it, must be capable of turning horizontally. Sometimes the whole mill is made to turn upon a strong vertical post, and is therefore called a *post mill;* but, more commonly, the roof or head only revolves, carrying with it the windwheel and its shaft, the weight being supported on friction rollers. In order that the wind itself may regulate the position of the mill, a large vane, or weathercock, is placed on the side which is opposite the sails, thus turning them always to the wind. But in large mills the motion is regulated by a small supplementary windwheel, or pair of sails, occupying the place of the vane, and situated at right angles with the principal windwheel. When the windmill is in its proper position, with its shaft parallel to the wind, the supplementary sails do not turn. But when the wind changes, they are immediately brought into action, and, by turning a series of wheelwork, they gradually bring round the head to its proper position.

On account of the inconstant nature of the motion of the wind, it is necessary to have some provision for accommodating the resistance of the sails to the degree of violence with which the wind blows. This is commonly done by clothing and unclothing the sails; that is, by covering, with canvass or thin boards, a greater or smaller portion of the frame of the sails, according to the force of the wind at different times. A method has been devised for producing the same effect, by altering the obliquity of the sails; and windmills have been so made as to regulate their own adjustment by the force of the wind. If we suppose a windmill, or windwheel, to consist of four arms, and that the sails were connected to these arms at one edge by means of springs, the yielding of these springs would allow the sails to turn back when the wind should blow with violence; and their elasticity would bring them up to the wind whenever its force abated. This effect has been produced by a weight acting on the sails through a series of levers. A loose iron rod, passing through the centre of the axle of the windwheel, receives the action of the weight at one end, and communicates it to the sails at the other. See the articles Mill and Thrashing-Machine.

WINDPIPE. The trachea or grand air-passage to the lungs of animals. It comprises the most admirable adaptations to the joint properties of flexibility and permanent tubularity; and is beautifully suited, in form and capacity, to the precise wants and habits of each species; and it is lined with a very vascular mucous membrane to supply all its interior surface with a secretion for defending it against the irritating effects of diversified temperature in the air. The windpipe of the ox comprises 8 or 10 more cartilaginous rings than that of the horse, or altogether about 60; but it is smaller in diameter, looser in construction, and weaker in the interposed ligamentous substance,—and it also exhibits other differences, involved in its perfect adaptation to the ox's habits.

WINDROW. The green part or border of a field dug up in order to furnish material for ameliorating the rest of the land,—and is called a windrow because it is laid in rows and exposed to the wind. A windrow is also a particular kind of heap or collecting of hay in the process of haymaking; and is likewise a row of peats in the process of cutting turbary for fuel,—and a row of turf in the process of georgical improvement by paring and burning.

WINE. Any fermented vegetable juice which contains sugar and an acid. All the truest wines consist of the fermented juice of the grape; but inferior wines may consist of the fermented juice of various other fruits, or even of the fermented juice of some leaves and stems. The chemical process by which the juice passes into wine is described in the article Fermentation; and the kinds of grape used for making the best wines are described in the article Grape-Vine.

The History of Wines.—The discovery or in-

vention of wine is enveloped in great obscurity, but must be referred to very remote times. The first portion of grape-juice which had been pressed out by accident or design, and allowed to remain a short time undisturbed, would be found to have assumed new and surprising properties; and repeated trials would soon prove the value of the discovery. By degrees, the method would be learned of preserving for constant use the beverage so obtained; and various processes would gradually be resorted to for enhancing its grateful qualities. The knowledge of the art would rapidly spread; and its simplicity would recommend its universal adoption. The Egyptians gave the honour of the discovery to Osiris, the Latins to Saturn, and the Greeks to Bacchus; while various authors have assigned it to other persons, not certainly so celebrated as the fabulous individuals just named, but not the less likely to merit the honour. Yet all these persons, or any of them, were probably mere improvers or early manufacturers of the beverage; and the real inventor or discoverer was either Noah or some one of the antediluvians. "Noah," says the inspired record, "began to be an husbandman, and he planted a vineyard, and he drank of the wine." From the manner of this passage, it is not unlikely that the art of wine-making had been known to the antediluvians; but, however this may be, it is mentioned in many a page of the sacred volume as quite commonly practised after the flood. "Corn and wine" seem to have been equally abundant, and are mentioned in the Old Testament as rather the necessaries and comforts than the luxuries of life. But though vineyards were cultivated to so great a degree in Palestine, wine seems not to have been so common in other countries. Indeed the quantity produced elsewhere was for a long time very small. Except in Egypt and Greece, wine was seldom allowed either to virgins, to matrons, or to young men. In Rome, most severe restrictions were laid on it for the first 200 years of that celebrated city. But about this period, that is 500 years before the Christian era, it began to be manufactured in greater abundance; and when afterwards the Romans carried the cultivation of vineyards to the greatest extent to which they ever reached, their productiveness was incredible, exceeding that of modern vineyards by about a half. The varieties of the vine, known to the ancients, were very numerous, amounting to about fifty; and some of them are described with sufficient minuteness to enable us to appreciate the relation in which they stand to our modern vines. Wine, however, was generally designated, not by the species of vine from which it was produced, but generally from the place where it was manufactured; thus we read of *Vinum Falernum, Massicum, Albanum, Chium, Rhodium, Maeonium*. Sometimes it obtained its name from its colour or age, as *Vinum album, nigrum, rubrum, vetus, hornum, trimum*.

The Chemical Constitution of Wines.—The essential components of all wines—irrespective of the water which forms their basis and of the various substances which constitute their differences and peculiarities—are one or more acids, a volatile oil or oily ether, extractive matter, colouring matter, and alcohol. The acids vary widely in kind, number, and quantity, according to the various nature of the juices; the oil or ether contains the flavour or aroma or bouquet, and is exceedingly richer in the prime wines than in the inferior; the extractive matter abounds far more in new wines than in old, and is mightily controlled in kind, quantity, and condition, by all the circumstances of the vintage; and the alcohol is the most important of the ingredients, and surmounts and modifies them all for dietetical and medicinal uses, and does not, as is often supposed, lie latent till formed by distillation, but comes necessarily and fully out of the process of vinous fermentation, and therefore exists essentially in all wine, and distinguishes it from must or mere vegetable juice. Saccharine matter, gluten, and acid are indispensable in any juice in order to its forming wine; and the quantity of the first, the kind of the last, and the amount of mutual reaction between the first and the second, contribute more than all the other ingredients and circumstances to determine or form the wine's character. When the saccharine matter is very abundant, a checked fermentation renders the wine sweet and luscious, and a brisk and exhausting fermentation renders it strong and spirituous; and when the saccharine matter exists in small quantity, especially if malic or citric acid rather than tartaric be predominant, the wine is thin and weak. When tartaric acid abounds in the must, the wine ought to be highly flavoured and long-keeping; when carbonic acid is voluminously developed in the fermentation, the wine ought to be brisk and sparkling; and when the acids of the must largely survive the fermentation, so as to continue free or uncombined, the wine ought to be light and dry.

The taste and smell which distinguish good grape wines from all other fermented liquids depend upon an ether of an oily nature,—the ether of a volatile and highly combustible acid,—called œnanthic ether. This is formed by deoxidation of the substances held in solution in the must; and contains the same proportions of carbon and hydrogen as sugar, but a far less proportion of oxygen. "The wines of warm climates," remarks Liebig, "possess no odour; wines grown in France have it in a marked degree; but in the wines from the Rhine the perfume is most intense. The kinds of grapes on the Rhine which ripen very late, and scarcely ever completely, such as the Riessling and Orleans, have the strongest perfume or bouquet, and contain proportionally a larger quantity of tartaric acid. The wines from the earlier grapes, such as the Rulander, and others, contain a large proportion of alcohol,

and are similar to Spanish wines in their flavour, but they possess no bouquet. The grapes grown at the Cape from Riesslings, transplanted from the Rhine, produce an excellent wine, which does not, however, possess the aroma peculiar to the Rhenish wine. It is evident, from these facts, that the acid of wines, and their characteristic perfumes, have some connexion, for they are always found together; and it can scarcely be doubted that the presence of the former exercises a certain influence on the formation of the latter. It is only in liquids containing other very soluble acids, that the fatty acids and œnanthic acid are capable of entering into combination with the ether of alcohol, and of thus producing compounds of a peculiar smell. This ether is found in all wines containing a free acid, but is absent from those in which no acids are present. This acid, therefore, is the means by which the smell is produced; since without its presence œnanthic ether could not be formed. On the Rhine, also, an artificial bouquet is often given to wine for fraudulent purposes, by the addition of several species of the sage and rue to the fermenting liquor; but the fictitious perfume thus obtained differs from the genuine aroma, by its inferior durability, and by being gradually dissipated. The juice of grapes grown in different climates differs not only in its proportion of free acid, but also in respect of the quantity of sugar dissolved in it. The quantity of azotised matter in the juice seems to be the same in whatever part the grapes may grow; at least, no difference has been observed in the amount of yeast formed during fermentation in the south of France, and on the Rhine. The grapes grown in hot climates, as well as the boiled juice obtained from them, are proportionally rich in sugar. Hence, during the fermentation of the juice the complete decomposition of its azotised matters, and their separation in the insoluble state, are effected before all the sugar has been converted into alcohol and carbonic acid. A certain quantity of the sugar consequently remains mixed with the wine in an undecomposed state, the condition necessary for its further decomposition being absent. The azotised matters in the juice of grapes of the temperate zones, on the contrary, are not completely separated in the insoluble state, when the entire transformation of the sugar is effected. The wine of these grapes, therefore, does not contain sugar, but variable quantities of undecomposed gluten in solution. This gluten gives the wine the property of becoming spontaneously converted into vinegar, when the access of air is not prevented; for it absorbs oxygen and becomes insoluble, and its oxidation is communicated to the alcohol, which is converted into acetic acid. By allowing the wine to remain at rest in casks with a very limited access of air, and at the lowest possible temperature, the oxidation of this azotised matter is effected without the alcohol undergoing the same change, a higher temperature being necessary to enable alcohol to combine with oxygen. As long as the wine in 'the stilling-casks' deposits yeast, it can still be caused to ferment by the addition of sugar; but old well-cleared wine has lost this property, because the condition necessary for fermentation, namely, a substance in the act of decomposition or putrefaction, is no longer present in it. In hotels and other places where wine containing much gluten is drawn gradually from a cask, and a proportional quantity of air necessarily introduced, its eremacausis, that is, its conversion into acetic acid, is prevented by the addition of a small quantity of sulphurous acid. This acid, by entering into combination with the oxygen of the air contained in the cask, or dissolved in the wine, prevents the oxidation of the organic matter."

Many of the wines of commerce contain ingredients or principles altogether foreign to their proper nature,—added to them for the purpose of adulteration, of concealing their bad properties, or of improving their odour or colour or taste. Such flavouring substances as orris root, bitter almonds, nitrous ether, oak chips, wormwood, and white leather are very extensively used for white wines; such colouring substances as common red and brown dye-stuffs, logwood, Brazil wood, elder berry, and iron are profusely used for red wines; such poisonous substances as litharge and white lead are not unfrequently used for correcting the acidity of wines which have become sour; and such terribly murderous substances as arsenic and corrosive sublimate have sometimes been used in the process of fining. Liquid potash precipitates the natural principles of wine green, and therefore serves as a good test for promptly ascertaining whether any specimen of the wines of commerce be an artificial mixture; and a few drops of the prussiate of potash throw down a whitish precipitate in any specimen which contains a salt of lead, and therefore readily detect the presence of litharge or white lead.

The Manufacture of Wines.—When the grapes are ripe, and have attained their sweetest or most saccharine state, the juice, then called the must, is pressed out of them, and put into suitable vessels for undergoing fermentation. "When the must is exposed to the temperature of 65° of Fahrenheit's scale," says Dr. Henderson, in his History of Ancient and Modern Wines, "it speedily begins to ferment. Small bubbles first collect on the top, and may be seen gradually issuing from the central parts of the liquor, and bringing up the husks, stones, and other grosser matters which it contains. As the disengagement of gas proceeds, a hissing noise is produced by the bursting of the bubbles; and a frothy crust or scum is formed by the viscid particles which they have carried to the surface. An increase of the temperature and bulk of the fermenting mass now takes place; the must loses its original consistency and its saccharine taste, acquiring a deeper colour and a vinous flavour, with an odour of

spirit of wine, which becomes more perceptible as the process advances. At length these commotions of the fluid abate spontaneously; and, after a few hours rapid fermentation, the ebullition ceases altogether, the mass subsides to its former bulk, and the crust and solid particles which disturbed the transparency of the liquor, are precipitated to the bottom of the vessel." In order to insure a regular and complete fermentation, it is necessary that the grapes should be all equally trodden, and that the vat which is to contain them should be filled as speedily as possible; within twenty-four hours at farthest. Fermentation proceeds with incredible rapidity, insomuch that the juice, as it flows from the grape, will often work and ferment before it arrives at the vat, owing to the pressure and motion to which, when being carried from the vineyard, it has been subjected. The most favourable temperature, as already stated, is 65° of Fahrenheit. Below that degree, fermentation is languid; above, it is violent; and when very high or very low, it ceases altogether. When the process has commenced, however, the temperature quickly rises, even so high as 30° above the point in question. Another circumstance necessary to fermentation is contact with the external air: without this, indeed, no fermentation can take place; but after the process has been established, such contact is not necessary. Finally, fermentation is brisk in proportion to the extent of the fermenting mass; so that in a cask it proceeds more slowly than in a vat. When, from any cause, fermentation does not go on successfully, means must be used to supply the defect. If, for example, the must is too thin and watery, and fermentation proceeds with difficulty, the objection may be removed by one of three ways,—either by boiling the must and allowing the superabundant water to evaporate,—or by merely throwing in a portion of must which has been thus thickened,—or by adding a quantity of sugar, as is the common practice in cold climates where the grapes seldom reach their full maturity. In some places baked gypsum is used, in order to absorb the excess of humidity; in others, the grapes are partially dried before they are trodden. The addition of tartar accelerates fermentation, particularly if the grapes abound in the saccharine principle. The stalks of the grapes, when added to the mash, act as a powerful leaven, and augment the strength of the wine; but to the weaker sort, they are apt to communicate a harsh and austere flavour, owing to the tannin and extractive matter which they contain. In the case of port they are always used; while in the manufacture of the more delicate red wines of Bourdeaux, they are generally excluded. For the white wines of the same district, however, they are thought to be advantageous, rendering them less apt to spoil. Yet the wines of the Rhine, which are distinguished by their great durability, are not fermented with the stalks, and would probably not bear the addition. The exact time required to complete fermentation varies, being dependent on the quality of the grapes and of the wine sought to be obtained. Weak wines require but a short time; the lighter wines, in truth, will not bear the vat longer than from twenty to thirty hours. If a brisk wine is wished, the contents of the vat must be drawn out into casks before the fermentation subsides. In general, the process may be regarded as terminated, when the saccharine flavour of the must has disappeared and the liquor has acquired a distinct vinous taste. —In transferring the wine from the vat to the cask, it undergoes a new process, which renders it again turbid, and generates the phenomena that marked the former action. A portion of the sugar, though the taste of it has nearly disappeared, remains undecomposed; and this being acted upon by the mucilaginous extractive matter which still exists in solution, a disengagement of carbonic acid gas, and a fresh deposit of sediment, will be the result. These movements become by degrees less perceptible; but still there goes on an insensible fermentation, as it is called, which, particularly in the case of the stronger wines, will continue for many years,—during which they become much ameliorated. A portion of the colouring matter and tartar is precipitated; the liquor loses its harshness; and the aroma and flavour that are peculiar to it become more apparent. These changes may be accelerated by various artificial methods, especially by the agitation of the lees, which always contain a quantity of fermentative matter, and by the assistance of heat. Hence the reason why certain strong and austere wines are so much improved and mellowed by being exported on the lees to a warm climate, while the lighter and more delicate wines are generally injured by being made to undergo a similar process, or even by the motion occasioned by the removal of them to any considerable distance.— The next step, when wine has attained a sufficient degree of maturity, is to free it from the lees by being racked, as it is termed, into a clean cask; and in order to prevent a renewal of fermentation, it is subjected to the operation of sulphuring. This process is generally performed by means of sulphur matches applied to the cask into which the wine is to be racked. Should the fermentation still continue, this application is renewed as often as may be necessary. Sometimes must, strongly impregnated with sulphurous acid gas, is added to the wine, which answers the same purpose as the other mode. After sulphuring, the greater proportion of wines require to be farther clarified, or 'fined,' before they attain a due brightness. For this purpose various substances are used, which, by their chemical or mechanical action, unite with such materials as disturb the purity of the wine, and precipitate them to the bottom. The substances

in general use are isinglass and the white of eggs; but as these, particularly in warm climates, are of a putrescent nature, gum arabic has been used instead of them. In Spain the white wines are sometimes clarified with fuller's earth. Powdered marble, gypsum, heated flints, beechwood chips, and a variety of other things, are used for the same purpose. The quantity, however, of any of these substances used is very small; one ounce of isinglass, for example, is sufficient for a hundred gallons of wine. Brandy is sometimes mixed with wine; and different wines are as frequently mixed with each other;—processes which require great attention and nicety.

The manufacture of French champagne, the finest of all brisk wines, may be selected for particular detail, both because it comprises the utmost niceties of the general process of wine-making, and because it very distinctly shows the production of a lively creaming wine to depend upon the expulsion of a certain portion of the yeast by overflow from the vent-hole, so as to leave in the liquor a preponderance of undecomposed saccharine matter. And this is described as follows by MacCulloch, in his Treatise on Wine-Making:—"The grapes are first squeezed by a gentle pressure, and poured into the vat, where they remain for one night only. The next morning the liquor is transferred into casks. If the wine is intended to be red, the fermentation is allowed to continue some time longer on the husks, till the red colour has been extracted; but the seeds are carefully separated, as they communicate a harsh taste. The first fermentation in the casks is violent, and the discharge of the yeast is encouraged for ten or twelve days, by keeping them full to the bung-hole. It then becomes more moderate, when the bung is put down, and a gimlet-hole, fitted with a spile, is made by the side of it. When the cask is thus closed, the vent-hole is opened every day or two, according to the state of the fermentation, for a space of eight or ten days, to allow the carbonic acid to escape. When this state is passed, fresh wine, reserved for the purpose, is poured in at the vent-hole, about once a-week, for the first three or four weeks, according to its waste, so as to fill the cask. This operation is then performed at longer intervals, of a month or more, till the end of December, when the wine usually becomes clear. It is afterwards decanted from the lees into a fresh cask, where it is fined with isinglass, in the proportion of half an ounce to a pipe; and this process of decanting is carefully executed in dry clear frosty weather. A new fermentation is now excited, by which the wine loses a portion of its sweetness, and becomes still further meliorated. If it should prove too sweet, this first operation of decanting is not performed until the fermentation in the first cask has been rendered more vigorous, which is done by stirring up the lees, and rolling the pipe; and by this the sweetness is overcome, and the wine strengthened and improved. To insure the fineness of this wine, which is one of its essential properties, and to render it at the same time durable, it is at the end of six weeks decanted a second time into a fresh pipe, and once more fined with half the quantity of isinglass. It is then completed, and is put into bottles in March,—clear dry weather being also chosen for this purpose. Notwithstanding all this care, a fresh deposit is still formed in the bottles, from a renewal of the fermenting process, which goes on in them. To remove this, and to render the wines marketable, those of the best quality are decanted clear into fresh bottles in about fifteen or eighteen months, when the wine is perfected. A certain loss, amounting to one or two bottles in a dozen, is sustained, by their exploding previous to this last stage. Another process is sometimes adopted for getting rid of the sediment, without the trouble of decanting. In this mode, the bottles are reserved in a frame proper for the purpose during a certain number of days, so as to permit the foulness to fall into the neck. While in this position, the cork is dexterously withdrawn, and that portion of the wine which is foul allowed to escape, after which the bottles are filled with clear wine, permanently corked, and secured with wire and wax."

The manufacture of British wines from gooseberries, currants, cherries, oranges, apples, pears, and other fruits is so generally known, and is concerned with such comparatively poor beverages, that nothing needs be said respecting it. But the manufacture of wines from green or unripe British-grown grapes, and from the leaves and prunings of the plants of British vineries, is so limitedly known, and has been found to produce such comparatively excellent beverages, that some notes upon it may be acceptable to many readers; and happily some highly satisfactory ones lie ready at our hand, in a paper by a very intelligent writer, who speaks from both scientific knowledge and actual experiment,—Mr. Towers. "The must," says this writer, "cannot with safety be converted to a dry wine, unless its gravity be considerable, because the leaven will act energetically upon a light and weak fluid, decompose the sugar in a very short period, and cause the poor thin wine, which will be the result, to run speedily into the acetous fermentation. Therefore, to prepare a dry and keeping white wine from green, immature grapes, it will require an increased quantity of both materials; and the following receipt may with confidence be taken as a standard,—let the quantity be considered six gallons. Grapes bruised without crushing the seeds, 36 lb. to be digested with water in a pan or tub, covered at top with a flannel. The gravity of the liquid should be tried by a saccharometer or by the comparison of weights with pure rain or distilled water after the materials have stood together two hours,—again, after twelve hours,—and a third time

at the end of twenty-four hours. The water first added should be in quantity sufficient to cover and float the pulp; perhaps four gallons may be generally used. During some hours the gravity will increase; and while it does so, the materials should remain together, and be stirred five or six times. The temperature of the room might be about 55°; and the eye of the operator should be on the alert to discern, and his hand ready to arrest, the very minutest appearance of fermentation indicated by small groups of air bubbles. The liquor is to be strained off—the pulp squeezed or pressed,—and finally washed with more water,—strained and again pressed,—and its gravity noted down. We will state this gravity at 20 in 1,000 above water at 60°, *i. e.* at 1·020. The liquor should measure five gallons at the least; and to it may be safely added 15 lb. of good loaf-sugar, or 12 lb. of sugar, and 3 lb. of honey, which latter always tends to confer a soft and vinous character on the must. If the gravity do not rise to 1·120, more saccharine material (sugar or honey) must be added cautiously, till that density be acquired. Fermentation may then be suffered to take place quietly, without any extraneous aid, and be promoted by warmth and agitation if the weather be cold. The liquor should be retained in the tun or pan till the gravity be reduced to 1·085, at which it will have acquired a decidedly vinous odour. It will be understood that the fluid is to be made up seven gallons by water before the fermentation begins, always adding sugar till the gravity be found 1·120. This quantity will suffice to fill the barrel to within an inch of the bung-hole, leaving a reserve of nearly a gallon for filling up, after a fermentation is nearly completed; the reserve is to be kept apart, in a stone bottle, covered with a small piece of flat glass. The cask must be perfectly clean, sweet, and dry; it should be raised a few inches above the floor of a good arched cellar, the temperature of which remains pretty equable at all seasons. The wine must not throw off its yeast; it is to be agitated by rolling, or stirred with a clean stick let down through the bung-hole. This hole is subsequently to be covered over with a piece of tile or slate, placed over a grape leaf. After the hissing shall have subsided to a gentle fretting, the clearest portion of the reserved wine is to be poured into the barrel, when the hole may be partly closed, by fitting it loosely with a sound and clean bung. In order to afford an example of the progress of vinification, we extract from a journal the minutes of several observations made during the season of 1838:—Sept. 29. The materials used to prepare 6 imperial gallons of wine were—grapes 33 lb., 2½ lb. grape leaves or tips of shoots digested in 2 gallons of boiling-water, pressed when cold, and the liquor poured over the crushed grapes; 16 lb. of loaf-sugar, and the washings of a few clean honey-combs, after the honey had been drained from them; the gravity was at least 1·120, and the bulk of must was made up 7 gallons. Oct. 4. The gravity of green grape liquor or must after the fermentation had been established during a few hours, 1·115. Oct. 6. (Temperature of the room 50° to 55°), gravity 1·096. Oct. 8. (Idem), barrelled at noon, gravity 1·0840. The hissing continued regularly,—the bung was loosely fitted,—and the wine was permitted to be at rest, in a temperate cellar, till February 1839, when it was found quite clear, pale, and rich, but not luscious. April 1. The gravity was reduced, by throwing off carbonic acid, and the production of vinous alcohol, to 1·026; 30 grains of isinglass, dissolved in a pint of the wine, poured in as finings. April 6. Racked off, reserving the bright wine, and bottling the lees to settle. Cleaned the cask perfectly, adding half an ounce of powdered white marble, and one pint of old bucellas. Returned the clear grape-wine, and bunged the barrel. As it was not quite full, the wine reserved in bottles, which became bright as the lees precipitated, was poured into the barrel, in which it is intended that it shall remain till March 1840.

"The wine from the leaves, tender shoots, and tendrils of the vine, if judiciously prepared, is so excellent, that Mr. MacCulloch compared it to 'white hermitage.' The claret vine leaves, as he observes, will produce a red colour, and this tree could be cultivated for the express purpose. Having repeatedly prepared red and white leaf wine, we can with the greater confidence offer a few abbreviated extracts from Mr. MacCulloch's book, previously observing, that the specific gravity of the liquor must here also be taken as the criterion of strength; the proportions are calculated for ten gallons of wine. 'The leaves should not have attained their full growth, and must be plucked with their stems. On forty or fifty pounds of such leaves, seven or eight gallons of boiling water are poured, in which they are to infuse for twenty-four hours; the liquor being then strained off, the leaves are to be forcibly pressed. A gallon more water is to be added, and the leaves again are to be pressed. A screw wine-press, with hair bags, is very useful in this process. Sugar, varying from 25 lb. to 30 lb., is then to be added to the mixed liquors, the quantity is to be made up to ten gallons and a half.' Such are the essentials of Mr. MacCulloch's directions. We need only add that, if a fermenting, lively wine, be contemplated, the manufacture must be conducted as in the process for champagne, and the smaller of the two proportions of leaves, &c., is to be employed. The specific gravity of the must should be 1·110 to 1·115. The fermentation must be carried on for a short time in the open vessel, or till the gravity be reduced to 1·090; and the barrel will require to be filled, and be kept full, in order to carry off the froth and leaven that rise to the top of the liquor. But we apprehend that grape leaves are better qualified to produce a dry wine, and therefore the larger proportion of leaves, &c., should be employ-

ed, and sugar, to an extent that will raise the gravity to 1·120. In this case the fermentation must be conducted in the manner already stated for the production of a dry wine from green grapes; and when perfected, and the wine become bright, it is to be fined and racked off, during clear and cold weather, then returned to a clean and sweet cask, and bunged close. A second fining and racking may be required. Grape wine, made from the green berries, we have ever found delicious in flavour, and quite fit for the table in two years or less. But the liquor obtained from the leaves contains a quantity of vegetable extract, which conveys a flavour that time alone can subdue; hence, we recommend that it be always retained two years in the cask, and be bottled in the second winter. It also ought to remain during an entire year in the bottles."

The Varieties of Wine, and their Characteristics.—Port wine, according to Brande, contains 22·96 per cent. of alcohol of specific gravity ·825. It takes its name from Oporto, whence it is shipped; and it is produced in the province of Upper Douro, in Portugal, under a monopoly granted to the "Oporto Wine Company," in the year 1756. Dr. Henderson gives the following account of it:—"A certain extent of territory is marked out by its charter as the only district on the Douro in which wine is to be raised for exportation. The entire and absolute disposal of the wines raised in this district is placed in the hands of the Company; who are further authorized to fix the prices to be paid for them to the cultivators, to prepare them for exportation, and to fix the price at which they shall be sold to foreigners! It is obvious that a Company with such powers cannot be anything else than an intolerable nuisance. What could be more arbitrary and unjust than to interdict the export of all wines raised out of the limits of the Company's territory? But even in its own district, its proceedings have been most oppressive and injurious. The Company annually fix, by a fiat of their own, two rates of prices—one for the *vinho de feitoria*, or wine for exportation, and the other for *vinho de ramo*, or wine for home consumption—at which the cultivators are to be paid, whatever may be the quality of their wines! They have, therefore, no motive to exert superior skill and ingenuity; but content themselves with endeavouring to raise, at the least possible expense, the greatest supply of *vinho de feitoria*, for which the Company allows the highest price. All emulation is thus effectually extinguished, and the proprietors who possess vineyards of a superior quality, invariably adulterate their wines with inferior growths, so as to reduce them to the average standard. In this way the finer products of the Douro vintages have remained in a great measure unknown to us; the Port wine has come to be considered as a single liquor, if I may use the expression, of nearly uniform flavour and strength; varying, it is true, to a certain degree in quality, but still always approaching to a definite standard, and admitting of few degrees of excellence. The manipulations, the admixtures—in one word, the adulterations—to which the best wines of the Cimo do Douro are subjected, have much the same effect as if all the growths of Burgundy were to be mingled in one immense vat, and sent into the world as the only true Burgundian wine. The delicious produce of Romanée, Chambertin, and the Clos Vougeôt, would disappear, and in their places we should find nothing better than a second-rate Beaune or Macon wine." The quantity of Port wine consumed in England, annually, averages about 2,500,000 gallons. Before it leaves Oporto, a large quantity of brandy is always added. On its arrival it has a rough full body, with an astringent taste, and a strong flavour of the brandy. When kept a few years in the wood, these flavours are ameliorated; but in order to arrive at perfection, it should be laid down in bottle for several years; for during the process of ripening, a portion of the extractive and colouring matter is precipitated in the form of crust. There are processes by which the change and the ripening may be accelerated; but the substances used to effect this are more or less deleterious. In fact, although Port is such a favourite wine, there is no doubt but that nine-tenths of the quantity consumed has been adulterated, by one process or another, after its arrival in this country.

Sherry wine, of the dry prime kind called Amontillado, has a deep amber colour, and a nutty and aromatic flavour; and, according to Brande, contains 19·17 per cent. of alcohol. This is produced in a district of Spain called Xeres, in the neighbourhood of Cadiz. Since the reduction of duty in 1825, the consumption of Sherry is nearly as great as Port, and has more than doubled its former extent. This is an excellent dinner-wine when ripe; but it requires to be kept four or five years in the wood, and double or treble that period in bottle, before it attains its full bloom. The adulteration practised in it is immense, owing to the facility afforded by the cheap and inferior Cape wines.

Madeira wine is rich and luscious, and has a pungent, aromatic, nutty or bitter-sweet flavour; and according to Brande and Prout, the true kinds of it contain 22·27 per cent. of alcohol, the West-Indian kinds 21·2 per cent., and the Sercial kinds 20·32 per cent. Since the reduction in the duty of French and Spanish wines, its consumption in this country has very much decreased, being superseded by Sherry. The best Madeira wine is produced on those estates which lie on the south side of the island of that name; and although this wine is naturally of a strong full body, considerable quantities of brandy are always added, in order to enable it to sustain the high temperature to which it is subjected on voyages to India, large quantities being placed on board ships trading to the East and to China

for the purpose of ripening. The process has been tried artificially by placing the wine in a heated atmosphere, or a hothouse; but the effect is not equal to the voyage, probably on account of the ship's motion. Where good samples are selected, and the wine seasoned, it proves of excellent quality, most of the adventitious spirit being evaporated, and it will keep for any length of time, improving by age. Indeed Madeira wine is not considered to have arrived at maturity, until it has been ten years in the wood, and twice that time mellowing in bottle. The quantity of wine made at Madeira has never exceeded 20,000 pipes, and a portion goes to America and the West Indies. Previous to the reduction of duties, about 300,000 gallons were entered for home consumption in England, and adulteration was practised to a greater extent upon this wine than upon Sherry at present. Teneriffe wine resembles Madeira, and, according to Brande, contains 19·79 per cent. of alcohol.

Malmsey wine took its name from Malvasia, a town in the Morea, whence the grape for it was originally obtained, but which does not now produce any good wine, and Malmsey Madeira wine is a luscious, sweet beverage, made from overripe grapes grown in a rocky part of Madeira,—containing only 16·4 per cent. of alcohol,—imported in very small quantities into Britain,—and used principally as a liqueur or at dessert.

Marsala wine is produced in the neighbourhood of Marsala, the ancient Lilybæum, in Sicily. It varies widely in quality; but was greatly elevated in character, and brought to a state of steady excellence, not many years ago, by some English producers who erected an extensive establishment in the district; and in consequence, it came rapidly into great repute, and rose rapidly in the scale of our imports. It closely resembles the lighter sorts of Madeira, and is much cheaper; and though the quantity imported into Britain in 1823 was under 80,000 gallons, the quantity rose against 1840 to about 400,000 gallons. Average specimens of it, according to Brande, contain 25·9 per cent. of alcohol; but a specimen of it, twenty years old, and submitted during five years to Soemmerring's process, contained, according to Prout, only 18·4 per cent.

Cape wines have been considerably improved of late years, and the consumption in England is great, not under this denomination, but for the purpose of mixing with Sherry, Madeira, and other good wines. The Cape of Good Hope being a British possession, the duty on its wine produce, at the time of the reduction, was fixed at 2s. 6d. per gallon, while that on foreign wines was fixed at 5s. 6d.; and hence there soon was an importation of upwards of 500,000 gallons annually of a very inferior wine, which has an earthy disagreeable taste, and a total want of aroma and flavour. There is a wine called Constantia grown at the Cape, upon two farms of that name, near the base of Table Mountain, and this is much esteemed, being very luscious, and little inferior to the muscadine of Languedoc. A specimen of it analyzed by Prout contained 14·5 per cent. of alcohol; and two specimens analyzed by Brande, the one red and the other white, contained respectively 18·92 and 19·75 per cent. Another kind called Steen wine resembles Rhenish, and was found by Prout to contain only 10·6 per cent. of alcohol. The Cape Muscbat is a sweet wine, and contains 18·25 per cent. of alcohol; and the Cape Madeira has a harsh and earthy taste, and contains 20·51 per cent.

Claret wines are produced principally in a district of France called the Bordelais, and in the fertile country on the banks of the Gironde. The most esteemed are the Lafittes, Latours, Chateau-Margaux, and Haut-Brion, these always fetching from 20 to 30 per cent. higher price than any other sorts in the district. Of the four named, the Lafitte is generally preferred, on account of its softness on the palate, bright colour, and exquisite perfume, partaking of the violet and raspberry. The Chateau-Margaux has the same delicate qualities, but not quite so high a flavour, while the Latour has fuller body, and the Haut-Brion is stronger than either, requiring considerable time to mellow in the wood and the bottle before it arrives at perfection. The second-rate clarets are innumerable, and of various qualities, some approaching to the first rates, and usually substituted for them in this country. The adulteration of clarets is great; and unless purchased in bond, or of a wine-merchant of established character, you can never be certain that the article is genuine. Average clarets contain about 15 per cent. of alcohol; good red clarets, such as the Haut-Brion and the Haut-Talanu, contain nearly 13·5 per cent.; and the amber-coloured clarets, such as the Barsac and the Sauterne, contain about 14 per cent. Most of the prime clarets, such as the Lafitte, the Latour, the Chateau-Margaux, the Leoville, and the Rauzan, have a deep purple colour, a delicate flavour, and more or less of a violet perfume; and some other good kinds, such as the Haut-Brion and the Merignac, resemble the better sorts of Burgundy, but are rougher. But some of the red sorts, such as the Canon and the St. Emilion, have a harsh taste and an odour somewhat like that of burning sealing-wax; and many of the best known white sorts, such as the Langon, the Cerons, the Preignac, the Beaumes, and the Buzet, are of inferior quality.

Champagne is the French wine held in most esteem in England, particularly by the ladies; and no beverage is more deserving of its high reputation, provided it be of the right sort. There are two kinds of champagne, the white and the red; and these are again distinguished as the still and the sparkling. Of the still, the Sillery is most esteemed, being of a light amber colour, with a delightful aroma and good body. The Ay is considered the best of the sparkling champagnes,

being the produce of a district a few miles south of Rheims; it is lighter and sweeter than Sillery; and that which creams on the surface, instead of frothing up like cider or perry, is considered the best. These, or imitations of them, are the French wines generally consumed in England. The province of Champagne produces altogether upwards of 1,100,000 hectolitres or about 24,200,000 gallons of wine; but the finest growths form but a small part of this quantity. Champagne is much improved by icing; and many assert that inferior qualities, and even the imitations called British, relish better than the superior sorts when this precaution is neglected in the one case and adopted in the other, particularly in warm sultry weather, when this delicious wine is so grateful to the taste. A specimen of Sillery analysed by Brande contained 13·3 per cent. of alcohol; and a specimen of Verzy, a red champagne, contained 11·93 per cent.

Burgundy wines are regarded by the majority of nice and fastidious judges as preferable to champagne. A sharp controversy on the merits of each took place during the reign of Louis XIV., which appears to have been decided in favour of Burgundy,—a wine, as Henderson remarks, "in richness of flavour and perfume, and all the more delicate qualities of the juice of the grape, unquestionably ranking the first in the world; and it was not without reason that the dukes of Burgundy in former times were designated as the *princes de bons vins*." Chambertin, Romanie-Conti, Clos-Vougeôt, and Richeburg, are the most celebrated of the red wines of Burgundy. The first was the favourite wine of Napoleon, and is produced on a spot of about 65 acres, a little to the south of Dijon, the annual vintage being about 140 puncheons. The white wines of Burgundy are not held in such repute as the red in this country, or by foreigners generally; but in France, they are considered little, if any, inferior in aroma or quality. The entire produce of wine in Burgundy and Beaujolais is about 3,000,000 hectolitres, of which the inhabitants consume 750,000; the rest is marketed at Dijon, Givry, Châlons-sur-Saône, &c. &c., and exported to all parts of the world. The best red wines of Burgundy have a beautiful, rich purple colour, an exquisite flavour, and a full body, and yet are delicate and light; and the best white wines of Burgundy, such as the Mont Rachet, have a high perfume and a nutty flavour. Brande states the proportion of alcohol in Burgundy wines at 14·57 per cent.

The German, Rhenish, or Hock wines, consumed in England, are produced on the banks of the Rhine and the Moselle. They are generally used for dinner, being drier and more aromatic than the French white wines; and the best of them have a peculiar flavour, much relished by good judges, and called by the natives gäre. By some they are considered acid; but this is the case with only the inferior sorts, or when there has been a bad vintage,—for the produce of warm dry seasons is quite free from this defect, and always commands the highest prices. The Johannisberger, grown on the estate of Prince Metternich, is universally admitted to be the best of the Rhine wines, from its choice flavour and perfume, and the absence of the least acidity. The Steinberger ranks next; it is a strong wine, and improves by age. Both these sorts are very rare, the district which produces them being extremely limited. The generality of Hocks consumed in England are grown on the banks of the Moselle, and some are of excellent quality, although they vary prodigiously in that respect. They require keeping for five or six years, in order to mellow. A specimen of old Johannisberger, analysed by Prout, contained only 8·71 per cent. of alcohol; specimens of Rüdesheimer and Grafenberg contained 10·72 per cent.; a specimen of Bodenheimar, a red Rhenish wine, analyzed by Zez, contained 13·96 per cent.; and average specimens of Hocheimer, or real red Hock, are stated by Brande to contain 13·68 per cent.

Bucellas, a Portuguese wine of pale colour and delicate flavour, contains 18·49 per cent. of alcohol; Carcavellos, a Portuguese wine of amber colour and sweet taste, contains 18·65 per cent.; and Vinho de Ramo and Collares, two Portuguese wines of deep purple colour, and rough, bittersweet, spirituous taste, contain respectively 15·62 and 19·75 per cent. Malaga, a Spanish white wine, contains 18·94 per cent.; and Tent or Tintilla, a Spanish wine of purple colour, sweet taste, and strong spicy flavour, contains 13·3 per cent.

Syracuse wine, a Sicilian production both red and white, contains 15·28 per cent.; Lissa wine, a Sicilian production resembling claret, contains 15·9 per cent.; and Etna wine, a Sicilian production, similar to Madeira but possessing the harsh flavour of Sicilian brandy, is the most spirituous of all the wines of commerce except red Hermitage, and contains so much as 30 per cent. Montepulciano, a sweet-tasted, high-flavoured wine of Italy, contains 22 per cent.; Aleatico, an Italian wine of brilliant purple colour, luscious taste, and aromatic flavour, contains 16·2 per cent.; and Lacrima Christi, a red, sweet, luscious Italian wine, contains 19·7 per cent. Among other Italian wines may be mentioned Verdea, of a greenish colour and high flavour; Albana, of a pale straw colour and light character; Trebbiano, of a golden colour and sweet taste; Orvietto, both red and white, and of light character; and Monte Somma and Gallite, fine varieties of Lacrima Christi.

Red Hermitage wine is a French production; and, in all its fine varieties, such as Beaume, Greffieux, Raucoule, Basas, and Meal, it has a dark purple colour, an exquisite flavour, and a somewhat similar odour to raspberry, and contains about 32·2 per cent. of alcohol. White Hermitage or Vin de paille has an amber colour and a sweet luscious taste, and contains 17·43 per cent. of al-

cohol. Cote Rotie or Verinay resembles white Hermitage in colour and flavour, but does not contain quite 13 per cent. of alcohol. Frontignac has a light colour, a luscious taste, and a grape flavour, and contains 12·79 per cent. of alcohol. Lunel or Clos-Mazet has a bright yellow colour, and is less luscious than Frontignac, and contains 15·52 per cent. of alcohol. Red Rousillon, in all its principal varieties, has great body and colour, and becomes tawny when old, and contains 18·13 per cent. of alcohol. Among other French wines may be mentioned white Rousillon, of a bright golden colour, a fragrant aroma, and a quince flavour; Clarette of Die, of light colour and character, sparkling, and delicate; Seyssuel, of a light colour and violet perfume; Cornas, of full rich red colour, and of the flavour of ratafia; Vin de Cotillon, of violet colour and sprightly character: and Tavel, Chuzlan, and Beaucaire, of bright rose colour, and of delicate flavour and aroma.

The far-famed Tokay wine is produced near the town of Tokay in Hungary; but is now scarce and dear in Britain, very seldom used, and difficult to be got genuine at any price. It is much more fit for a cordial than for a beverage. It is rich, luscious, and of exquisite aroma; and has a brownish-yellow colour when new, and a greenish colour when old; and contains only 9·88 per cent. of alcohol. A kind called Tokay Essence is syrupy, thick, and muddy. Another Hungarian wine, called Menser, resembles Tokay and is sweet; and a fourth kind, called Ansbruck, is thinner and more vinous.

The Vino Santo of Cyprus has a pale straw colour and a sweet taste. The Rithymo or wine of Candia is a fine flavoured white wine. The red wine of Ithaca has a flavour similar to Hermitage. The wine of Tenos is sweet and luscious. The white Muscadine of Smyrna is also sweet and luscious; and the red Muscadine of Tenedos resembles Tokay. The modern wines of Greece and the Levant, in general, are comparatively poor; though the ancient wines of these regions were rich and diversified,—and though, so late as the times of the Venetian Republic, Cyprus and Candia alone supplied all Europe with the choicest dessert wines.

The grape wine of England resembles Rhenish, and contains, according to Brande, 18·11 per cent. of alcohol. Our raisin wine is diversified, and contains, on the average, about 25·12 per cent. Our currant wine is still more diversified, and contains about 20·5 per cent. Our gooseberry wine has a briskness similar to that of Champagne, and contains 11·84 per cent. Our elder wine is thick and narcotic, and contains 9·87 per cent. Our orange wine is sweet and luscious, and has a flavour similar to that of raw oranges, and contains 11·26 per cent. And our apple and pear wines are simply cider and perry, and contain respectively 9·87 and 7·26 per cent.

The Dietetical and Medicinal Uses of Wine.—"Wine when good, and of a proper age," says Dr. Anthony Todd Thomson, "is cordial and tonic; but when new, it is flatulent, debilitating, and purgative, and intoxicates sooner than old wine. In a dietetical point of view, the temperate use of wine promotes digestion, and gives additional energy to the action of the heart and arteries, strengthens the animal functions, exhilarates the spirits, sharpens the wit, and calls into action all the intellectual powers. But when taken in excess, it intoxicates, producing sickness, headach, vertigo, and diarrhœa, with nervous tremors, which continue for two or three days; and, like ardent spirit, its habitual excessive use extinguishes the faculties of both body and mind, producing dyspepsia, emaciation, and debility, hepatic and pulmonary inflammation, palsy, gout, dropsy, delirium, tremors, and a long train of diseases and wretchedness. We nevertheless hear of very extraordinary quantities of wine being drunk with impunity by some individuals. I knew a man who had not retired sober to bed for twenty years; and yet lived to upwards of eighty years of age. Drunkenness, however, is the vice of barbarians; and, as nations merge from that state, it evidently becomes less prevalent. In Britain it is now happily confined to the dregs of the people. As a remedy, wine is stimulant, antiseptic, tonic, and anti-spasmodic. Its stimulating properties are less diffusible, but more permanent, than alcohol; and thence its dose is more easily regulated, and its effects are more certain. In all diseases accompanied with much debility, as typhoid fevers, and in cases of extensive ulceration or gangrene, wine is not only the best addition to cinchona bark and opium, but is a remedy on which alone there is much reliance; in some convulsive affections, as symptomatic tetanus, and chorea, much benefit has been derived from its use; and in the convalescences from all severe diseases, it is the most efficacious and the quickest mean we can employ for restoring the exhausted strength and vigour. Wine operates less powerfully on the system in a state of disease than in health; the quantity, however, to be given, and the proper period of exhibiting it, require to be regulated with much judgment. The skin being open, and not dry or hot, the strength sinking, and the ulcerations, if any exist, assuming a gangrenous appearance, indicate the use of wine; and when, in the event of the pulse being low and fluttering, wine restores its firmness without increasing delirium, and induces sleep, it may be given with a confidence of the greatest benefit. But if, on the contrary, it renders the pulse quicker, increases heat, thirst, delirium, or watchfulness, its exhibition ought immediately to be discontinued. The quantity to be given depends entirely on the nature of the disease, and the intentions for which it is administered. In typhus, the proper rule is to give it till the pulse fills, the delirium abates, and the extremities warm; and it should be re-

peated on the smallest appearance of stupor, quick and sinking pulse, or tremor. A few glasses, and these even diluted with water, given in the space of twenty-four hours, will often produce all that is required from wine; but sometimes very large quantities are necessary. In a case of symptomatic tetanus, mentioned by Currie, five bottles of Madeira wine were taken every day for some time, without producing the least symptoms of inebriety, or morbidly exciting the pulse; but, on the contrary, with the utmost advantage in allaying irritation, and relieving the patient. In ordinary cases of fevers, however, wine is, perhaps, in general, too freely given, so as to occasion exhaustion instead of supporting strength. In a dietetical point of view, wine is useful or prejudicial, in proportion as the fermentation is more or less perfect. In wines containing the malic acid, when the fermentation has been imperfect, the fermentative state of the liquor is recommenced in the stomach, and much carbonic acid and other gases are evolved, which, distending that organ, oppress the individual; and if he be dyspeptic, produce depression of spirits and all the horrors of hypochondriacism. When wine, however, is good, it stimulates gratefully the nerves of the stomach, and, consequently, promoting a more healthy secretion of the gastric fluid, greatly assists the chymification of the food. *Sweet wines* are more apt to become acescent than the dry wines; but it is erroneously conjectured that the same objection applies to the use of the *Rhenish wines;* for, as these wines contain much free tartaric acid, and scarcely any malic or gallic acids, they are less liable to ferment than many of the stronger wines. Sparkling, brisk wines, such as Champagne, intoxicate more speedily than the stiller wines, but the morbid excitement is of short duration, and the subsequent exhaustion is comparatively trifling. They are said to induce gout in those strongly predisposed to that disease; but, probably, more is to be attributed to the luxurious dishes which generally accompany the use of Champagne, than to that exhilarating beverage. In febrile habits, Burgundy, Port, and the stronger white wines, are to be avoided; but in diseases of debility, particularly where the stomach requires the aid of a tonic, these wines will prove beneficial. In convalescence, however, from acute diseases, if wine be admissible, claret or some of the better kinds of Rhine wines—for example, Moselle or Hock—are preferable; and this is particularly the case, if with a low pulse and much exhaustion the nerves are so excitable as to produce a febrile action in the arterial system, on the application of stimulants, either corporeal or mental. In those who have a disposition to obesity, the Rhine wines, on account of their diuretic properties, are preferable to every other kind for daily use. Where health abounds, wine is altogether unnecessary; but, as habit has rendered the use of it general, it is to be lamented that, in this country, the high prices of the more wholesome kinds force the great majority of the middling ranks to indulge in the use of those which contain too large a quantity of alcohol, and the lower classes to the abuse of spirituous liquors. When wine is prescribed as a cordial in a state of convalescence from acute diseases, or in a weakened state of the habit, it should not be taken with dinner or any other meal, but at noon, upon an empty stomach."

WINE-PALM,—botanically *Manicaria saccifera.* An Indian palm-tree, of commonly about 30 feet in height. It constitutes a genus of itself; and was introduced about 26 years ago to the palm-houses of Britain. See the article PALM.

WINE (SPIRIT OF). See ALCOHOL.

WING. The wings of birds correspond to the fore legs of quadrupeds and the arms of man. The clavicle of birds is a hollow tube of great strength, and the fork is peculiar to winged animals. The different bones of the wing are bound together, and connected with the bones of the body, by strong ligaments; and the muscles by which motion is communicated to them are the most powerful with which the animal is provided. All this peculiar apparatus is necessary to give due force to these instruments of locomotion. The construction and disposition of the feathers are not less curious, and admirably adapted for the purpose of flying. The best form of windmill sails, which human ingenuity and science have been able to devise, bears a striking resemblance to the arrangement of the feathers in the wings of birds, and is one of many beautiful instances of the mathematical exactness of the principles on which the works of creation are constructed. The form of the wings is most accurately adapted to the habits of the birds. There are two forms, which have received the names of the *rudder-formed* and the *sail-formed* wings: the former are long, slim, and tapering, as in the falcons, swallows, &c.; the latter broad, long, and rounded at the end, as in the swan, goose, &c. The former are for quick, sudden, and rapid motion, and are moved often; the latter for floating a long time more slowly through the air.—The wings of insects are membranous, elastic, for the most part transparent, and traversed by firm air-vessels, which sometimes form a beautiful net-work. In some they are naked; in others, as in the butterflies, they are covered with fine, soft, feathery scales: in some they are extended and straight, in others folded. Some insects have four wings, and others but two; the latter are commonly provided with poisers or balancers (*halteres*). The difference in the structure and disposition of the wings is one of the distinctive marks on which the division of insects into orders is founded: thus we have the *hemiptera*, the *coleoptera*, the *lepidoptera*, the *neuroptera*, &c.—Quadrupeds which fly are provided with membranes extending over the bones of the extremities, by which they are enabled to

impel themselves through the air; others merely have the skin so loose on the sides as to be spread out when the limbs are extended, and, being buoyed up in this manner, they are able to make surprising leaps.

WINNOWING. The cleaning of thrashed grain from chaff and dust. In rude states of society, this is done simply by exposing the grain to the currents of the atmosphere, either superficially or by tossing according to the strength of the wind; but in better states of society, even from remote times, it has always been done with more or less of implemental aid,—and in the improved husbandry of Britain and other highly civilized countries of the present day, it is done by means of special machinery, either attached to the thrashing machinery as in the case of the Scottish thrashing-mill, or used separately as in the case both of small Scottish farms and of all the English farms which use travelling or ordinary English thrashing-machines. See the articles Barn-Management, Thrashing-Machine, and Winnowing-Machine.

WINNOWING-MACHINE. Implements similar to modern shovels, but differing from one another in different ages and in different countries, were used by ancient Orientals, Greeks, and Romans for tossing thrashed corn upon their out-of-door thrashing-floors so as fully to expose it to gently-blowing winds; for if corn, in the open air, is thrown several times across the wind, and well scattered in throwing, the chaff, being light, not only falls short, but also is blown away. Two other implements seem also to have early come into general use,—the one of the nature of a large fan for wafting off the chaff when no sufficient natural wind was blowing, and the other similar to a modern sieve for freeing the grain from adherent and intermixed earth and dust. "The oxen likewise and the young asses that ear the ground," says the prophet Isaiah, "shall eat clean provender, which hath been winnowed with the shovel and with the fan." "I will command, and I will sift the house of Israel among all nations," says the Most High by the prophet Amos, "like as corn is sifted in a sieve, yet shall not the least grain fall upon the earth." The fan also is alluded to in a passage of the New Testament which metaphorically describes the ministry of the Redeemer; and the sieve in another which foretold the terrible trial of the apostle Peter's faith at the time when the Redeemer was betrayed; and both, as well as two winnowing kinds of shovel, are mentioned in numerous extant passages of Greek and Roman authors. "When the corn is mixed with the chaff," says Columella, "this ought to be separated in the wind. The west wind is reckoned the best for this purpose, because it blows soft and equal during the summer months. Yet, to wait for this wind is the sign of a slothful husbandman; for, while he is expecting it, he may be overtaken by a severe storm. In the thrashing-floor, therefore, the corn that is thrashed should be so heaped up, that it may be cleaned with any wind. But if for several days the weather should continue quite calm, the corn must be cleaned with fans; lest, after a calm, a severe tempest should destroy the labours of the whole year." The fan, conjointly with the shovel, continued in use throughout all the middle ages, and has even been perpetuated, in the least improved districts, to the present day. An esteemed form of it in comparatively late times consisted of four pieces of wood, placed longitudinally in the direction of an axis, each having fastened upon it a piece of cloth or canvas; and this was made to revolve by means of a handle or winch, so as to produce a steady and somewhat strong current of air,—and the corn was tossed into the current, or scattered across it, with the shovel.

The first fanning apparatus, turned by machinery for driving off chaff and dust, was invented by the Chinese, and applied to the cleaning of rice. It was thence introduced to Holland, and attached to mills for making pot or pearl barley; and, in the early part of last century, it was introduced from Holland to Scotland, through the patriotism of Andrew Fletcher of Salton, and the ingenuity of James Meikle, father of the inventor of the thrashing-mill. A large and improved form of it, applicable to all sorts of grain, yet requiring the corn to be twice or thrice passed through it before complete cleaning could be effected, began to be manufactured about the year 1733 by Rogers of Cavers in Roxburghshire. Another form, also of general applicability, and probably somewhat better than Rogers', yet likewise requiring the corn to be twice or thrice passed through it, was patented in 1768, by A. and R. Meikle. An improvement, "so combining the properties of various machines, that the grain at one operation could be both separated from the chaff and lighter seeds and completely riddled of all sorts of refuse," was afterwards made by Moodie of Lilliesleaf. A highly improved machine—which continues in use and is eminently approved to the present day, and which obtained a prize from the Royal Agricultural Society of England so recently as the year 1841—was patented in 1800 by Mr. Cooch of Northampton. "This machine," says Mr. Ransome, "dresses all kinds of seeds; and its work is performed in a perfect manner. Its principle involved more mechanical combinations than were at that time generally understood by the class for whose use it was intended; and this, together with its then cost, long retarded its more general adoption." Another eminently efficient implement, quite as useful as Cooch's, but simpler in the arrangement of its parts, easy to be worked, and apt to keep long and steadily in order, was patented in 1812 by John Elmey; and this, under various modifications adapting it to hand-work or to the thrash-

ing-machine, or introduced by the taste of different manufacturers or the ingenuity of different improvers, is now par excellence the winnowing-machine of almost all Scotland, and of a large part of England. A full and minute description of one of the best ordinary varieties of Elmey's machine, therefore, will substantially serve as a very satisfactory account of the whole of this class of implements; and such a description, ably and technically written, together with illustrative diagrams, lies happily at our hand in the 3d Volume of the Quarterly Journal of Agriculture.

"AB and CD, *Fig.* 1, are two standards of ash 3 inches square, and 4 feet long, with their fellows on the opposite side. These standards are fastened together longitudinally by a rail, one at each side, as seen at EF, also of ash, 3 inches square, and 3 feet 11 inches long, inserted into GB and CD, 3 feet 2 inches from B and D; and transversely they are connected by ash-rails 1 foot 9 inches long, and 3 inches by 2 in breadth, at C, I, G, H and B: thus a frame of ash is formed upon which the rest of the implement is constructed. This frame is lined inside of the standards, on both sides with thin fir deal, from C as far down as D; from A 11 inches below F to H; 1 foot 2 inches from A to *t*; and 6 inches from H to *q*. The large cast-metal wheel L, 2 feet 4 inches in diameter besides the teeth, is divided into 6 segments, either of which are removable by screws for the purpose of repair; it contains 144 teeth, and is fixed to an iron axle, both ends of which rest on brass lockers 6 inches long, on the rail EF, and its fellow. The shank of the handle M is 9½ inches in the straight line; and the handle, a hollow cylinder of wood moveable round an iron spindle fastened at right angles to the shank, is 9 inches long. The shank screws on to the axle in the line of motion, as from M to E. The pinion N, also of cast-metal, 6 inches in diameter besides the teeth, contains 28 teeth; is fastened on the end of the axle of the fans O;

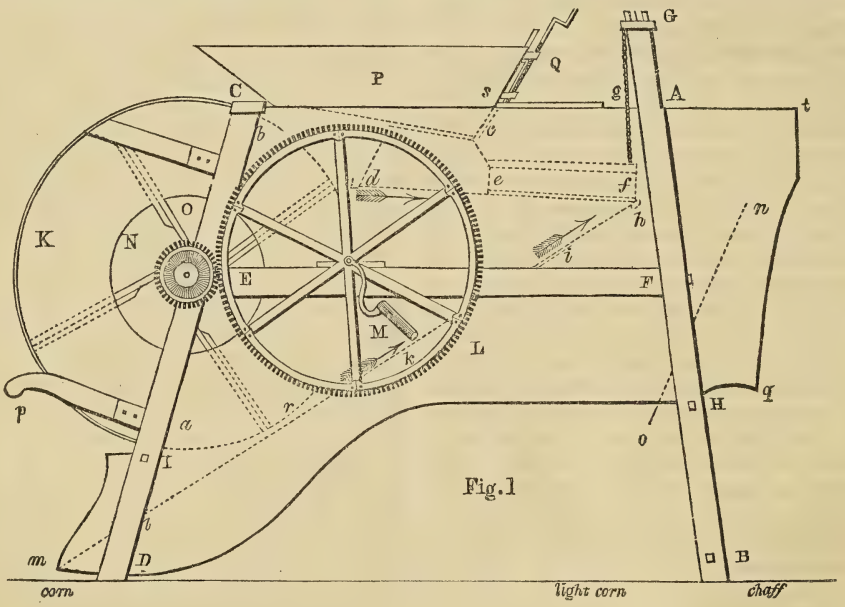

Fig. 1

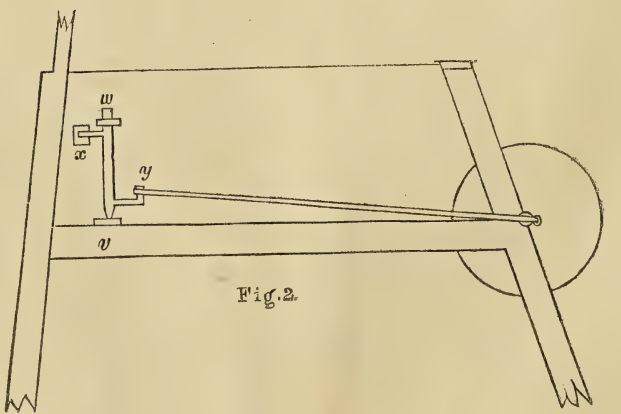

Fig. 2.

and is acted on by the large wheel L. The fans O are four in number, and stretch 2 feet 8 inches in diameter. They are each fastened on, parallel to a face of the square block of wood, which moves round with the axle of the pinion N. The coom, as it is termed, K, which embraces and closes in the fans, is 2 feet 9½ inches in diameter, and 1 foot 10 inches in breadth; and can be removed at pleasure, for the purpose of repairing the fans, by unscrewing the nuts at *a* and *b*. The circular space N, O, E, through which the supply of the air to the fans is furnished, is 1 foot 4 inches in diameter. The hopper P rests from C to *s*, 2 feet along the top of the machine, and is at the extremity of the projection at C 6 inches, and at Q 7 inches above it, measured perpendicularly. The top of the hopper spreads out in length 2 feet 6 inches, and in breadth 2 feet 4½ inches. Its bottom descends 4 inches to *c* below the line of C *s*, and at *c* has a semielliptical hole cut out across its whole breadth. There is also a rectangular hole of about 4 inches high cut out of its front, over which the slide *s* passes up and down by means of the screw Q, which regulates the quantity of grain emitted from the hopper in the process of cleaning. The top of the apparatus *d e f* fits under the bottom of the hopper, and forms its shoe, which, by operating on the grain through the elliptical hole made there, puts it in motion. This apparatus is suspended by an iron pivot at *d*, which is placed in a rail fastened across the breadth of the machine there; and its other end is supported by two chains 1 foot ½ inch long each, hanging from the cross rail G, which connects the top of the standard AB and its fellow; and which are both produced 8 inches above the top of the machine, in order that these chains may have more liberty to oscillate. The frame *e f*, 1 foot 3 inches long and 4½ inches deep, is fastened together transversely by iron rods 1 foot 4 inches in length rivetted at both ends. Into the part corresponding with the dotted line immediately above the letters *e* and *f*, are slid the riddles which are used for the sifting of the different kinds of grain. These riddles, made of iron-wire, fastened to a narrow frame of thin iron, are 1 foot 3 inches in length, and nearly 1 foot 4 inches in breadth. That for wheat contains 4 squares in the length of an inch; for barley, 3 squares; for oats 2¾ squares; and that for roughs, as the roughest uncleaned grain is termed, a square of 1½ inch to the side. The riddle is moved by a small iron rod *u y*, *Fig.* 2, 3 feet 8 inches in length, fastened at one end, which is eyed, by a nut which screws into a crank, fastened on the end of the fan axle opposite to that of the pinion N. This crank must not exceed 2 inches in play. The other end of the rod, which is also eyed, is fastened by a nut to the under arm *y* of the crank *w v*. A piece of leather, placed on each side of the eyes of the rod, softens the noise of the machine very much. The other arm *x* is fastened by two intermediate joints to a jointed staple in the frame *e f*, through a hole in the lining of the machine. These arms are 2½ inches long, and set at right angles to each other, and also at right angles to the shank of the crank *w v*, which is 9½ inches long, and which at *v* performs a quadrantal motion in a socket, and at *w* through the staple. The grain falls upon the inclined plane *h m*, the upper part of which, *h i*, 1 foot long, is made of sheet iron, and slides up and down at pleasure. From *i* to *m* is of deal nailed firmly, with the exception of the part from *k* to *l*, which forms a screen of wire-gauze 8 squares to an inch in length, stretched on a frame of wood, and nailed with tacks through a selvage of tin. This screen permits all the dry earth, sand, or seeds of wild plants which may have been in the grain to pass through. *n o* is a board 2 feet long, which moves up and down at pleasure, and is kept in its place by a wooden catch on the cross bar at H. The chaff is blown over the top of this board at *n*, and falls down beyond B. The light corn falls over *h*, and down below *o*, while the clean grain slides down *h m* to *m*. The space between the standard AB and its opposite fellow, is lined up with deal, 2 feet 3 inches, as far up as H, to keep the chaff and light corn separate. The top of the machine is covered in front of the hopper P, as far as to *g*, 1 foot 1 inch. The coom is continued as far round as from *b* to *d* above, and I to *r* below, the current of air passing up in the direction of the arrows at *k* and *i*, *p* and *q* form two handles, by which two females can lift the whole machine anywhere with great ease. To save the inside of the lining where the frame *e f* beats against it, it is necessary to place a stout piece of plate iron around the point of contact on each side; and it must be fastened with screw nails, as the constant beating will soon start common nails. It is recommended not to use any oil, because the dust of the barn soon forms a paste with it, which will clog the motion of the machine. The gudgeons should rather be turned smooth on a lathe at first. The peculiarities which are apparent in the construction of the machine described above, consist in placing the standards at an angle to each other, the distance between A and C being only 3 feet 4 inches, whereas the distance between B and D is increased to 5 feet 2 inches, and which is produced 4 inches more to *m;* by this arrangement, the part *m*, at which the clean grain issues out, is placed more prominently, and of course more conveniently, for the person who takes away the grain to be riddled. This arrangement, too, obviously increases considerably the length of the inclined plane *h m*, and of the wire-gauze screen *k l*, over both of which the grain slides in its descent to *m*, and through the latter of which it deposits any sand, earth, or small seeds of wild plants which are mixed with it, and even any shrivelled light corn that may have escaped the force of the wind. It also lowers the angle of the inclined plane to 32° instead of 45°, by which

the grain, in descending, gets more time to deposit its impurities. The coom K is by this arrangement placed a little more out of the way of the person's head, who takes away the grain. The large wheel L is also an improvement. The pinion N, upon which it operates, makes fully five revolutions for one of the large wheel; and as in ordinary cases the latter only requires to make twenty-eight revolutions in a minute, the fans O will therefore make 144 in the same time. This easy motion to the driver of the wheel, for which a woman has sufficient strength, thus generates an immense current of air by the rapid motion of the fans. This current, though amply filling the place from *d* to *r*, 2 feet, is forced in the direction of the arrows, through the riddle, and of course between the grains of corn which are at the same time passing through it, and makes its escape by an aperture of only 10 inches from *f* to *g*, the width of the machine between the linings being only 1 foot 8 inches. To facilitate still farther the driving of the machine, it is necessary to make the shank of the handle M 9½ inches long, and which, as a radius, will be found to describe a circle round the axle of the wheel, the most convenient in size for the easy motion of the body of the driver. The slide *s* should only be elevated above the bottom of the hopper 1 inch, and in order to make the emission of the grain from it more complete, the hopper should always be amply supplied with corn. Many contrivances have been adopted by introducing pinions and shafts and rollers, pitch wheels and pitch chains, and sheaves and belts, to shake the riddle, and supply the corn regularly to it from the hopper, in order to supersede the use of the old spear and crank and shoe, as described above. These contrivances have no doubt to a certain degree succeeded. But none of them can supply the grain *more* regularly, or imitate the vibratory motion of the human hand in riddling *so well*, as the combined motion arising from the simultaneous action of the loose spear and crank, the quick oscillations of the long chains *g*, the sort of undulating vermicular motion of the shoe *d* at the pivot, and the five gentle beats of the riddle frame *e f* against the lining of the machine, to one turn of the large wheel; while any set of these other contrivances imposes a considerable additional weight for the driver to overcome."

The machine, when attached to the thrashing-mill, is made comparatively heavy; and, when used separately, is made so light as to be easily removeable from one part of the barn to another. In different forms of it, a single sieve may be made to do all or nearly all the work of the two sieves,—the heavy corn may be made to fall out either at the end or through a spout at the side,—the light corn may be discharged either below the machine or through a spout,—and the part of the inclined plane through which the dust and sand fall may either be a fixture so as to act as a mere screen or steady riddle, or be oscillatingly moveable so as to act as a shaking sieve. An improvement of the machine, by Mr. Docker of Findon in Banffshire, for better adapting it to conjoint working with the thrashing-mill, assumes that it is commonly too narrow for due efficiency in connexion with very powerful mills, and that it cannot be made broad enough in its ordinary construction without suffering disproportion between the strength of its blast and the increased width of its fan; and it provides for this defect by adopting a double-headed fanner or a conjunction of two comparatively narrow fans, and by admitting the air between the heads as well as on the outsides, so that the two blasts become combined on leaving the fans. Another improvement or variety, invented by Mr. Common of Denwick, has bands instead of wheels. A light supplementary implement, called a fan or a blowing machine, is used in some barns for dusting and cleaning grain which has not come clean enough out of the winnowing process, or which has acquired dust and impurities from exposure; and this is quite simple in construction, and has a straight vent for the blast, and has not any riddling or sifting apparatus. See the article THRASHING-MACHINE.

Parsons and Clyburn's patent winnowing machine, manufactured at the Earl of Ducie's Iron Works in Gloucestershire, differs widely from all other winnowing machines. "The fan or blower," say the makers of it, "is about 3 feet in diameter at its greatest radii, and 2 feet 6 inches at the smallest. The fans are placed at an angle of 45°, so that when put in motion, the wind enters at the smallest side and is driven out at the largest, filling a space or chamber 3 feet square, with wind. The riddle is placed in the middle of the chamber, with a vibrating motion. As the grain with the chaff in it drops from the feed-roller to the riddle, it meets with the wind from the upper side of the fan, which blows out the chaff before it gets into the riddle; the grain after passing through the riddle, is concentrated in the small hopper; when it leaves the hopper, it meets with the wind from the lower side of the fan, which drives the light grain farthest from it into a spout provided for that purpose, leaving the best and heaviest to fall down into another spout nearer to the wind, thus completely separating the light from the heavy grain. One of the great improvements in this machine, is making the fan of such a form that it will give a greater degree of wind for the grain to fall through, than in the other machines; another is, its having one of Hornsby's registered feeding apparatus attached to it."

Salter's winnowing machine, invented by T. F. Salter, and patented in 1839, combines the apparatus for winnowing and dressing grain with the principles of a barley hummeller. "The undressed grain from the hopper," says Mr. Ransome, in his Implements of Agriculture, "passes

through a cylindrical sieve, having within it a rotatory spindle, upon which short blunt arms are arranged in a spiral direction; these agitate the grain as it passes along, and thus separate the small dirt and dust as well as the awns of barley, which fall through in a closed box or cupboard. The cylinder is placed in a slanting direction, and is provided at each end with slides, which regulate the quantity and speed with which the grain shall pass. Through the slide aperture at the lower end, the grain is introduced upon other sieves, which, having a backward and forward motion, distribute it equally over their surface while it is subjected to the blast of the fan, driving obliquely through the sieves; this carries the chaff out of the machine; the grain falls on a screen, which, having a similar motion to the sieves, separates from it all small seeds, and the dross corn is carried away in a division formed for the purpose. The grain, dross corn, and chaff are thus all thoroughly separated from each other; and the dust, dirt, and small seeds, having fallen in an enclosed box from the cylinder, may be entirely removed. I have heard this machine highly approved by many,—and when pains are taken to separate the corn from the short straw, &c., previously to submitting it to the machine, I believe it to be very effective; but as there is some degree of complication in its details, it is chiefly suitable to those to whom a high degree of excellence in the manner of 'making up their corn' is a matter of more importance than the time or labour it may require."

WINTER. The season which intervenes between autumn and spring. It is the season of repose to vegetables, and of torpidity to hybernating animals,—of invigoration to soils, and of the digestive preparation of the food of plants,—of frost and snow and storm and tempest,—of the busiest labours of the farmery, and the roughest toils of the farm-field,—of the lowest activity of brutes and the most slovenly existence of fools and libertines,—but of the strongest outgoings of human friendships, and of the loftiest soarings of enlightened intellect. We have sufficiently indicated its natural phenomena and its rural occupations in the article CALENDAR, and have given a large notice of its biological characteristics in the article HYBERNATION; and we may here, in the words of Mudie, very briefly suggest its great moral lessons to reflecting men,—and most of all to men residing in the country. "Winter is the season of Nature's annual repose,—the time when the working structures are reduced to the minimum of their extent, and the energies of growth and life to the minimum of their activity, and when the phenomena of nature are fewer, and address themselves less pleasingly to our senses, than they do in any other of the three seasons. There is hope in the bud of spring, pleasure in the bloom of summer, and enjoyment in the fruit of autumn; but, if we make our senses our chief resource, there is something both blank and gloomy in the aspect of winter. And if we were of and for this world alone, there is no doubt that this would be the correct view of the winter, as compared with the other seasons; and the partial death of the year would point as a most mournful index to the death and final close of our existence. But we are beings otherwise destined and endowed,—the world is to us only what the lodge is to the wayfaring man; and while we enjoy its rest, our thoughts can be directed back to the past part of our journey, and our hopes forward to its end, when we shall reach our proper home, and dwell there securely and for ever. The winter is, therefore, the especial season of man,—our own season, by way of eminence; and men who have no winter in the year of the region in which they are placed, never of themselves display those traits of mental development which are the true characteristics of rational men, as contrasted with the irrational part of the living creation. It is true there must be the contrast of a summer, in order to give the winter its proper effect; but still, the winter is the intellectual season of the year—the season during which the intellectual and immortal spirit in man enables him most triumphantly to display his superiority over 'the beasts that perish.'"

WINTERA. See DRIMYS.

WINTER ACONITE,—botanically *Eranthis*. A small genus of ornamental, tuberous-rooted, small plants, of the ranunculus family. The common winter aconite, *Eranthis hyemalis*, called by Linnæus *Helleborus hyemalis*, was introduced to Britain from Italy toward the close of the 16th century; and has long been almost universally cultivated as one of the earliest and most common winter beauties of the flower border. Its flower is yellow, and sits upon the leaf at the height of two inches or so from the ground, and blooms from January till March; and though neither delicate nor brilliant nor conspicuous enough to compare for a moment with any of the chief floral ornaments of summer, it has abundance of beauty to charm the eye amid the rigours of winter and early spring, and constitutes a delightful companion to the snow-drop. The roots send out numerous offsets, and may be taken up and transplanted after the leaves decay, or between the beginning of June and the latter part of October; but as they are small, and of similar colour to common garden soils, they must be carefully searched for, else many will be left in the ground; and as the plants are only one-flowered, and do not make a good appearance when thin or scattered, the roots should be planted pretty close to one another and in small clusters. The Siberian winter aconite, *Eranthis sibericus*, is similar to the common species, but does not bloom till a considerably later period in the spring, and was not introduced to Britain till 1826. Both species thrive in any common garden soil.

WINTER'S BARK. See DRIMYS.

WINTER BERRY,—botanically *Prinos*. A genus of white-flowered, ornamental shrubs, of the buckthorn tribe. One tropical evergreen species, and ten hardy species—four of them evergreen and the other six deciduous—have been introduced to Britain from America; they vary in height from 18 inches to 6 or 7 feet; and all love a light soil and are propagated by layering.

The whorled winter-berry, *Prinos verticillatus*, is a native of Virginia, Pennsylvania, and other parts of the United States, and was introduced to Britain in 1736. It is one of the tallest species, and deciduous. Its branches are numerous, and feather it down to the ground, and are covered with a brownish-coloured bark; its leaves are alternate, and stand on slender footstalks, and are lanceolate, serrated lengthwise, pretty large, and of a strong green colour; its flowers come out in ones and twos at the joints of the branches, and appear in July and August, but make no show; and its fruit are purple-coloured berries, and remain on the trees throughout the winter, and have a fine appearance. When this plant is raised from seeds, they must be sown in beds of fine sandy earth soon after they are ripe; and as few will come up till the second spring, the beds must be kept in a clean and dressed state throughout the intervening summer; and the plantlets must remain in the beds till the second March after they appear above the ground, and must then be transplanted at very small distances into a nursery plot, and kept there till fit for their final situation.

The smooth winter-berry, *Prinos glaber*, is a native of Canada, and was introdueed to Britain in 1759. It is an evergreen, and somewhat resembles an alaternus. Its branches are numerous, and come out from the lowest as well as highest parts of the stem, and give the plant a very bushy habit; its leaves are alternate, oblong-lanceolate, acute, serrated, and of a strong green colour; its flowers come out in twos and threes on a footstalk from the wings of the leaves, and bloom in July and August; and its berries have a red or purple colour, and continue throughout the winter. The raising of this species from seed is more operose than even that of the preceding; for it requires all the same care, with the addition that each plantlet needs to be set in a pot and kept for a series of winters under special shelter, and finally put down in a protected situation.

WINTER CHERRY. See CHERRY (WINTER).

WINTER-CHICKWEED. See WINTER-GREEN.

WINTER-CRESS,—botanically *Barbarea*. A genus of yellow-flowered, evergreen herbaceous plants, of the cruciferous order.—The common winter-cress, or bitter winter-cress, or yellow rocket, *Barbarea vulgaris*, called by Linnæus *Erysimum barbarea*, grows wild among rubbish, and on waste grounds, and about hedges, in many parts of Britain; and it has some claim, though but a slight one, to a place in the kitchen garden as a salad plant. Its root is tapering and rather woody; its stem is strong, angular, furrowed, leafy, either simple or branched, and from 15 to 24 inches high; its lower leaves are lyrate, with a roundish terminal lobe; its upper leaves are obovate, dentated, strongly ribbed, quite smooth, and of a fine texture; its flowers grow in round-headed corymbose clusters, and have a bright yellow colour, and bloom from May till August; and its pods are quadrangular and about an inch in length. The herbage is nauseously bitter and somewhat mucilaginous. A variety with a profusion of exceedingly double flowers, which bloom in long succession, and pass from yellow to dirty white as they turn old, is common in flower gardens.—The early winter-cress, or Belleisle cress, *Barbarea præcox*, called by Linnæus *Erysimum præcox*, grows wild on the banks of brooks and ditches, and on watery grassy spots, in various parts of England. Its root is biennial or in only the lowest sense perennial; its stem or stems are erect, smooth, somewhat branched, of a violet hue at the bottom, and commonly from 10 to 20 inches high; its lower leaves are lyrate; its upper leaves are deeply pinnatifid, and have linear, oblong, entire segments; its flowers are fewer, smaller, and paler than those of the common species, and bloom from April till October; and its pods are thrice as long as those of the common species, smooth, and exactly square. This species has a better claim than the common one to a place in the kitchen garden, and may be eaten in the same manner as water-cress; and very much resembles that plant in flavour, but is rather more pungent.—Three hardy exotic species have been introduced from Tauria, Iberia, and the Levant; but they possess little interest.

WINTER-GREEN,—botanically *Trientalis*. A small genus of hardy, curious, perennial-rooted, annual-stemmed, white-flowered, herbaceous plants, of the primrose family. The European species, or the winter-chickweed, *Trientalis europæa*, is an indigen of the moist woods, mountain pastures, and turfy heaths of Britain. Its root is slightly tuberous; its stem is solitary, erect, somewhat cylindrical, almost naked except at the top, and commonly from 3 to 8 inches high; its leaves are smooth, and form a tuft at the top of the stem; its flowers are very handsome, and bloom in May and June; and its seeds are dotted, and have snow-white reticulated tunics of an appearance like lace. The American species resembles the European, and was introduced to Britain in 1816. Both love a soil of sandy peat, and are propagated by radical division.

WINTER-GREEN,—botanically *Pyrola*. A genus of small, ornamental, evergreen, herbaceous plants, of the heath family. They take their botanical name from the similarity of their leaves to those of the pear-tree, and their popular one from the habit of remaining beautifully green throughout the winter. All are very handsome, and at the same time rather difficult to cultivate. They love a soil of sandy peat, and

thrive best in a shady border, and may be propagated either from seeds or by radical division. All possess tonic and astringent properties; and two plants which formerly belonged to them, but are now assigned to another genus, and have been noticed in our article CHIMOPHILA, are eminently medicinal. Six species inhabit the woods of Britain,—principally in moist and lofty situations; and three have been introduced from North America. All the nine have a height of about 6 inches, and bloom about midsummer or in July; and most have either white or reddish flowers, often highly fragrant. Two of the indigenous species, the rose-coloured and the intermediate, occur in England but not in Scotland; two, the side-flowering and the smaller, are semi-aquatics; one, the single-flowered, occurs only in very lofty situations; and the remaining one, the round-leaved, in common with the two non-Scottish species, inhabit ordinary woods. A curious circumstance in the natural history of the smaller species, *P. minor*, is that it has frequently been found growing in small patches in young plantations where the ground was previously in cultivation, and yet could not be discovered in previously uncultivated ground in the vicinity, even though the soil and the situation were exactly similar.

WINTER-SWEET. See MARJORAM.

WINTER WEED. The ivy-leaved speedwell, *Veronica hederæfolia*. See the article VERONICA.

WIRE-WORM. The larva of a click-beetle or elateridous insect, living in the soil, and preying destructively on the roots of cultivated plants. See the article ELATER. Four species of elateridæ, as stated in that article, have been perfectly ascertained to produce vast multitudes of the wire-worms of both field and garden; and eight other species are strongly suspected or presumptively known to produce many more; and we shall first give descriptions of all these twelve species,—next notice their general economy and habits,—and next detail the principal known means, natural and artificial, of keeping them down or exterminating them,—simply premising that, after having searched very many authorities and papers on the subject, we feel ourselves driven to rely mainly on an ample and most able article by Mr. Curtis, in the 5th volume of the Journal of the Royal Agricultural Society.

The spitting click-beetle, *Agriotes sputator*—called by Linnæus *Elater obscurus*—is the smallest of the four species which are certainly known to produce destructive wire-worms. It is shining, piceous, and clothed with very short ochreous pubescence. The head and the thorax are black, and thickly and distinctly punctured; the latter orbicular, convex, the hinder angles forming short stout teeth, sometimes rufous; and down the centre is a channel. The scutel is subovate. The elytra or wing-cases are not broader than the thorax, but more than twice as long, elliptical, convex, slightly rugose, with nine punctured striæ on each. The antennæ and legs are rufous; the former not longer than the thorax, slender, the joints obconic, the basal ones the stoutest, the second a little longer than the third, which is the smallest. The feet have five distinct joints. The length of the insect is from 3 to $3\frac{3}{4}$ lines, and the breadth from 1 to $1\frac{1}{8}$. Some specimens are entirely tawny, excepting the black eyes and tips of the mandibles; whilst others have the head and thorax only black, the hinder margin of the latter and the spines being tawny as well as the elytra. From this great difference of colour, this species was named *Elater variabilis* by Herbst; and Paykull, thinking it was the same as the next described species, gave it the name of *Elater obscurus*. It is very abundant everywhere from the beginning of May to the end of June in hedges, on grass under oaks, in corn-fields, &c.; it occurs also in profusion amongst rejectamenta left by floods.

The dusky click-beetle, *Cataphagus obscurus*—called by Linnæus *Elater obscurus*, by Eschscholtz *Agriotes obscurus*, by Fabricius *Elater variabilis*, and by De Geer *Elater obtusus*—is rather more robust than the *Agriotes sputator*, and has more convexity on the sides of its thorax. It is piceous, densely clothed with short depressed ochreous hairs. The head and the thorax are thickly and distinctly punctured; the latter is as broad as it is long, orbicular, very convex; the posterior angles are produced into strong spines, and there is a channel down the back. The scutel is oval. The elytra are not broader than the thorax, and nearly three times as long, elliptical and convex, the extremity when united conical, the apex of each rather acute, reddish brown and punctured, each having nine punctured striæ somewhat in pairs. The antennæ are a little clavate, quite as long as the thorax; the basal joint stout, the second and third of equal length, shorter and smaller than the following, the terminal one ovate-conic, reddish brown as well as the legs. The feet or tarsi are distinctly five-jointed. The length of the insect is from $4\frac{1}{4}$ lines to $4\frac{1}{2}$, and the breadth $1\frac{1}{2}$ to $1\frac{3}{4}$. The pubescence is so thick on perfect specimens as to give them a dull brown tint all over; whilst others which are old and rubbed appear blackish. From April to Midsummer this beetle is abundant in fields, pasture-lands, woods, and gardens.

The striped click-beetle, *Cataphagus lineatus*—called by Linnæus *Elater lineatus*, by Panzer *Elater striatus*, by Gyll *Elater segetis*, and by Eschscholtz *Agriotes lineatus*—is supposed by some entomologists to be only a variety of *Cataphagus obscurus*, with the elytra or wing-cases striped, the spaces between the striæ being alternately dark and light, forming four brown and five testaceous lines. It is an exceedingly common species in various situations, and is the most frequently bred from the larvæ by those who have taken the pains to rear them. In

April it has been found in great numbers under stones by the sea-shore; and in May it has been seen congregated upon a yellow ranunculus or buttercup in an osier-holt. It abounds also on grass, in hedges, corn-fields, &c.; and specimens of it have been obtained as late as July, with the pupæ and exuviæ. Bouche says that its larvæ live sometimes in great multitudes in dung and vegetable earth.

The rufous-rumped click-beetle, *Athous ruficaudis*—called by Gyll *Elater ruficaudis*, by Olivier *Elater sputator*, by Herbst *Elater analis*, and by Fabricius *Elater hæmorrhoidalis*—is long, narrow, piceous, and shining, and clothed with ochreous and longish hairs. The antennæ are dusky, and similar in their relative proportions to those of *Cataphagus obscurus*, but a little longer and compressed; the basal joint is stout, the second and third slender, the remainder obtrigonate, the apical one narrower, the tip conical. The head and the thorax are black, and thickly and minutely punctured; the former is semi-orbicular, with truncated and reflexed clypeus; the latter is much longer than broad, a little narrowed towards the anterior angles, the posterior spines short and trigonate, and the margin beneath projecting considerably in a semicircle to receive the head. The scutel is black. The elytra are reddish brown, and twice as long as the head and thorax, being rather broader than the latter, but linear, the apex ovate, and the tip of each rounded; and they are minutely punctured, with nine striæ on each. The abdomen is ferruginous. The legs are short and ferruginous. The feet appear four-jointed until magnified; and are very pubescent beneath, —the basal joint the longest, the second and third decreasing in length, slender at the base, and somewhat trumpet-shaped, the apex furnished with a membranous margin,—the fourth minute,—the fifth long, slender, and terminated by two simple claws. The length of the insect is 6 lines, and the breadth 1½ line. It is abundant from April till the end of June in corn-fields, on nettles, on commons, in pastures, &c. It has been observed in the beginning of June flying about hedges and banks, and in May infesting the oak-leaves and underwood in extensive woods.

The satin-coated click-beetle, *Lepidotus holosericeus*—called by Linnæus *Elater holosericeus*—is the first of the eight species which are but presumptively known to produce the destructive wire-worms. It is elliptical or boat-shaped, deep brown, thickly and minutely punctured, and clouded with silky ochreous pubescence. The antennæ are scarcely so long as the head and thorax, and are slightly pubescent, and eleven-jointed; the basal joint the stoutest, somewhat chopper-shaped, and chestnut-coloured,—the second minute,—the third long, slender, and clavate,—the fourth and six following produced internally and obtrigonate,—the apical joint elongate-ovate, and the apex narrowed. The head is small. The palpi and eyes are black. The thorax is convex, semi-ovate, concave before, broadest at the base, which is bisinuated, the angles produced, each forming a strong trigonal lobe, not very acute; the pectoral lobe rather small and tapering. The scutel is large and orbicular. The elytra are more than twice as long as the thorax, and scarcely broader at the middle, the ochreous pubescence often forming two ocelli on the disc; and there are nine punctured striæ on each elytron, most distinct at the base. The wings are ample. The legs are short, slender, and pale ferruginous. The length of the insect is 5 lines, and its breadth 2. This click-beetle has often been observed in corn-fields, and also found under stones and on birch-trees; and it continues from the end of April till August.

The mouse-coloured click-beetle, *Agrypnus murinus*—called by Linnæus *Elater murinus*—is rather broad and boat-shaped, and entirely clothed with very short ash-coloured depressed hairs, marbled with brown, more or less ochreous, and is thickly and minutely punctured. The antennæ are shorter than the thorax, rather stout, and eleven-jointed, of bright ferruginous colour, the basal joint stout, oblong, and piceous,—the second small and semiovate, —the third smaller and pear-shaped,—the fourth and six following compressed, produced internally, and obtrigonate, —the apical joint longer and ovate,—and the apex suddenly narrowed. The head is semi-orbicular and depressed. The eyes are scarcely visible. The thorax is twice as broad, orbicular, convex on the back, with two tubercles on the disc; beneath are two deep fissures to receive the antennæ, and the pectoral spine is long and attenuated, and the apex subulate. The scutel is ovate-conic. The elytra are a little broader than the thorax, and more than twice as long,—the hinder portion attenuated,—the apex rounded, sloped suddenly towards the thorax at the base; and there are nine indistinctly punctured striæ on each elytron, and the costal margin is deeply emarginate to receive the hinder thighs. The wings are ample. The legs are short and shining pitchy. The tips of the thighs and the tarsi are fulvous; and the latter are five-jointed and tapering,—the basal joint the stoutest and the longest in the hinder pair. The claws are moderate and acute; the tibiæ are rough, with series of minute bristles. This insect is commonly about 6 lines long and 2½ broad; but is sometimes much larger. It is found in corn-fields and in sandy places from the end of April till the early part of autumn.

The tawny-legged click-beetle, *Melanotus fulvipes*—called by some entomologists *Elater fulvipes* and by others *Elater castanipes*—is very long, narrow, and shining black, thickly punctured, and clothed with very short fine ochreous pubescence. The antennæ are as long as the thorax, compressed, pubescent, fulvous, and eleven-joint-

ed,—the basal joint stout and subpyriform,—the second minute and nearly globose,—the third small and obovate,—and the fourth and six following, produced internally, and obtrigonate, but slightly decreasing in diameter to the apical joint, which is spindle-shaped. The mouth is pale ferruginous, the labrum and tips of mandibles piceous. The head is rather broad, and semiorbicular. The eyes are hemispherical; the clypeus forming a sharp projecting shelf over the mouth. The thorax is convex, somewhat semiovate, and almost straight before,—the base nearly straight also, the angles forming rather narrow lobes, and appearing pointed above, but truncated laterally; there is also a dorsal impression broadest at the base, and a short longitudinal channel on each side, close to the lobes. The pectoral spine is rather long and narrow. The scutel is tongue-shaped. The elytra are thrice as long as the thorax, but not broader, linear, the apex subovate; and they are more finely punctured than the thorax, and there are nine punctured striæ on each. The costal margin is gently hollowed towards the base. The wings are ample. The legs are moderately long, and chestnut coloured. The tarsi are tapering,—the basal joint the stoutest, and a little elongated,—the fourth small. The claws are minute. This species varies in length from 6 to 9 lines, and in breadth from $1\frac{3}{4}$ to $2\frac{3}{4}$. It sometimes abounds in corn-fields, and in hedges and grassy places, and appears in May, June, and July; but its larvæ live in decaying trees, and probably do little injury to crops.

The reddish-brown spitting click-beetle, *Agriotes sputator* or *Elater sputator*, is confounded in name with one of the four species whose larvæ are certainly known to be devastating wire-worms, and is nearly allied in natural characteristics to the dusky click-beetle or *Cataphagus obscurus*. It is clothed with short depressed ochreous pubescence. The antennæ are scarcely so long as the thorax, compressed, and pubescent,—the basal joint stout,—the second rather longer than the third, which is oval,—the remainder short and obovate,—the terminal joint elongated,—the apex conical. The head and thorax are black, shining, and thickly punctured; the anterior margin of the latter, and the hinder lobes, reddish-brown. The head is somewhat orbicular; the clypeus narrowed. The thorax is longer than broad, narrow, oblong, very convex, with a dorsal impression behind, the posterior angles forming truncated lobes. The scutel is oval, and truncated at the base. The elytra are not broader than the thorax, and twice as long, nearly linear, the apex ovate; and they are somewhat scabrose, with nine striæ on each, not neatly punctured, and deepest at the base,—the costal margin very concave towards the base. The wings are ample; the under side castaneous-brown. The angles of the thorax and the pectoral spine, which is rather long and slender, are ferruginous. The legs are moderate and slender; feet tapering,—the basal joint a little elongated; the claws slender. The length of this insect is 3 lines, and the breadth 1 line. The colour varies considerably, some specimens being entirely bright ochreous, whilst others have the head and thorax partially variegated with black. This species abounds in grass fields, and feeds in company with the dusky and the striped species. The perfect insects of it occasionally occur in multitudes in the rejectamenta left by floods in the fen districts of England; and in the months of spring and summer, they are abundant everywhere.

The black click-beetle, *Athous niger*—called by Linnæus *Elater niger*—is boat-shaped, shining black, finely punctured, and clothed with yellowish pubescence, which is not depressed. The antennæ are longer than the thorax, compressed, tapering, and hairy, the basal joint stout,—the second minute and ovate,—the third obtrigonate,—the following similar but larger, produced on the inside, but decreasing towards the apical joint which is fusiform. The head is suborbicular; the clypeus forming a projection over the trophi. The thorax is twice as broad, oval, very convex, the posterior angles not acute, a little divaricating; the pectoral lobe not long and tapering. The scutel is ovate-trigonate. The elytra are broader than the thorax, elliptical, the apex ovate or sub-conical, with nine punctured striæ on each, most distinct at the base. The wings are ample. The legs are not long. The thighs are stoutish; the three basal joints of the tarsi cushioned beneath,—the second and third dilated,—the fourth minute,—the fifth slender,—the claws small. This species is from $5\frac{1}{2}$ to 6 lines long, and from $1\frac{3}{4}$ to 2 broad. It is very abundant, during May and June, in corn-fields, hedges, and meadows; and it is said to live two years in thoroughly rotten or highly decomposed horse-dung, so that its larvæ or wire-worms may often be conveyed in this kind of manure into fields and gardens.

The margined click-beetle, *Dolopius marginatus*—called by Linnæus *Elater marginatus* and by Marsham *Elater saturalis*—is narrow and elliptical, shining, testaceous, and clothed with short ochreous pubescence. The antennæ are longer than the head and thorax, slender, compressed, fulvous, and pubescent,—the basal joint the stoutest and clavate,—the second and third the slenderest and elongated,—the fourth and following stouter and clavate,—the terminal joint subfusiform. The head and thorax are thickly and strongly punctured; the former obtuse, convex, and pitchy; the latter longer than broad, very convex, piceous, the anterior and posterior margins bright ochreous, including the angles, which are very acute and slightly divaricating. The scutel is subovate. The elytra are linear, thrice as long as the thorax, sometimes rather broader, attenuated or ovate behind, ochreous or reddish brown, with a space down the suture,

and sometimes the costal margin brown; they are somewhat scabrose, with nine distinctly punctured striæ on each, the outer margin slightly concave towards the base. The wings are ample; the under side more or less fuscous or castaneous. The pectoral spine is long and narrow, but thick. The apex of the abdomen is testaceous. The legs are moderately long, slender and pale ferruginous; the tarsi, with the terminal joint the slenderest, the basal joint elongated; the claws minute. The total length is $3\frac{1}{4}$ lines, and the breadth $\frac{3}{4}$. This is an exceedingly variable species in outline and colour, some specimens being broader than others; and the antennæ are apparently stouter in the males. Some examples are entirely bright ochreous or chestnut, and others are uniformly of a pitchy colour. It abounds, in June, July, and August, upon oaks and alders in woods, and is not infrequent in corn-fields; but its peculiar habits or economy as a species are altogether unknown.

The pointed click-beetle, *Adrastus acuminatus* or *Elater acuminatus*, is almost a miniature of the preceding, and is about the same size as the *Elater limbatus* of Linnæus, but has a narrower and less convex thorax, and is generally marked with a sort of shallow groove down the crown of the head. It is elliptical, narrow, shining, testaceous, and clothed with short ochreous pubescence. The head and thorax are black and punctured; the latter longer than broad, the anterior margin and posterior angles acuminated and testaceous. The antennæ are longer than the head and thorax, compressed, and castaneous,—the basal joint elongated and stout,—the second and third obovate, the latter a little the shortest,—the fourth and following somewhat obovate, truncate,—the terminal joint fusiform. The scutel is dark and oval. The elytra are nearly thrice as long as the thorax, punctured, testaceous, the suture often dusky, especially near the apex, with nine punctured striæ on each; the underside piceous; the pectoral spine long and slender; the legs ochraceous. The total length is about 2 lines, and breadth about $\frac{1}{2}$. This species frequents corn-fields, meadows, hedges, and similar situations; but whether its larvæ belong to the destructive wire-worms has not been ascertained.

The long-necked click-beetle, *Athous longicollis* or *Elater longicollis*, frequents corn-fields, hedges, grassy grounds, and woody places from April till August. The male is long and narrow, ochreous, and clothed with very short pubescence of the same colour. The head and thorax are thickly and coarsely punctured, and of a dull black colour; the anterior margin of the latter, the sides and base, including the angles as well as the clypeus, are more or less ferruginous in many examples; and this portion of the head is very concave, the margin thickened and slightly reflexed. The antennæ are more than half the length of the body, slender, and compressed; the basal joint is clavate, and not stouter than the following, which are elongate-clavate, and truncated, excepting the second, which is minute, and the terminal joint, which is subfusiform. The head is subquadrate. The eyes are very prominent. The thorax is long and narrow, not much broader than the head before, gradually and slightly increasing in diameter to the base; the angles short and truncated laterally; the sides nearly straight, but slightly convex near the middle; and down the back is a faint channel, with a slight fovea on each side near the base. The pectoral spine is long and slender. The scutel is small, black, and punctured. The elytra are more than twice as long as the thorax, and a little broader, linear, the apex ovate, the costal margin fuscous and very gently concave near the base; they are slightly glossy, a little rugose, with nine distinctly punctured striæ on each. The wings are ample. The underside is more or less piceous, excepting the body, which is ochreous and very glossy, sometimes pitchy down the centre, or having two fuscous spots on each segment. The legs are longish, slender, and of a deep ochreous colour; the tarsi tapering, the basal joint elongated, the fourth minute. The total length is $4\frac{1}{4}$ lines, and the breadth rather more than one line. The female differs so considerably from the male in form that the name of *longicollis* is not appropriate. The neck is much broader and larger; the antennæ are not so long, the third and following joints being obtrigonate. The female varies also greatly in colour, some specimens being entirely brown, others of an ochreous-chestnut, &c.

The eggs of the click-beetles are very minute, of a yellowish-white colour, and nearly globose or slightly oval. Whether they are laid in the soil close to the root of a plant, or between the sheaths or enveloping leaves near the base of the stem, has not been ascertained. The larvæ must at first be almost invisible to the naked eye; they grow very slowly, and become when full grown about three-fourths of an inch, or in rare cases eleven lines, in length; they have a wire-like form, a smooth surface, and extreme toughness,—and thence are called wire-worms; and they live five years in the proper state of larvæ, and cast off their skin, probably at three successive periods, as they increase in size. They perform their moult by splitting the skin along the thorax, and drawing themselves out at the aperture; and their exuvia has a brown colour, and retains the form of every part of the body, including eyes, horns, feet, and perhaps also internal organs. The larvæ, immediately after the moult, are very tender and of a whitish colour; but as soon as they recover, they move about with the greatest facility; and in all their ordinary states, they have a perfect adaptation of skin for free and agile diving into the soil, burrowing in the earth, and gliding upward and onward in any direction they please.—A wire-worm has a pale ochreous colour, becoming darker when dead, with a few

hairs scattered over its polished shining skin. It is semicylindrical, the back being convex, the belly more flat. Its head is flattened or wedge-shaped, and there are twelve abdominal segments. The mouth is rather small, and comprises an upper-lip, with a horny base, the margin leathery and bilobed; it is small and concealed beneath the clypeus, which is rigid, with a ciliated lobe on each side, and three minute teeth in the middle; beneath is a large semiovate space formed by the union of the base of the maxillæ with the mentum or chin, which is long and narrow; the under-lip is small and somewhat obtrigonate, the base truncated, the margin undulating and furnished with two small biarticulate palpi or feelers, sometimes with an indistict third joint; on either side is the maxilla, having a minute and densely pubescent lobe on the inner angle, with a larger biarticulate one behind it, and a four-jointed palpus or feeler on the outside, the terminal joint the smallest; above these are the mandibles or jaws, which meet over the mouth, one being placed on each side,—they are strong, horny, and of a pitchy colour, being more or less pointed, with a tooth below the apex, and frequently a smaller one at the middle,—and below this is a ciliated space. Two little antennæ or horns are placed in front of the head near the anterior angles; they are triarticulate and similar to the palpi in form, the basal joint being the largest, the terminal one short and slender; and sometimes there is a tubercle projecting from one of the angles of the second joint. On each side of the head and behind the antennæ is a minute dot like a little eye. The first abdominal segment is much longer than the two following; the eight succeeding have a minute spiracle on each side; the terminal one is the longest and conical, with a brown or blackish oval aperture, larger than the others on each side towards the base; beneath this segment is also a false leg or prehensile foot, which assists in walking, and is probably the vent for the evacuation of the digested food. The three first or thoracic segments are furnished with six short legs, a pair being attached to each near the hinder margin; and these are nearly alike and four-jointed, the joints being rough with short brown spines, the apex furnished with a strong claw, slightly curved and nut-brown. When the wire-worm has arrived at maturity, it descends a considerable depth into the earth, and forms an oval cell there entirely composed of the surrounding particles of soil, and not even lined with silk; it then casts its skin again, and becomes a pupa or chrysalis, generally, it seems, at the end of July or beginning of August.—The pupa is long and narrow in form, like the perfect insect, but is of a yellowish-white colour. There are two minute spines projecting from the anterior angles of the thorax; all the oral organs are visible; the horns and legs are folded or incumbent upon the breast; and the wing-cases as well as the wings are small and the least developed of any part; the scutel and abdominal segments are distinct, the apex being furnished with two moveable spines and two lobes terminated by nipples in the middle beneath. Of course at this period the animal is at rest, being deprived of the power of locomotion, and is consequently no longer injurious. The insects commonly remain in the pupa state two or three weeks; but many no doubt pass the winter buried and protected from casualties and the rigour of that inclement season. When the appointed time for their transformation comes, they burst from their shrouds and earthy tombs, and rising through the soil arrive at the surface changed to perfect beetles, but of a whitish colour, soft, and extremely tender; and after being exposed to the air and light, their bodies harden and their colour gradually changes, so that in a few hours they attain their horny coat, their specific colour, and all their permanent characters.

Wire-worms occur in most land, and attack almost all kinds of crops; but they specially abound in some particular conditions of soil and in some particular situations, and they greatly prefer certain plants to others. The tastes of individuals of different species, and those also of different ages of the same species, probably differ; so that, though all the specimens which can be obtained in any field or garden may seem to be perfectly like one another in every thing but size, several entirely distinct kinds, with appreciably different habits, or even with powers of mischief ancillary and supplementary to one another, may be simultaneously carrying on the work of devastation. Wire-worms are particularly rife on land which has lain long fallow, and on ploughed land newly or recently broken up from old pasture or from clover ley; they seem specially to multiply from the undisturbed deposition and hatching of their parents' eggs on grass lands and wastes, and from the free supplies of food afforded them by grasses, weeds, and all sorts of luxuriant, perennial, herbaceous vegetation; and, within the sphere of cultivation, they prey most on oats, wheat, barley, artificial grasses, turnips, carrots, mangel-wurzel, rape, cabbages, potatoes, onions, lettuces, hops, irises, carnations, pinks, lobelias, and a multitude of the most common ornamental plants of the flower-border. So many as from four to eight wire-worms have been turned up by the spade in a space of four feet; and so many as from four to twenty plants have been observed to be bitten in a very short time by one worm.

The most important crop which suffers from the wire-worm is wheat. A writer in the Linnæan Transactions, speaking of this in cases of sowing upon clover leys, recently broken-up old pastures, and pea and bean stubbles, estimates it at about a twentieth part of the whole, and thinks this a very fair and moderate calculation. "The number of cultivated acres of land in England at the time in question," says he, "was

computed at seven millions, of which 2,400,000 were calculated to be sown with wheat, and as only one-half of the wheat sown is supposed to be on clover leys, old pastures, &c., our calculations must be confined to 1,200,000 acres, instead of 2,400,000; this will give 60,000 acres as annually destroyed by the insect in question, which replanted, at one bushel per acre, will require 60,000 bushels of seed, which, at 8s. per bushel, are worth £24,000. Besides this, although no extra expense is incurred by the farmer in preparing the land, yet he has to pay for dibbling-in the seed, which, at 5s. 3d. per acre, will cost £15,750, or at the full price, 6s. per acre, £18,000. If the land require harrowing, there will be a further charge of 9d. per acre, or £2,250, not to name other items, which render it difficult precisely to ascertain the loss of the farmer. If the above calculation be thought a fair one, and I see no reason why it should not, we find the quantity of wheat lessened to the market by the depredations of these insects is very frequently, if not annually, 60,000 bushels, which occasions to the farmers an additional expense of at least £15,750." Instances are frequent of a far greater proportion of wheat crops being destroyed than this calculation supposes; and even a case of the most excessive destruction has not been a-wanting,—so excessive as to require the whole field to be ploughed up. The attacks, in general, do not seem to begin till spring,—though they have been supposed by some observers to be made also during the winter; and they are indicated by the dying off of the lower leaves,—and in the worst cases by the falling of the plant.—Oats, in consequence of being a favourite crop on newly broken up leys and pastures, are oftener devastated to an excessive extent than wheat. Dr. Dickson says, "When this sort of grain is cultivated on such leys as are newly broken up, there may frequently be danger, especially where the land has been long in the state of grass, both from the destructive attacks of insects, and the soil becoming too light, open, and porous, from the decay of the grassy materials for the support of the plant." The discouraged farmer, in fact, is sometimes compelled to lay down valuable land as pasture to a very great disadvantage; and in 1842, in many parts of England, the oat-crops suffered so severely from the ravages of the wire-worms, that it became necessary to plough them up and sow a second time.—When the season is dry and cold in the early spring months, the barley-crops are frequently greatly injured by the attacks of the wire-worms; and this is indicated by the young plants changing from a healthy green to a sickly yellow.—Potatoes greatly suffer in some districts, and do not suffer at all in others. This is a very remarkable fact, and resembles the curious anomaly in the habits of the black caterpillar, which in some districts will not touch Swedish turnips and in others will not feed on anything else; and hence one writer asserts that the wire-worm will not injure potato crops, while others assert that, in many localities, it has annually reduced them to less than one-third.—Crops of cabbages, also, whether in the field or in the garden, are sometimes greatly ravaged or almost totally destroyed; and crops of carrots, in kitchen-gardens, which have not undergone proper rotations, or which have been suffered to lie in a rank and weedy condition, are often so inveterately attacked that entire series and successions of them more or less completely fail.—The turnip, however—even notwithstanding its being the prey of so many other insect enemies—suffers more severely from the wire-worm than any other green crop; and is attacked by it in the foliage as well as in the root, and at all seasons of the year except during frost; and is deprived of as much substance by one individual of it as by five or six turnip-flies. "The wire-worm," says Mr. Le Keux, "begins on the edge of the leaf and eats it away like a caterpillar, and often cuts the leaf off at the top of the stalk, and it may sometimes be found on the ground half devoured. The wire-worm," he states, "seldom feeds above ground in the day-time, unless it be cloudy and dark. At such times I have observed them devouring the young turnip plants before the rough leaf has been formed; but their most destructive operations are carried on beneath the surface of the earth, where they attack the root; in the very early state of the plant, after eating this through, the upper part of the plant is gradually drawn down into the earth and devoured, so that the plants disappear without any perceptible cause, and without any trace of them being left. In the more advanced state of the plant their devastation appears to be confined to eating through the root; and having thus killed one plant, they proceed to another. If a turnip-plant appears drooping (as if from the want of water), whilst those in its neighbourhood are fresh and erect, a wire-worm (sometimes half-a-dozen) will be sure to be found at the root, if the earth around it be carefully removed."

Wire-worms are to the full as mischievous in the garden as in the field; and, in consequence of the great variety of plants attacked by them, they are a kind of universal plague to at once the cottage cultivator, the market-gardener, the nurseryman, the orchardist, and the florist. Those of the spitting click-beetle and the dusky click-beetle are particularly abundant and wondrously destructive; and as the former of these beetles is strongly attached to umbelliferous flowers and to nettles, all classes of cultivators ought vigilantly to keep down fool's parsley, hemlock, and all similar weeds on the banks and hedges in the vicinity of their grounds. In the garden as in the field, the wire-worm is particularly destructive for a few years after ground has been broken up from pasture; and, at a time when the Botanic Garden at Hull was in this condition, it de-

stroyed a large proportion of the annuals sown in it. Pansies, lobelias, and dahlias are much attacked by it; and all the fine kinds of dianthuses are peculiarly liable. "The wire-worms," says Mr. Smith in the Florist's Magazine, "invariably attack the pink and the carnation at the bottom of the stem near the root, and make holes through it in every direction, while the only indication of their presence is the entire destruction of the plant. The larva is in general found in the loam; therefore great care should be taken, in sweetening that soil, not to allow one to escape when it is turned over; and their colour being a light brown, makes the finding of them more difficult."

As to the particular soils and seasons and circumstances in which the wire-worms are most mischievous on farm-lands, the following important information is presented by Mr. Curtis:—"Mr. Porter of Covehithe, where the lands are for the most part light, says that the wire-worms do most mischief in March, April, May, and June; that wheat suffers the most among the corn-crops, and white turnips amongst the green crops, but that rye is sometimes swept off by acres; and with regard to barley, he has observed that when it is drilled-in 3 inches deep, the plant droops and turns yellow, as if attacked by the wire-worm, whereas at 1½ inch deep it makes a vigorous plant. I may observe with respect to this difference of result from the depth of sowing, that it is possible the wire-worm may not be able to exist near the surface in a light sandy soil, and consequently the barley escapes when drilled-in at the lesser depth. Turnips and beet-root he finds most affected at the end of June and the beginning of August; yet 12 acres of the latter, which produced a fine plant, were completely taken off by the wire-worm the last week in May. Swedes were afterwards sown the second week in June, and to his surprise produced a fine crop. The success of the swedes must be attributed, I think, to the greater part of the wire-worms having arrived at maturity when they had destroyed the beet, in which case they would change to pupæ, and afterwards to beetles, in both which states they are harmless. Turnips do best at Covehithe if sown about the 21st June on the light lands, and a week earlier on heavy lands. On the lower part of fields bordering on marshes, where the land is springy and friable, barley, turnips, and beet have generally fallen a sacrifice; and such land is most subject to their attacks. When white-clover or suckling and rye-grass layers have been left for seed, it is scarcely possible to get a wheat-crop on account of the wire-worm; the only chance is to break up the land and work it well about for a couple of months in the autumn. Potatoes never suffer on Mr. Porter's farm from the wire-worm.—Mr. Robinson, of Henstead, informs me that in his neighbourhood the gravelly and sandy soils are most infested, and the strong loam and clay most free from the wire-worms. That they inhabit every aspect was proved by their ravages over all parts of a field which was lowest in the centre. A dry season is most conducive to their increase; yet if the following year be wet, it does not kill the wire-worms, but it probably destroys the elaters, and prevents the deposition of the eggs. Early in March 1841, when his wheat was well out of the ground, and about 1½ inch high, it began to die off, and on pulling some up he found the wire-worm had eaten into the stalk and consumed the inside. This was upon dry gravelly hills which had been a clover layer, and the valleys and better parts of the field did not suffer; but barley on strong land in the same parish drilled in the spring, did not produce above one-third of a crop, owing to the attacks of the wire-worms. Some low wet common land was broken up, pared and burnt (which with the draining cost £10 per acre); it first produced a good crop of turnips, and afterwards a prodigious crop of oats; but another portion under a different owner was pared but not burnt, and the crop was lost. —Mr. Bates says that the following is the order in which the crops probably are affected in degree in his part of Suffolk, viz., wheat, turnips, barley, oats, and beet, and that they are generally least injured on good soils. If wheat be sown in dry weather, it has proved favourable to the inroads of the wire-worm. Oat stubble ploughed several weeks previously, and sown with wheat the third week in November, suffered from their attacks. Barley and oats were injured in May, in a cold wet season. Turnips have been swept off after being up a fortnight, but generally they fall a sacrifice when three or four weeks old, having at that time four or six leaves; yet he finds the eating through of the tap-root after the second hoeing does little mischief to the turnip-plant. That all lands exposed to the sun by being fed off short, as clover layers, are greatly infested with the wire-worms, but that no potato-crop is destroyed by them."

Three of the most effectual preventives of the ravages of wire-worms are judicious fallowing, the judicious breaking up of leys and pastures, and the judicious surface treatment of ploughed lands. "May not this insect," said a perspicacious writer in 1816, "which is now more prevalent among our crops than ever, owe its prevalence to the system of fallowing and burning the refuse of such crops being nearly exploded?" A clean and careful summer fallow, in fact, when accompanied with such a thorough burning of rubbish as will surely destroy both the larvæ and the eggs of the click-beetles, is a perfect remedy against wire-worms wherever they have been working devastation; and if it occurred at regular though even pretty remote intervals in a cycle of years, would always be a more or less powerful hindrance to their obtaining any lodgment. In every case, however, it must be truly clean and careful,—and in particular must completely clear

away all couch-grass and similar weeds, whose roots might afford sufficient sustenance to a large number of the wire-worms till the corn crop should be sown and strike root. See the article FALLOW. Any pasture or old ley intended to be broken up for corn should be carefully examined; and if any considerable proportion of wire-worms are found in the roots and stems of its plants, it should either be sown with some substances fatal to them at the time of breaking up, or subjected to a searching summer fallow previous to the sowing of it with corn. In breaking up any old pasture, where so extreme a precaution as either of these may be thought unnecessary, a breast-plough should be used to take off not more than 2 inches of the turf in the first instance, which will secure the crop from the attacks of the wire-worm, for an additional depth of only 2 inches has so encouraged that pest that it has been known to destroy an entire field of wheat. This difference probably arises from the effects on the roots of the grass; if the top of the turf only be pared off, the roots will die, whereas by going 4 inches deep they lie and vegetate, so that when it is afterwards all ploughed-in, the worms find the requisite pabulum, until the corn is forward enough to afford the wire-worms a more agreeable substitute. Dr. Dickson says that the destructive attacks of insects on leys newly broken up "may in some measure be obviated by eating such lands very closely with sheep previous to their being broken up, as by such a method the ova of such insects may be much destroyed and their propagation prevented; and the treading the crop by sheep as well as the roller may likewise be beneficial; horses have also been turned in for the same purpose by some cultivators." The folding of oxen and sheep upon infested fields is supposed by many to check the wire-worm by stopping their burrowing; but it seems more likely to prevent the beetles from being able to get out of the earth from their pupæ cases, and to compel those which do effect their escape, in consequence of their finding no appropriate place for the deposition of their eggs, to depart for a more suitable locality. This operation might therefore be most advantageously adopted early in the spring before the beetles hatch. An eminent cultivator preserved his turnips by harrowing and hard-rolling the land in March and April, but found this operation of no use later in the season. In another place, alluding to barley, Dr. Dickson also says, "If the plants suddenly change from a healthy green to a yellow cast, the use of the roller should be had recourse to, in order that the superficial parts of the soil, which are probably become too loose and porous, may be effectually pressed, and thereby rendered too close and compact to admit the worm to prey upon the tender roots of the young plants. That this effect may be produced in the most effectual manner, the roller should be of such a size, or so loaded, as to afford a pressure equal to the draught of three or four horses, which should be yoked double, in order to increase the effect by their treading. It has been suggested that if by this method the injury can be counteracted until such time as rain falls, there need not be any apprehension for the crop, as the plants will soon push forward in such a manner as to become too strong to be in danger from this insect." The use of some of the recently-invented rollers, of the clod-crushing and soil-biting kind, particularly Crosskill's, is still more eminently serviceable; and a top-dressing of lime before using the rollers, whether they be of the old kind or the new, materially adds to the efficiency.

A good remedy for wire-worm may be found in a crop which, while taking entire possession of the soil, either affords no proper nourishment for the larvæ or contains some principle which operates fatally on their life; so that, while excluding every other plant on which they might feed, it shall exterminate them either by starvation or by poisoning. Two crops of this kind are woad and white mustard. On breaking up damp meadow and pasture land in Lincolnshire, the sowing of it with woad instead of corn has been found to exterminate wire-worms; and in the ordinary rotational management of arable land, the sowing of it with white mustard preparatorily to corn, will destroy all the wire-worms by which the corn would otherwise be infested. "White mustard-seed," says Mr. Tallent of Little Houghton, "will protect the grain from the wire-worm, and this fact I have demonstrated perfectly to my own conviction. I first tried the experiment on half an acre, in the centre of a 50-acre field of fallow, which was much subject to the wire-worm. The mustard-seed being carried, the whole field was fallowed for wheat, and the half-acre that had been previously cropped with mustard-seed was wholly exempt from the wire-worm; the remainder of the field was much injured. Not only was the half-acre thus preserved, but in the spring it was decidedly the most advanced part of the crop; and the prosperous appearance which it presented caused me to repeat the experiment, by sowing three acres more of mustard-seed in the worst part of a field of 45 acres, also much infested with the wire-worm. The remainder of the field was sown with early frame pease, which, with the mustard-seed, were cleared in the same week. The land was then ploughed for wheat; and I had the pleasure of noticing these 3 acres to be quite free from the worm, and much superior in other respects to the other part of the field, which suffered greatly. Thus encouraged by these results, I sowed the next year a whole field of 42 acres, which had never repaid me for nineteen years, in consequence of nearly every crop being destroyed by the wire-worm; and I am warranted

in stating that not a single wire-worm could be found the following year, and the crop of wheat throughout which was reaped last harvest was superior to any I had grown for twenty-one years. I am therefore under a strong persuasion that the wire-worm may be successfully repelled and eradicated by carefully destroying all weeds and roots, and drilling white mustard-seed, and keeping the ground clean by hoeing."

Another good remedy for wire-worm would be the application to the soil, in the way of sprinkling, top-dressing, or intermixture with manure, of some substance which, without injuring the plants or deteriorating the land, will kill the larvæ. More carefully conducted experiments, and on a more extensive scale than any that have yet been undertaken, will be necessary to show what kind of substance is best adapted for this purpose. Probably different substances will be found most useful in different situations, according to the nature of the soil and the chemical ingredients which enter its composition. The latter consideration should be particularly attended to in all experiments on the subject, as most likely to suggest the most appropriate remedy; and it might even happen that the substance employed to destroy the insects might be so managed as to produce a most beneficial change in the chemical qualities of the soil. If a strong saline solution, for example, should be found to kill the insects, as it is very likely to do, there are few soils which would not derive benefit from it. Of course many substances prove speedily fatal to wire-worms, and among these the choice would have to be determined by cheapness and ease of application. Beirkander, a Swedish observer, who has investigated the habits of wire-worms, found that they live 9 days among garlic, 14 hours among spruce leaves, 12 hours among fir leaves, 9 hours among *Ledum palustre*, and 2 hours among *Myrica gale;* and he suggests that such of these plants as prove most speedily fatal should be mixed with the manure. Several liquid applications have been tried with more or less success in gardens, —principally, however, in flower-gardens, and under circumstances widely dissimilar from all field cultivation; and the chief of these are spirit of tar, chloride of lime water, and some strong saline solutions. Lord Albemarle recommends that when a field intended for wheat is infested with wire-worms, rape-cake should be used as a manure, to be pulverised and sown across the field; and if this do not destroy the insects, it at least saves the crop from their attacks. Mr. Burgess, writing in the second volume of the Royal Agricultural Society's Journal, says, "This year I applied the nitrate of soda to my wheat, when, from the wet season and the wire-worm, the plant was nearly destroyed, and I found it particularly beneficial, the wire-worm either being killed by the application or forsaking the roots; and consequently I think I have above an average crop of wheat." The ammonia which invigorated the plants at the same time destroyed the insects; and it is added that the turnips grew so fast that they soon got out of the way of the fly, *Altica nemorum*. It is also positively affirmed that if lime and soot be applied to the soil before sowing any grain, it will kill the wire-worms. Common salt likewise, on light sandy soils, is highly efficacious in destroying them; and of its effects upon these animals it is in the power of every one to convince himself, and also of the strength required for their destruction, by dissolving a tea-spoonful or more of salt in a tea-cupful of water, with some wire-worms in another, half full of pure water, when, by gradually adding the salt water, the exact effect produced upon the life of the animals will be ascertained; and the same of course may be done with spirit of tar, or with any other liquid application. Wire-worms die in five minutes in alcohol, and almost instantaneously in oil of turpentine.

An excellent remedy for wire-worm in the plots and borders of the flower garden, is to lay slices of potato, turnip, carrot, beet-root, parsnip, apple, cabbage, or broccoli, as baits, on or near the surface of the soil, or to plunge potatoes, carrots, beet-roots, or parsnips, at intervals, and periodically take them up, hand-pick them, and replunge them. The Editor of the Gardener's Gazette, speaking of beds of pinks and carnations, says, "We have completely eradicated every worm from two or three beds very much infested, by plunging full-grown carrots, about 6 inches apart, and drawing them every morning. At first we found three or four worms at every carrot, and even during that period they attacked nothing else. After three or four weeks we could find none. We, however, do not think the garden generally was infested, but that the ten or fifteen loads of compost brought in for the beds, or some portion of it, may have been full of them. We had also, once a serious falling off in a tulip bed, and suspected wire-worm; adopting the same remedy, that is, plunging a few carrots, we took out enough to have destroyed the whole bed had they been neglected. Whether difference of soil or situation, or the presence of other matter, would make a difference, we know not; but we believe this little pest to prefer a carrot to anything, and, as they can work their way a third of their length into the root in a comparatively short time, when the root is drawn, they come out with it, for they cannot extricate themselves. There is nothing required but to pull them out and destroy them, and replace the carrots in the hole."

One of the best remedies in the field is hand-picking. Bierkander, after all his experiments, appears to have depended most upon this; for he says, "In a field where rye was intended to be sown, I last autumn (1778) employed a child to follow the plough and pick up the worms; by

this means 351 were collected in a piece of land 600 feet long and 56 broad. The quantity which was taken in other fields was not counted. There were caught in the furrows, according to their length, 4, 6, 10, to 14 worms. It would be serviceable if children always followed the plough and gathered these yellow worms into a bottle; they would by that means be considerably diminished, and perhaps in time entirely exterminated." "A striking instance of the use of hand-picking," says Mr. Spence, "appeared in the 'West Briton,' a provincial paper, in November, 1838, stating that Mr. G. Pearce, of Pennare Goran, had saved an acre and a half of turnips, sown to replace wheat destroyed by the wire-worm and attacked by hosts of these larvæ, by setting boys to collect them; who, at the rate of 1½d. per 100, gathered 18,000; as many as 50 having been taken from one turnip. Thus, at the expense of only £1 2s. 6d., an acre and a half of turnips, worth from £5 to £7, or more, was saved; while, as the boys could each collect 600 per day, 30 days' employment was given to them at 9d. per day, which they would not otherwise have had."

A number of birds, both tame and wild, are greedy destroyers of wire-worms; and some may be entirely encouraged in their warfare against them, and others occasionally or limitedly according to circumstances. The chief are ducks, turkeys, common poultry, pheasants, partridges, plovers, blackbirds, thrushes, robins, wagtails, and, above all, rooks. "Wary as the rook is on most occasions," says Mr. Curtis, "he follows the plough fearlessly, to feed upon the wire-worms and other insects; and here his services are most invaluable, for if you dig up the wire-worms and lay them upon the earth, they will often burrow down and disappear in a few seconds; many, therefore, of the feathered race have little chance of catching them in the ploughed field; but the form of the bill, combined with the strength and assiduity of the rook, is well adapted for detecting them in their hiding-places. To pick them from the growing crops is likewise the occupation of the rook when we see him gravely surveying a turnip or corn crop, and with astonishing sagacity selecting those plants only which have a few yellow leaves outside, the sure indication of the presence of the wire-worm and other insects. A gentleman in Norfolk, who well understands this subject, says, 'The rooks convey the first tidings of the presence of this formidable enemy by hovering over a field in flocks, and actually pulling up the turnips by the roots to search for them, and I cannot but believe that their sagacity directs them to the infested plants, which are distinguished by their drooping leaves and dark unhealthy aspect.' An equally observant friend, in Surrey, says, 'The rooks are accused of doing injury by pulling up the wheat, but I, as well as others here, believe that they pull up the attacked plants to get the wire-worms, and do not touch the healthy plants.' The bailiff to the same party informed me, during a period when the wire-worms were abundant, that the rooks had been busily occupied amongst the barley in May, and where it looked sickly had drawn the earth away from the roots to find the wire-worms, and where they had been 'working the earth' he could not find any of the worms. But there is still stronger and incontrovertible evidence in their favour; for in the stomachs of rooks which have been shot when following the plough in barley-sowing, a few grains of corn only were found, but abundance of wire-worms and other insects. Mr. J. Denson, sen., says, 'I have repeatedly examined the crops of rooks: in six young that had been shot, the crops were nearly filled with wire-worms; in the crops of others, I have found the larvæ of the cockchafer, and other grubs that I am not entomologist enough to know the names of. In one or two instances, in frosty weather, I have examined the crop of one or more rooks that had been shot; it contained dung, earth, and a small portion of grain. I will just notice that the land adjoining Mr. Wiles's rookery is yearly sown with pulse or grain, and in no instance have I known or heard that the land has in consequence failed of a crop.' The following remarks also, by Mr. T. G. Clithero, are exceedingly interesting:—'In the neighbourhood of my native place, in the county of York, is a rookery, belonging to W. Vavasour, Esq. of Weston, in Wharfdale, in which it is estimated that there are 10,000 rooks; that 1 lb. of food a-week is a very moderate allowance for each bird, and that nine-tenths of their food consist of worms, insects, and their larvæ; for although they do considerable damage to the fields for a few weeks in seed-time and a few weeks in harvest, particularly in backward seasons, yet a very large proportion of their food, even at these seasons, consists of insects and worms, which (if we except a few acorns and walnuts in autumn) compose at all other times the whole of their subsistence. Here, then, if my data be correct, there is the enormous quantity of 468,000 lbs., or 209 tons, of worms, insects, and their larvæ, destroyed by the rooks of a single rookery in one year. To every one who knows how very destructive to vegetation are the larvæ of the tribes of insects, as well as worms, fed upon by rooks, some slight idea may be formed of the devastation which rooks are the means of preventing.'"

WISP. A small hand-bunch of hay or straw, used for rubbing down horses and cattle, or for any similar purpose.

WISTARIA. A small genus of ornamental exotic plants of the kidney-bean division of the leguminous order.—Consequa's species, *Wistaria Consequana*—called by some botanists *Wistaria sinensis*, and by others *Glycine sinensis*—was introduced to Britain from China in 1816; and is

one of the most ornate ligneous climbing plants in the world. It somewhat resembles the laburnum in its habit of inflorescence,—with the important difference that its flowers are delicately blue; and it is almost as handsome in its foliage as in its bloom, and possesses the most wondrous power and prolificity in dispreading its branches over trellises and roofs in any style of training which fancy can desire. It has already, for some years, formed a gorgeous ornament athwart the surfaces of greenhouses and warm walls in many parts of Britain; and, as it constitutionally possesses considerable hardiness, and may be expected to become still hardier by acclimatation, and is very facilely propagable by layering, it probably may, in the course of some years, supersede the ivy and the honeysuckle and the clematis, or at least share with them, in decorating the walls of farm-houses, cottages-ornées, and entrance-lodges. It begins to bloom in the latter part of May, or about the same time as the laburnum; and it usually produces a small second crop of flowers, and sometimes even carries a third crop in August. A plant of it at Coughton Court, the seat of Sir Charles Throckmorton, Bart., when only of seven years' growth, at the beginning of June, covered 905 feet of wall, and was 116 feet in length, and carried 2,275 blossoms. Its usual height or length in ordinary cultivation, however, is only about 15 feet. It thrives best in a soil of loam and peat or of rich mould.—The bundle-flowered species, *Wistaria floribunda*—called by some botanists *Glycine floribunda*, and by others *Dolichos polystachyos*—was introduced from China in 1820, and has a creeping or trailing habit, and carries purple and white flowers, and is in some respects a handsomer plant than even Consequa's.

WITCH HAZEL. See HAMAMELIS.

WITHERINGIA. A genus of ornamental exotic plants, of the nightshade family. Seven species have been introduced to Britain, principally from South America; and nine or ten more are known. One of the introduced species is an annual, one is a tuberous-rooted perennial, three are herbaceous evergreens, and two are evergreen undershrubs. They vary in height from 6 inches to 3 feet; two have respectively blue and white flowers, and the rest have yellow flowers; most bloom from May till autumn; and nearly all love a soil of loamy peat.

WITHERS. The long upright processes of the first few dorsal vertebræ of the horse, rising above the shoulders, and often forming a considerable ridge. In consequence of their giving attachment to the elastic ligament which supports the head, their length and direction in a great measure determine the character of the horse's carriage; and in consequence of their being rendered prominent by a proper backward direction of the shoulders, they serve as a good index of the safe-going character of the horse's action. A considerable or comparatively high elevation of the withers is essential in a saddle-horse, both for preventing the displacement of the saddle, and for maintaining at a maximum the pleasantness of the animal's action.

WITH-WIND. See BINDWEED.

WITHY. The flexible shoot or bough of a willow.

WITSENIA. A genus of ornamental, evergreen, herbaceous Cape-of-Good-Hope plants, of the iris family. The corymbose species, *W. corymbosa*, was introduced to Britain in 1803; and has a height of about 6 inches, and carries pale blue flowers from April till September. The Moorish or dark-flowered species, *W. maura*, was introduced in 1790, and has a height of about 4 feet, and blooms from January till September; and, excepting in some trifling resemblance in the foliage, it differs so widely from the preceding that no person but an experienced botanist would suspect the two plants to be any way nearly related. The flowers of the Moorish proceed in pairs from imbricated sheaths at the apex of the stem; and they have a yellow limb, and a peculiarly long tube, which is green on the lower part, and gradually merges into a blackish purple at the top. The branched species, *W. ramosa*, is about a foot high, and has pale blue flowers, and blooms from April till June. All the three species love a soil of sandy peat, and are propagable from cuttings.

WOAD,—botanically *Isatis*. A genus of herbaceous plants, of the cruciferous order. The pod is flat, elliptical, one-celled, and one-seeded, and has adhesive and somewhat boat-shaped valves; the seeds are ovate-oblong; and the cotyledons are flat, incumbent, and seemingly in the same direction as the almost obliterated dessepiment of the pod should be. One species grows wild in Britain, and is at the same time an agricultural plant; about a dozen species have been introduced from other countries, principally Southern Europe and South-western Asia; and a few other species are known. All the introduced species are hardy and yellow-flowered; one is perennial-rooted, and the rest are, in about equal proportions, annuals and biennials; two have indehiscent and comparatively broad pods, girt by a broad leafy wing, and the others have subdehiscent and comparatively linear pods, with suberous margin; all are summer-bloomers, and have a height of less than 2½ feet; and some have a weedy appearance, and the rest only a half ornamental character.

The indigenous species, or dyer's woad, or woad par excellence, *Isatis tinctoria*, concentrates in itself the main interest of the genus. It occurs in a wild state in the corn-fields and field-borders of England; but is rare, and has neither the smoothness nor the luxuriance which it possesses in a cultivated state. The ancient inhabitants of the British Islands coloured themselves with a blue preparation obtained from it; and therefore those in the north were called Picts by their Ro-

man conquerors from the Latin word *pictus* signifying painted, and those in the south were called Britons from the Celtic word *britho* signifying to paint. Woad was at one time very extensively cultivated both in England and in Scotland; but, in consequence of being generally superseded for the dyer's purposes by indigo, one-thirtieth part of which yields as much colouring matter, it has in almost all districts been driven out of cultivation except in a few parts of Lincolnshire. But it is indigenous throughout most of Continental Europe, and is still cultivated to a considerable extent in Flanders and in the South of France. Its root is tapering, thick, fibrous, and branching; its stems are upright, much branched, and about 3 or 4 feet high; its radical leaves have pretty long footstalks, and are ovate-lanceolate, notched, and about a foot in length; its cauline leaves are clasping, almost entire, and about 3 inches long and ½ an inch broad; its flowers have small petals, and are of a bright yellow colour in both calyx and corolla, and bloom from May till July; and its pods stand on slender pendulous footstalks, and are nearly half an inch long and two inches wide, and have a chestnut or dark brown colour, and a shining surface. An old popular name of this plant was glastum, from the Celtic word *glas*, signifying blue; and this name gave rise to the appellation of the town Glastonbury.

The best soil for woad is rich mellow loam, containing a large proportion of vegetable mould; and it must be deep and in fine condition. The rich alluvial pastures of Lincolnshire, when newly broken up, serve excellently for woad, and at the same time are cleared by it from wire-worms so as to be rendered eminently fit for subsequent crops of grain. Arable land intended for woad, be it what it may, must be both light and fertile, in a well drained condition, and not retentive of moisture. In autumn, it should be well ploughed and ridged up; throughout winter, it should enjoy full exposure to the action of frost and wind and rain; and in spring, it should be harrowed down, ploughed across, reploughed, and reduced by subsequent tillage to a state of perfect cleanness, and fine pulverization — or, when practicable, treated in the manner of summer-fallowing up to the time of sowing. Pasture or ley land, intended for woad, must be treated according to its character and condition; and in some instances, may need vastly less preparation than land which has been under a series of tillage crops,—in others, may require to be pared and burned.—The seed is sown in the latter end of July or beginning of September, and again at intervals in the spring, from February till May, so as to vary the time for stripping the plants of their leaves. About six bushels of seed are sown on the acre broadcast, but much less in drills. As the value of the woad plants depends upon the luxuriance of their growth, and the thickness of their leaves, much attention is necessary to the after-management of the crop. In the spring-sown crops repeated hoeing should be attended to, all weeds removed, and the plants thinned out as they extend in growth, until they stand 6 or 7 inches apart, or more, according to the fertility of the soil, always leaving sufficient space to prevent their being crowded. After this nothing more is done till the first cropping of the leaves has been performed, when the plants are again well weeded; and this is repeated immediately after each operation, the extent of ground cleared in the day being weeded before night. In the late mode of sowing, after the second weeding in October, nothing further is required until April, when the mould should be well stirred about the roots, and the ground carefully weeded. This will keep the plants clean till the first crop is gathered, and then the process of weeding must be performed as before directed.—In the spring-sown crops, the leaves are generally ready for gathering from the end of June till the first week in July, according to soil and season. The gathering should be performed as soon as the leaves are fully grown, while they retain their perfect green colour, and are highly succulent; for if left until their colour turns, they are much deteriorated. The leaves are gathered into baskets made for the purpose; and the crop, if well managed, will afford two or three gatherings in the season. The portion left for seed is generally cropped of its leaves the first year, and left to run up for seed the next; but some cultivators remove the side leaves only. The plant is sometimes fed down by sheep in the winter.

In the preparation of woad for the dyer, several processes are necessary. It is first conveyed in horse-carts so contrived as to be lifted from the axle, and by folding-doors in the bottom to discharge their contents upon the floor above the mill, which is of a peculiar kind, having several wheels for grinding the plants with less diameters on one side than the other, being about three feet in width, and constructed with iron bars for crushing the woad. The materials are preserved under the grinding wheels by proper contrivances, which, as soon as they are sufficiently reduced, force it out of the tracks upon the stone floors and the sides, thus making way for new parcels without the mill being stopped. The bruised woad is then thrown into rooms by the sides of the mill destined for its reception. It there remains till the juice is so much drained off as to leave it in a proper condition to be formed into balls; which is done by labourers, with apparatus for the purpose, and then laid upon trays to be conveyed to the drying-houses. These are placed on the sides of galleries for the convenience of removal. The woad is kept in these until dry enough to be laid up in other rooms, and the whole of the crop has undergone this operation, when it is ready to be manufactured. In order to prepare it for the use of dyeing, it is necessary for it to take on a proper state of fer-

mentation, which is accomplished in the course of 7 or 8 weeks, and is called 'couching.' It is effected by regrinding the balls in the same mill as before to a fine powder, and then spreading it upon the floor of the rooms in which the balls were formed to the thickness of three feet. It is then moistened with water so as to keep it in a slow state of fermentation, which is managed by frequent turnings, and to be properly done requires practice and judgment, for the goodness of the article will depend on its being stored and dried in a proper manner. When this attention is neglected, the woad will not on being broken between the finger and thumb draw out into fine hair-like filaments, or, as the manufacturers call it, beaver well; as the use of this substance in the vat of the dyer is not only to afford the colour of the plant, but, by bringing in a very gentle fermentation, excite the indigo in the same vat to yield its colouring principle more perfectly. This is even necessary for its own colouring matter being fully imparted. The substance should, therefore, be so prepared in the different operations as to produce this effect in the most certain and perfect manner. When the heat in the process of 'couching' has gone too far, the substance will be what is called foxy; and when it has not proceeded to a sufficient degree, it is called heavy. If the material is good, it does not soil the fingers on being rubbed between them; but such as is heavy does. In the conclusion of the process, the cooling is effected in so gradual a manner as to render it not fit for taking on the same process, and, of course, proper for being preserved in casks or in any other way. It is then fit for use.

The French process of preparing this dye differs materially, and is thus described by Astruc, in his Natural History of Languedoc:—The plant puts forth at first five or six upright leaves about a foot long and six inches broad; when they hang downwards and turn yellow, they are fit for gathering; five crops are gathered in one year. The leaves are carried directly to a mill, much resembling the oil or tan mills, and ground into a smooth paste. If this process were deferred for some time, they would putrefy and send forth an insupportable stench. The paste is laid in heaps pressed close and smooth, and the black crust which forms on the outside reunited if it happens to crack; if this were neglected, little worms would be produced in the cracks, and the woad would lose part of its strength. After lying for 15 days, the heaps are opened, the crust rubbed and mixed with the inside, and the matter formed into oval balls, which are pressed close and solid in wooden moulds. These are dried upon hurdles; in the sun they turn black on the outside, in a close place yellowish, especially if the weather be rainy. The dealers in this commodity prefer the first, though, it is said, the workmen find no considerable difference between the two. The good balls are distinguished by their being weighty, of an agreeable smell, and when rubbed of a violet colour within. Those injured by wet have an earthy appearance inside and a disagreeable smell; the mouldy and rotten are light, having lost their substance. For the use of the dyer these balls require a further preparation: they are beaten with wooden mallets on a brick or stone floor into a gross powder, which is heaped up into the middle of the room to the height of four feet, a space being left for passing round the sides. The powder, moistened with water, ferments, grows hot, and throws out a thick fetid fume. It is shovelled backwards and forwards, and moistened every day for 12 days, after which it is stirred less frequently without watering, and at length made into a heap for the dyer. The French, who certainly excel us in the art of dyeing, still consume a vast deal of woad, and this may be attributed to its superior quality produced by their peculiar method of manufacturing it.

Woad has sometimes been recommended for cultivation as a forage plant; and, when so destined, is sometimes designated by its French name 'pastal.' But its value in this capacity is not great; for though it has a hardy nature, a vigorous growth, and a nutritious composition, it makes excessive demands upon both the fertility of the soil and the tillage labours of the husbandman, and refuses to yield large produce in any of the inferior or the ordinary circumstances of soil and tilth in which other forage plants, scarcely or not at all inferior to it in hardiness and bulk, are abundantly productive. Even the practice of feeding sheep in winter upon crops of it intended for the dyer is questionable; for it probably occasions more loss in the ultimate value than affords profit in the present use.

WOLD. See Dyer's Weed.

WOLDS. See Downs.

WOLFSBANE. See Aconite.

WOLVES' TEETH. Any teeth in the horse which acquire such rough or pointed surfaces as to lacerate the tongue or gums. See the article Teeth.

WOMB. See Abortion, Parturition, and Inflammation.

WOOD. Either the characteristic principle and main constituent of trees and shrubs,—and that is discussed in the article Lignin; or the hard portion of the stems and boughs of trees and shrubs, suitable for use in carpentry and turnery,—and that is discussed in the article Timber; or the chief bulk or entire substance of trees and shrubs,—and that is discussed in the articles Tree and Shrub; or any collection or assemblage of living trees and shrubs,—and that is discussed in the articles Coppice, Shrubbery, Grove, Forest, and Plantation.

Small woods on farms are common in some parts of Britain, particularly in the South of England, and are useful for hop-poles, fence-rails, hurdles, faggots, and many other objects of the

farm-field or the farmery, and also furnish ready supplies in a small way to coopers, cloggers, and other parties who can deal more facilely with a farmer than with a landowner; but they are subject to more inconveniences and liable to more mismanagement than other kinds of woods,—and have connexion with some troublesome customs or rules of tenancy which do not work well for either tenant or landlord. One thing which injures them is the ignorance which prevails among farmers on right practices of forestry, or the want of such a knowledge of the kinds and habits and adaptations of the different species of trees as is ordinarily possessed by the planters and managers of very extensive woods. If farmers had as good a knowledge of forestry as of farming, they of course would manage their woods as efficiently as their farms; but, in too many instances, they are little better qualified to have charge of a wood than an Irish bog-trotter is to conduct the business of a great farm of the mixed husbandry. Another evil is the pernicious practice of allowing cattle to feed in woods, under an idea that, after they are of a certain age, as seven years, the shoots are grown out of the way and cannot be hurt. Now though in strong thriving woods, cattle may possibly do but little harm to the underwood, after it is seven or eight years old, yet all the young plants, which either spring up spontaneously, or are artificially planted, must be liable to be cropped and kept down, and in weak decaying woods, there is always a great deal of the underwood so low as never to get out of the reach of cattle. Another evil is the want of draining such parts as are subject to excessive moisture; nothing being so prejudicial to a wood as too much wet. A fourth evil is the custom of suffering woods to grow too old before cutting; whereby the stronger shoots get leave to smother the weak ones, and eventually to kill the very stalks on which they grow. And to these evils may be added the practice of permitting the buyer to cut the wood, thereby making it his interest to destroy every sapling, and to cut the underwood as close to the stock as possible—which in old woods is highly prejudicial to the succeeding shoots—as well as the custom of not obliging the buyers to clear the woods early in the summer, so as to prevent the new shoots from being injured by their cattle, carriages, and other circumstances.—"The average time of cutting farm woodlands," says Bayldon in his Art of Valuing Rents and Tillages, "may be stated at from 8 to 12 years, and the value from £6 to £14. In some instances, the price is much higher according to the quantity and the local value of the materials grown on an acre. These woods are cut in winter and cleared by May, that damage may not happen to the tender shoots. Young plants that grow with a stem directly from the ground are called 'maiden trees,' and are in all cases the property of the landlord, and are never cut without leave, but grow for timber; and in some places the landlords pay a trifle, ½d. or 1d. per 'teller,' as they are often called, for as many young plants as may be thought fit to keep for growing timber, and which grow on a stock or stool, and are farmer's property. In other cases, a clause in the lease gives power to the landlord to reserve without any remuneration a number of young plants, not exceeding 30 on an acre, and sometimes no number is mentioned. This system of mixing timber trees and underwoods is very injudicious and hurtful; but the custom has once got hold, and must remain, like other customs, till another banish it by slow degrees. The trees cover a large space, and hurt or kill the wood below, and they spread into a large circumference of branches without a trunk or bole of length and value. The one object defeats the other; the two purposes should be separately effected, a few outside trees being always left when cutting woods, in order to keep up the view of the scenery. Trees called 'pollards' are found in many places in considerable quantities, in hedge rows, and even in woods, cut over, some 6, 8, or 10 feet high, and consequently produce a number of sapling shoots like a stool cut near the ground. The stocks or stems are the landlord's property, and the tops often called 'frith,' belong to the farmer, and are cut periodically as the underwoods. The cuttings of these woods are found to be a valuable appendage to lands on account of the scarcity of other fuel, and in many cases add much to the eligibility of the farm. Proprietors are now getting more inclined to keep the entire management of the woodlands, cutting a portion yearly for sale and accommodation for fuel; and pollards are now being cut down in many places. This plan lessens the amount of valuation. The growth of these woods since last cutting, and which is standing at the time the tenant quits a farm, is his property; he has paid rent and taxes for the land, and has got no return, and consequently must be paid for it. The value differs greatly, from the quality of soil, and the amount of produce, from 7s. to 20s. an acre for a year's growth on woodlands, and a corresponding value will be given for pollard tops by the growth since last cutting. Considerable quantities of shoots on old stools are often found in hedge rows, which will also be looked at and valued. Where the fences are much neglected and out of repair, such growth is often given for repairing them, according to the judgments of the valuers, who are usually persons living in the neighbourhood, and well-acquainted from long practice with the customs of the place, and what constitutes a fair value."—The subject of woods in the hedge-row disposition is disposed of in the article ENCLOSURE,—of woods for sheltering purposes, in the article SHELTER,—and of woods in parks and for general purposes of decoration, in the article LANDSCAPE GARDENING.

WOOD-ASHES. See ASHES.

WOODBINE. See HONEYSUCKLE.

WOOD-BORING BEETLES. See Bostrichidæ.

WOODCOCK,—scientifically *Scolopax Rusticola*. A British bird of passage, belonging to the longirostrous family of Grallæ, and constituting the type of a large portion of that family. It is a bird thoroughly known to all sportsmen; and though not classed as game, affords them to the full as much diversion as any birds which are so classed. It begins to appear in Britain about Michaelmas, and departs in March; and it is regulated, as to the precise period of its migration, more by the wind than by the moon. It arrives in flocks during the night or in a fog; and it soon becomes less gregarious, and afterwards pairs while in this country. The woodcocks which arrive first in the season are the largest, and fly heavily, and are muffled in the under parts of their head, and somewhat also in the other parts of it, with short feathers; those which arrive in November and December are rather smaller, and have smoother feathers and a shorter bill; and those which arrive about Candlemas are quicker of wing than their predecessors, and take longer flights, and are more difficult to be shot in consequence of their not rising above the spray. The weight of the woodcock, on the average, is from 12 to 14 ounces; the length is 15 inches, and the breadth 26; the bill is 3 inches long, hollowed lengthwise with deep furrows, reddish at the base, dusky towards the end, and furnished with a somewhat fleshy tip, which appears susceptible of a sort of touch for detecting its prey in the moist earth; the upper mandible hangs over the lower, and forms the round point of the bill; the tongue is slender, long, sharp, and hard at the point; the eyes are large, and situated near the top of the head; the head has a remarkable shape, being rather triangular than round; the ears are placed far forward, nearly on a line with the corners of the mouth; a black line extends from the bill to the eyes; the forehead has a reddish ash-colour; the crown of the head, the hind part of the neck, the back, the coverts of the wings, and the scapulars, are prettily barred with a ferruginous red, black, and grey, but on the head the black predominates; the under eye-lid is white; the chin is ash-colour; the fore part of the neck is yellowish, and marked with dusky minute dashes; the under parts of the body are dirty white, barred with numerous transverse dusky lines; the quill feathers are dusky, and marked on the outer web with triangular rufous spots; the tail consists of twelve feathers, dusky or black on the one web, and marked with red on the other; the tips of the tail are ash-coloured above, and white below; the shades of the plumage are so blended that the bird, as usually observed by the sportsman, exactly resembles the withered stalks and leaves of ferns, sticks, mosses, and grasses, on the back ground of the scenery by which it is sheltered; and the legs and toes are pale flesh-coloured brown,—and the latter are almost entirely divided, having only a very small web between the middle and the interior toes. The nest is placed on the ground, generally against an old stump or great root of a tree, and consists merely of a few dried fibres and leaves. The eggs amount to 4 or 5, and are larger than those of the pigeon, and have a rufous grey colour, marked with dusky blotches. The flesh is regarded by most epicures as delicious, and thought superior in flavour to that of the partridge.

WOOD EVERLASTING PEA. See Lathyrus.

WOOD EVIL. A disease in cattle somewhat similar to enteritis. It arises from browsing on the buds of trees, particularly those of the oak and the ash; it does not comprise so much intestinal inflammation, or so speedily run its course, as enteritis; it is indicated by heat of the mouth and skin, thirst, colicky pains, depression, excessive constipation, difficulty of voiding urine, hardness of the fæces, and redness and powerful odour of the urine; it continues during from 12 to 20 days, and, in bad cases, terminates in gangrene and death; and it must be treated with bleeding, purging, the application of blisters or hot water to the belly, and the restriction of the diet to gruel and mashes. The name wood evil is also given by some cow-doctors to some rheumatic complaints, and to general debility resulting from inflammatory action.

WOODLAND. Land occupied by assemblages of trees. See the articles Wood, Coppice, and Plantation.

WOODLAND. Any dark-coloured, humous, argillaceous soil of similar appearance and properties to that of old and ill-drained woods, which is kept perpetually moist by the dropping of trees, the fall and decay of leaves, the want of ventilation and sunshine, and a low and embarrassed state of evaporation. The name woodland, in this application of it, is provincial and lax, yet conveys a considerable degree of descriptive meaning. The soil designated by it retains for a long time any water which falls upon it, and in wet weather sticks firmly to the ploughshare, and in prolonged drought is very apt to crack, and, when not worked well and constantly by cultivation, commonly produces rushes and other coarse aquatic vegetation.

WOOD-LARK. See Lark.

WOODLOUSE,—scientifically *Oniscus*. A genus of minute animals, classed by some naturalists as apterous insects, and by others as isopodous crustaceans. Their body has a flattened appearance, or is broader than thick; their feet amount to fourteen, and are unguiculated, and have not any vesicular appendage at the base; and the under part of their tail is furnished with very apparent appendages resembling leaflets or vesicular bursæ. They inhabit retired and obscure places, such as fissures in walls, old buildings, cellars, and the interstices between boulders and

the ground; they seldom issue from their retreats except at night or in rainy weather; they move rather slowly, except when alarmed, but are capable of exerting some degree of nimbleness; and they feed on vegetable substances and animal matters, and are great pests in gardens. Their ova are enclosed in a pectoral pouch; and their young have only twelve feet, and have one thoracic segment less than the adults. They are known in France under the strange name of pigs of St. Anthony; and they had long an abominable reputation among some medical men, and still have it among some of the peasantry, as an internal remedy for some diseases,—being boiled in milk, and supposed to possess aperient, diuretic, and absorbent properties.

The common woodlouse, *Oniscus asellus*, is about half an inch long and a quarter of an inch broad, of an oval shape, and of a dark mouse colour. Round its outer edge are eight or nine spots of a paler colour; and its back is armed with a strong bright shell. If unable to escape quickly when touched, it usually rolls itself up in a ball, and appears lifeless, till the apparent danger is over. Its eggs are very numerous, very minute, shining, and of a very pale yellowish white colour; and they appear to be hatched in a few hours after deposition. The young have a pale colour, and though very small, begin to crawl slowly about; and in a day or two they become very active, and change to a pale reddish brown colour. When half grown, they assume the same colour as the parents, but without the markings on the back; they can then run very nimbly, and are remarkably voracious, devouring everything eatable which comes in their way; and as they advance in growth, they cast their skins, after the manner of spiders. When full grown, they become heavy and less active; and appear to require less food than during their growth. This insect is very injurious, and where very prevalent is not readily got rid of. It shuns light, particularly that of the sun; and commits its depredations during the night. It cautiously creeps from its place of retreat, and feeds on leaves, flowers, fruits, or whatever else it can find; and if not wholly destroying any plants or fruits which it attacks, it so injures and disfigures them, that they with difficulty recover.

The methods of keeping down woodlice and destroying them are many; and only some of the most obvious and of the most efficient need be mentioned. A live toad kept in a house will keep it free from them. The newt feeds on them, and might be advantageously encouraged in any garden frames which they infest. The beetle trap effectually destroys them. Boiling water poured into any crevices or cracks of walls or buildings where they are known to have their retreats, will destroy as many of them as it can reach. Loose stuffings of hay or dry moss in a flower-pot or any similar vessel, placed near their retreats, will decoy them by way of shelter; and, every morning, such as betake themselves to the vessel may be emptied out and destroyed. Longitudinal sections or halves of old bean stalks or of cabbage stalks, nine inches or so in length, laid in different parts of the house or garden which they frequent, will also entice them for shelter, and gather a collection of them for every morning's clearance. A little bit of old cheese, pulverized with a grater, spread in a vessel, sprinkled over with a little white sugar, and covered with hay or dried moss, will greatly add to the power of the decoy, and attract large assemblages of them for destruction. Slices of bryony root, apple, pear, potato, or any other succulent vegetable substance most attractive to them, put into pans or feeders, such as are generally used under strawberry pots, and covered with hay or dried moss, act as excellent decoys, and may be used to assemble the frequenters of beds, frames, and all other parts of the garden for a destructive bath in boiling water. Several methods of poisoning with arsenic are practised,—and resemble these decoy methods, with the simple difference that they kill the woodlice as well as decoy them; but they merely save the trouble of getting up some boiling water or other ready means of destruction in the mornings, and are therefore not worth the additional pains and great danger of using the arsenic.

WOODPECKER,—scientifically *Picus*. A genus of birds of the scansorial or climbing order. They are well characterised by their long straight angular bill, the end of which is compressed into a wedge, and fitted for splitting the bark of trees, —by their slender tongue, armed near the tip with spines that curve backwards, which, by the action of the elastic horns of the hyoid bone, can be thrust far out of the bill,—and by their tail, composed of ten quills with stiff and elastic stems, which acts as a prop in supporting them while they are climbing. They are very eminent climbers, wandering over trees in every direction, striking the bark off with their bills, and insinuating their long tongues into its cracks and crevices to obtain the larvæ of insects, on which they feed. This tongue, besides its armour, is constantly moistened with a viscid fluid, secreted by large salivary glands; it is drawn back into the bill by two muscles, which are wound round the trachea like ribands; and while it is in this state of retraction, the horns of the hyoid bone ascend under the skin and round the head, as far as the superior base of the bill, and the sheath of the tongue is doubled into folds in the bottom of the throat. They have an almost membranous stomach, and have no cæca, and yet they eat fruit. They are timid and wary; and pass most of their time in solitude; but during the pairing season, the males may often be heard summoning the females by loud and rapid tapping on a dry branch. The nests are built annually in holes of trees; and the eggs are brooded over alternately by the male and the female. Six or seven species in-

habit Europe; and four of these are occasionally met with in Britain.

The great black woodpecker, *Picus martius*, is the largest of the British species,—almost as large as a crow, and measures 16 inches in length; and it is all over of a uniform black colour, with a beautiful rich blood red in the calotte of the male, and a mere spot on the occiput of the female. It prefers pine forests to all other haunts.

The green woodpecker, *Picus viridis*, is the most common and the best known of the British species; and is popularly known, in different districts, by a variety of more or less descriptive names, such as rain-bird, woodwale, hew-hole, yaffil, whittle, and witmale. It occurs in all or almost all the woodland districts of both England and Scotland; and is generally seen either climbing a tree in search of its insect-food, or passing by a short, undulating, and somewhat laboured flight from one tree to another; and it usually prefers the beech and the elm to all other trees. It is one of the most beautiful largish birds in Europe. Its total length is about 13 inches; its back, its wings, and other parts of the upper surface of its body, have a dark green colour tinged with yellow; the under parts of its body are whitish; its calotte is bright scarlet; and its rump and upper tail coverts are sulphur yellow. Its young are marked with black spots beneath, and with white spots on the mantle.

The great spotted woodpecker, *Picus major*, is the next best known British species, and is somewhat common in gardens, parks, groves, and plantations, in the woodiest districts of the midland counties of England; and it is popularly called in some places the whitwall, and in others the wood-pie or the French-pie. It prefers evergreen trees, and often approaches human dwellings, but scarcely ever lights on the ground; and it feeds on larvæ, on insects, on seeds, and on ants. Its total length is 9½ inches; its occiput is bright scarlet; the top of its head is dark bluish black; its irides are red; its forehead, its ear-coverts, and a circle round each eye are dull dirty white; its throat, its neck, its breast, and its belly are dirty white; its back, the nape of its neck, its rump, and its upper tail-coverts are black; and its vent and its under tail-coverts are red.

The little spotted woodpecker, or small barred woodpecker, *Picus minor*, is not uncommon in the vicinity of London, and in the midland English counties, but has such retiring habits and is so much smaller than the other species that it readily escapes observation, and is considered comparatively rare. It is said by some naturalists to search on foot for ants,—and it has thence been called the grasspecker; but its really having such a habit is at least doubtful. Its total length is 5¾ inches; the middle of its back is white, barred transversely with black; its wing-coverts and its tail are black; its chin, its throat, and all the under surface of its body are dull white; and the crown of the head of the male is bright scarlet.

WOODRUFF,—botanically *Asperula*. A genus of ornamental herbaceous plants of the madder family. Two species grow wild in Britain, and nearly 30 have been introduced from other countries, principally the south and south-east of Europe. One of the introduced species is a hardy annual, one is a frame evergreen, one is a hardy perennial creeper, and all the others are hardy, annual-stemmed, erect perennials. They vary in height from one or two inches to upwards of two feet, but most have a height of between 6 and 15 inches. Their flowers are either white, flesh-coloured, pink, red, purple, lilac, or yellow; and, in most instances, bloom in June and July. Most of the species are very handsome, and possess the agreeable habit of flourishing under the shade of trees, and thrive in any common or even somewhat moist soil.

The small woodruff or squinancy-wort, *Asperula cynanchica*, is a native of the chalk hills of England. The root is perennial; the stems are numerous, ascending, profusely clothed with whorled foliage, and from 4 to 10 inches high; the leaves are linear, smooth, and four in a whorl,—and the upper ones are very unequal; and the flowers grow in terminal panicled tufts, and have a whitish or flesh colour, and are sometimes very fragrant, and bloom in July. This plant was formerly regarded as, in both external and internal use, a remedy for quinsey or squinancy,—and it thence derived both its popular and its botanical names; but it was utterly undeserving of any such reputation. An infusion of it, however, is astringent, and might serve as a gargle.

The common or sweet woodruff, *Asperula odorata*, is a native of the dry woods of many parts of Britain. The root is perennial and creeping; the stems are simple, clothed with whorled foliage, and from 4 to 10 inches high; the leaves are lanceolate, spreading, bright green, about an inch long, and eight in a whorl; the floral panicles stand on longish footstalks, and generally grow three together; the flowers have a short tube and a pure white colour, and bloom in May and June, and are fragrant chiefly at night; and the fruit are small capsules so armed with ascending bristles as to feel quite rough. This plant, when cut and laid out to dry, emits a strong and delightful fragrance similar to that of *Anthoxanthum odoratum*, bitter almonds, and heliotrope; and it continues to give out some of this fragrance during a considerable time after it is quite dry; and it has, in consequence, been much used for scenting clothes, flavouring wine, and similar purposes. The herbage, in a green state, is eaten by goats, sheep, and cattle, and is believed to have the property of increasing the secretion of milk. The edges of its leaves stick to the hands and garments by means of the minute hooked bristles which constitute their roughness; and they possess this property in common with many other plants of the rubiaceous order.

The dyer's woodruff, *Asperula tinctoria*, is a native of the South of Europe, and was introduced to Britain in 1764. Its root is perennial; its stems are reclining, and about 9 or 12 inches long; its lower whorls of foliage are six-leaved, its middle ones four-leaved, and its upper ones two-leaved; its leaves are linear and three-nerved; and its flowers are trifid, smooth, and whitish, and bloom in June and July. The roots are used in Dalmatia and some other countries for dyeing wool and cloth of a reddish colour; but they are not better than madder, and do not produce so large a crop.

WOOD-RUSH. The indigenous junceous plants of the genus luzula. See the article RUSH.

WOODSIA. A small genus of very handsome ferns of the polypody tribe. The Ilva or oblong species, *W. ilvensis*, occurs wild in many parts of Britain, and has a height of about 6 inches; and blooms in June and July; and the northern species, *W. hyperborea*, inhabits some of the lofty rocky mountains of Scotland, and has a height of about 3 or 4 inches, and blooms from July till September. Both species have fibrous roots, and stalked, erect, tufted, pinnate and pinnatifid fronds, clothed with simple hairs or with narrow pointed scales; and they thrive best in a mixture of peat and loam, and may be propagated either from seed or by radical division.

WOOD-SORREL,—botanically *Oxalis*. A large and diversified genus of thalamiflorous plants, constituting the type and the main part of the natural order Oxalideæ.—This order has a near botanical affinity to the rue, the zygophyllum, and the balsam families, and it is distinguished principally by the peculiar habit of its plants, and it comprises within the gardens of Britain, species belonging to the genera oxalis, biophatum, and averrhoa. — The wood-sorrel genus has a calyx of five segments, either quite distinct or united at the base,—a corolla of five petals, ten stamens, and five pistils, with the five exterior stamens shorter than the five interior ones,—and a seed-vessel of an oblong or cylindrical form. It is a genus of considerable utility and of very great beauty, and begins to challenge the serious attention of the farmer, and has long engaged much care and admiration from the gardener and the florist. Two species grow wild in Britain; about 120 have been introduced from other countries, principally the Cape of Good Hope and South America; and a great many more are known. A few of the introduced species are annuals; a few are fibrous-rooted evergreen herbs; three or four are evergreen undershrubs; and most of the remainder are bulbous-rooted herbs. Several are cultivated for culinary and economical purposes; and all possess more or less elegance in the flower garden. The roots of some and the leaves of several are esculent; and almost all have more or less of a very agreeable acidity, which depends on the presence of a small quantity of oxalate of potash,—and a few of the tropical ones possess this property in so eminent a degree as to contain a comparatively large quantity of oxalic acid. A few are hardy; a few require the stove; and the vast majority are suited to the greenhouse. The largest of ten groups or divisions of the genus—so large in fact as to comprise about one-third of all the species—takes the common British sorrel as its type, and has no stems, petiolate trifoliate leaves, and one-flowered scapes; another and much smaller tribe takes the other indigenous sorrel as its type, and has leafy stems, palmate-trifoliate leaves, sessile leaflets, and one, two, or many-flowered scapes; a third has elongated leafy stems, trifoliate sessile leaves, and axillary one-flowered scapes; a fourth has elongated sparce-leaved stems, stalked and from three to five leafleted leaves, and axillary one-flowered scapes; a fifth has no stems, stalked and from three to many leafleted leaves, and one, two, or many-flowered scapes; a sixth has no stems, simple leaves, and one or many-flowered scapes; a seventh has no stems, winged petioles, bifoliate or trifoliate leaves, and one-flowered scapes; an eighth has leafy stems, petiolate and from three to five leafleted leaves, and leafy stems; a ninth has no stems, palmate and peltate petioles, from five to thirteen leafleted leaves, and one-flowered scapes; and the tenth has leafy stems, trifoliate leaves with the middle foliole petiolate, and many-flowered scapes.

The little sorrel, or common wood-sorrel, *Oxalis acetosella*, grows wild in woods, under hedges, and in other shaded situations in many parts of Britain. Its root is squamosely bulbous, horizontal, toothed, fleshy, and of a reddish colour; its leaves are radical, petiolate, and ternate like those of trefoil; its leaflets are obcordate, quite entire, hairy, of a yellowish green colour above, and purplish underneath; its scapes are radical and single-flowered; its flowers are bell-shaped, drooping, either white or purplish, and always streaked with fine branching purple veins, and bloom in April and May; its capsules are membranous and two-sided; and its seeds are invested with a white, fleshy, dehiscent tegument. This plant is inodorous, and has a strong, pleasant, acidulous taste, and makes a refreshing and wholesome conserve with fine sugar. It is an object of great beauty, and seems to have been the true or original shamrock of Ireland. See the article SHAMROCK. The expressed juice of it reddens vegetable blues, coagulates milk, and precipitates lime from solution. The plant is a very agreeable and wholesome salad; and possesses refrigerant, antiseptic, and antiscorbutic properties; and when boiled in milk gives off its acidulousness to the whey;—and either this whey or the expressed juice of the plant, much diluted with water, may be used as a good refrigerant drink in fevers. The plant thrives in any common soil, and is easily propagated from offsets; and these should be planted in a shady border.

The small horned or yellow procumbent wood-

A. Fullarton & Co. London & Edinburgh.

sorrel, *Oxalis corniculata*, grows wild in shady, moist, rocky or waste grounds in many parts of Britain, and has become almost a weed in some gardens. Its root is annual and fibrous; its stems are procumbent, branched, leafy, and about 3 inches high; its leaves are palmately trifoliate, and have sessile leaflets; and its flowers grow in small umbels on footstalks, and have a yellow colour, and bloom from May till October.

The crenate-flowered, notch-petalled, tuberous-rooted, or potato-bulbed wood-sorrel, *Oxalis crenata*, is a native of Peru, and was introduced to Britain in 1829, and has for several years been claiming the attention of farmers as possibly a valuable agricultural plant. A coloured figure of it is given in *Plate LXIV.* Its roots are tuberous and esculent, and are used in the same way as the tubers of the potato; its stems are succulent, branching, and about 3 feet long, and they bend over or trail on the ground, but are upright toward the point of the shoots; its leaves are trifoliate and slightly hairy, and have inversely heart-shaped leaflets; and its flowers have bright yellow petals, with crenate or notched edges, and bloom in September. The average weight of each tuber, in experimental growths of the plant at Ayton House in Berwickshire, was two ounces; and the average aggregate weight of all the tubers at each plant, in experimental growths at Meadowbank Nursery near Edinburgh, was half a pound. The foliage and the tender juicy stems of the plant, as well as the tubers, are esculent, but are used in the way of salad; and it is cultivated in its native country for the sake of both them and the tubers. It thrives best in dry light soils of medium fertility, and requires a warm and well sheltered situation, and should be planted at distances of between 2 and 3 feet. The tubers do not begin to form till toward the end of autumn; and, when cooked, they have a yellowish colour, a very mealy consistency, and a taste slightly and pleasantly acidulous, but in other respects similar to that of a fine potato. The presumption is that, bulk for bulk, they are much more nutritious than potatoes, and that, at the same time, they possess decided antiscorbutic and antiseptic properties, so as to be greatly more wholesome than potatoes for use along with a flesh-meat diet.

Deppe's wood-sorrel, *Oxalis Deppei*, is a native of Mexico, and was introduced to Britain in 1827. It possesses similar agricultural recommendations to the preceding, and is also figured in *Plate LXIV.* But it is a much smaller plant than the crenate-flowered wood-sorrel, and has very beautiful coppery-red flowers, and blooms throughout the long period from March till November, and thrives best in a soil of sandy peat.

The four-leaved wood-sorrel, *Oxalis tetraphylla*, is also a native of Mexico, and was introduced to Britain in 1823. Its roots are thick and fusiform, and send up many spreading filaments from the crown, with attached small scaly bulbs, which produce new plants in the following year; its leaves are radical and quadrifoliate, and have inversely heart-shaped leaflets; and its flowers come out either solitarily or four together, on an upright footstalk of about 6 inches in height, and have a light purple colour, and bloom in June and July. The leaves of this plant, like those of the common and the crenate-flowered species, are eaten in the way of salad; and both the bulbs and the fleshy fusiform roots are eaten in a cooked state.

A few of the best known or most interesting of the many ornamental species of wood-sorrel, are the small convex, *O. convexula*, bulbous-rooted, stemless, trifoliate-leaved, about 6 inches high, carrying pink flowers from January till November, and introduced from the Cape of Good Hope in 1789; the pretty, *O. pulchella*, similar in root and leaf and habit to the preceding, about 3 inches high, carrying white flowers in October and November, and introduced from the Cape of Good Hope in 1795; Piotta's, *O. Piottæ*, similar in root and leaf and habit to the two preceding, about 3 inches high, carrying orange-coloured flowers from January till September, and introduced from the Cape of Good Hope in 1816; the various-coloured, *O. versicolor*, bulbous-rooted, leafy-stemmed, glandularly and linearly leafleted, about 3 inches high, carrying crimson flowers from January till March, and introduced from the Cape of Good Hope in 1774; the yellow, *O. flava*, bulbous-rooted, stemless, petiolately, palmately, and numerously leafleted, about 6 inches high, carrying yellow flowers in March and April, and introduced from the Cape of Good Hope in 1775; the cloven-leaved, *O. bifida*, tuberous-rooted, stemless, trifoliate, about 9 inches high, carrying violet-coloured flowers in September and October, and introduced from the Cape of Good Hope in 1791; the beaked, *O. rostrata*, bulbous-rooted, stemless, simple-leaved, about 3 inches high, carrying purple and violet flowers in October and November, and introduced from the Cape of Good Hope in 1795; the goat's foot, *O. caprina*, noticed in the article Goat's Foot; the flesh-coloured, *O. incarnata*, bulbous-rooted, with elongated sparcely-leaved stems, stalked leaflets, and axillary peduncles, about 6 inches high, carrying flesh-coloured flowers from April till June, and introduced from the Cape of Good Hope in 1839; the rosy, *O. rosea*, fibrous-rooted, leafy-stemmed, evergreen palmate trifoliate leaved, about 6 inches high, carrying red flowers in March and April, and introduced from Chili in 1823; and Barrelier's, *O. Barrelieri*, an evergreen undershrub, with leafy stems and trifoliate leaves, about 18 inches high, carrying pale red flowers throughout most of the year, and introduced from Caraccas in 1824.

WOOL. The filamentous substance which constitutes the peculiar natural covering of sheep. It resembles hair at once in physiological charac-

ter, in chemical composition, and in natural uses; but differs from it in texture, in form, in softness, unctuousness, and pliability, and in adaptation to artificial purposes. See the article Hair. It grows from a soft pulp included in a bulb-like sac, which communicates through minute nerves and blood-vessels with the surrounding tissue; it springs from the cellular tissue, immediately below the true skin; it passes up thence to the exterior of the epidermis in the form of a fine cylinder; and, in all its development externally from the skin, it has a scaly texture with the lamina pointing from the root toward the tip, and extends in a spiral direction or with wavy curvatures, and has minute and regular serratures along its edges, and is protected and rendered soft and supple and pliant by a peculiar secretion called its yolk.

All wool is complete in its formation at the point where it issues from the skin; and receives constant accessions to its length at its radical extremity, or at the point where it issues from the bulb-like sacs. Some persons think that the lengthening of it occurs at the top, and is effected by a sort of pushing outward or upward in a manner analogous to the growth of acrogenous plants; but they may easily convince themselves of their error by staining a portion of growing wool with a solution of lunar caustic at an equal distance from the root and from the top,—for in the course of a month or so, they will readily perceive the distance between the mark and the root to have increased, while that between the mark and the top remains the same. All intelligent shepherds and store-farmers, too, know well that the white unstained wool which grows between the time of salving and the time of shearing, and which many of them familiarly call 'the rise,' is found, never at the top, but always at the root. The degree of increase is greater at some seasons of the year than at others, and differs widely at every season in different breeds of sheep; yet is powerfully controlled, in every instance, by the condition of the animal's health, the nature and quantity of its food, and the circumstances of its situation, insomuch that, under successive and wide differences of health and feeding in one year, the parts of the wool of each filament or of the whole fleece, when examined by the microscope, will be found to possess corresponding differences of character. The increase of the wool of any salved or mountain sheep, from the time of salving about the middle of November till the time of shearing about the middle of July, may readily be ascertained by measuring 'the rise,' and, in the case of a black-faced sheep of average character, pastured on a farm of medium quality, will be found about two inches; and if it be examined and measured at successive and regular intervals between the two periods, it will be ascertained to have effected one half of all its increment during the two months immediately before the shearing, or to have been proportionally double in each of the months of summer of what it was in each of the months of winter and spring. But this difference largely accrues from the comparative scarcity and plenty of food; and in the degree of its doing so, is accompanied with a corresponding difference in the quality of the successive parts or increments of the staple. Whatever wool is produced partly under full feeding and partly under deficient feeding does not exhibit an uniform glistening appearance, but is comparatively opaque in the portions which grew during the deficient feeding, and seems shrivelled and contracted, and is very liable to break, and, in consequence, is not only of deteriorated market value, but wants due fitness for many of the manufacturing purposes to which it might otherwise be applied.

The aggregate character of wool is mightily modified, and even may be totally altered, by the influences of climate, of the long continuance or violent changes of particular depasturement or feeding, and of the steady pliance of cross-breeding, peculiar farm-feeding, special shelter, and other home practices for forming or altering varieties and breeds of sheep. The covering of the wilder races, particularly in tropical or subtropical countries, comprises scarcely any wool at all, but consists almost wholly of hair, similar to that of goats; and even the covering of many of the domesticated breeds, in the more temperate regions of the world, particularly in places where defective or unskilful attention has been given to the arts of culture, contains a greater or less intermixture of real hair. But by frequent shearing, combined with the constant influence of judicious domestication, the fleece of very hairy breeds gradually parts with its hairiness and acquires more and more true wooliness, till it eventually becomes all over a tissue of genuine wool; and in the most favourable circumstances of climate and situation and treatment, it may even attain properties of comparatively high fineness, softness, and tenuity. In Britain, however, the improveableness of the fleece is much limited by the severity of our winters, the many, great, and sudden vicissitudes of our weather, and the natural limitation or embarrassment of some of our strongest appliances of domestication. Hair without any mixture of wool, indeed, covers only the face and part of the limbs of any of our sheep; yet real hair, in very many cases, is more or less mixed with the wool in the other parts of the body; and the wool itself, even when free from intermixture, continues stubbornly averse to assume as high a fineness as that of the best breeds in some other countries. Most attempts to improve the quality of our fleeces, too, have been accompanied with diminution of the quantity; and some of them have been carried so far as not only to reduce very seriously the weight of the clip, but also to affect severely the appearance and the value of

the flocks, and to render them so ill-clad as to be unable to withstand the storms of winter. The eye of patriotic poetry, indeed, may see in British sheep-walks loftier beauty and more glorious amenities than a farmer's eye can discern in those of even the richest wool countries of the world; and John Dyer, the author of a poem called "The Fleece," published in 1757, accordingly sung,—

> Our spacious airy downs and gentle hills,
> With grass and thyme o'erspread, and clover wild,
> Where smiling Phœbus tempers every breeze,
> The fairest flocks rejoice.
> —— No fleeces wave in torrid climes,
> Which verdure boast of trees and shrubs alone—
> Shrubs aromatic, coffee wild, or tea,
> Nutmegs, or cinnamon, or fiery clove,
> Unapt to feed the fleece. The food of wool
> Is grass or herbage soft, that ever blooms
> In temperate air, in the delicious downs
> Of Albion, on the banks of all her streams.

But, however rich and grateful may be the herbage of our dry and improved pastures, the prevailing dampness of our climate, as well as its occasional rigours and its many and violent changes, is an insuperable hindrance to the production of fine wool. Our system of management, also, can never have reference to any higher qualities of wool than the second-rate, and must always bear with main force upon the properties of the mutton. Even our driest pastures, the chalky downs of the South of England, give a roughness to the wool of our very best breeds; and our indispensable practice of aiding the pastures, and sometimes superseding them, with turnips and other succulent articles of diet, is fatal to all fineness of fleece. Dry pastures in a dry climate, aided when necessary by supplies of straw and other dry food, are essential to the production of prime or even excellent wool,—and constitute the secret of all the success of the wool-growers of Australia and Spain and Germany,—and are things which cannot possibly be attained, in sufficient amplitude and power, in Britain. The usages of our population, too, particularly in its paramount demand for abundance of good mutton, and in its contentment to derive all the main material for the finest kinds of woollen manufacture from other countries, compel our farmers, out of due regard to their own interest, to pay far more attention to the carcase than to the fleece; and exactly the influences of almost every kind which are most favourable for producing bulk and excellence of mutton are correspondingly unfavourable for producing good wool.

The clothing of sheep in Britain and in all similar latitudes is naturally renewed once every year,—the heavy old fleece falling gradually off in the early part of the warm season, and the light new one gradually rising beneath it and displacing it; and the annual shearing of sheep, practised by all British store-farmers, is simply the anticipating and the regularizing of the natural process. Wool, like hair, might be shorn at any time and often, and would always grow again after each cutting; but, according to universal experience, as well as on principles of obvious deduction from the character of our seasons, it cannot be economically shorn in Britain oftener than once a-year, or at any other time than about the commencement of the hottest part of summer. The shearing of lambs is quite unsuited to such a cold climate as ours, and is practised only in the most genial situations in a few of our warmest districts; and the great bulk of the lambs' wool used by our manufacturers is either obtained from the skins of lambs killed by the butcher, or imported from other countries. The greater portion of our home-grown wool, or that which is taken from the bodies of living sheep, is prepared for the market by the processes described in our articles Shearing of Sheep and Fleece; and the lesser portion, or that which is obtained from the skins of slaughtered sheep, is prepared by the fellmonger, simultaneously with the preparation of the hides, in a process which is described as follows by Mr. Southey:—"The first operation is to place the skins, one by one, on a flat stone, and to beat the parts round the head with a wooden mallet, for the purpose of loosening any clots or tufts of coagulated blood adhering to them. The skins thus prepared are then thrown into a vat of water to soak, in order to soften any substance or concretion which might attach to the wool. After remaining immersed from ten to twelve hours, the operation of washing commences by the following method:—This process is accompanied by beating the skin with a pole while in the water, which is done for the purpose of removing any dirt which the wool may still retain, it being desirable that it should be made as free from impurities as possible. When this operation is concluded, the skins are placed one upon another, to the number of twenty or thirty, for the purpose of draining; and when this is accomplished, they are laid one by one on a table, with the flesh or pelt side uppermost, when a strong solution of lime and water should be applied to the fleshy side of the skin. The brush used on such occasions is similar to the one which whitewashers work with in colouring rooms; and when thus properly smeared over by one person, another should be in attendance to fold the skins, one by one, taking care that the pelt sides are placed inwards; and so soon as this is done, they are put on poles and laid about six deep, one above another. This mode is adopted for the purpose of causing the skins to heat, preparatory to the wool being pulled, as the process operates in such a manner as to open or loosen the pores of the skin, by which means the wool is more readily drawn from it. The day after the skins have undergone the operation of liming and washing, they are taken down from the pole to shake off any water from

the extremity or points of the wool, which, if suffered to remain, would tend to discolour it. The skins, however, remain on the poles until the pores are partially relaxed, which may be ascertained by trying to separate the wool from the skin, as it will leave the pelt when in a proper state of preparation. The skins are then placed in an enclosed shed or warehouse, from which the air is excluded, and each skin suspended by the nostril or nose to afford greater facility in the operation of pulling. Before this commences, a lad is usually employed to cut off the pitch or any hard substance that may adhere to the skin, taking care not to shorten the wool. Previous to the operation of pulling being commenced, the skins should be inspected and assorted somewhat after the following method:—Those which are found deteriorated with kemp, or dead hairs intermixed with the wool, or marked with party colours, should be laid aside by themselves and kept separate from those which are entirely white. It would, in fact, be advisable, where the skins are numerous, to separate those which produce long wool from others of a shorter growth, as each class of wool is by the manufacturer applied to different purposes. There are very few party-coloured sheep in English flocks, and not many interspersed with dead or kemp and black hairs. When any perchance do appear, they should be separated from the rest, and their wool kept distinct, any intermixture being extremely detrimental to the consumer, who carefully avoids buying objectionable wool, except at low prices; and to this minute attention should be paid by all those who aim at producing skin wool of an approved quality. The coarse hairy parts about the legs should in like manner be first withdrawn and thrown aside, being entirely useless to the English manufacturer and injurious to his interest. When the skins have been properly limed and folded, in the course of two or three days, when the weather is warm, they are generally in a fit state to be pulled, which being done, the wool should be placed in a loft or open warehouse, and exposed to a free current of air to dry and become fit for packing, as otherwise it might be discoloured by heat, or even ignited. During a wet season, or in the winter months, the skinner usually has recourse to an enclosed warehouse, heated by iron pipes raised perpendicularly from the floor, in which a large fire is made of coke. These pipes are passed through the several floors where wool is exposed for drying; and at periods when the sun does not afford sufficient warmth to the atmosphere, it is customary to place the skins in an artificial heat of this kind, which proves a substitute for the sun's rays, and prepares the skin for the process of being pulled. The English fellmonger draws out the wool from the pelt by hand, the men placing the skins before them on an inclined board, but has occasionally recourse to the aid of an implement called a pulling-knife, which the operator uses in order to assist him in removing the wool from those parts of the skin which have not been sufficiently decomposed, owing to their not being so equally saturated as the rest. The skins, after being divested of their wool, are usually placed in a pit or vat filled with lime-water of a moderate degree of strength, compared with that usually applied to skins with the wool attached to them. There they remain two or three days, for the purpose of extracting any portion of the grease usually found attached to the pelt. Thence they are removed by long iron tongs to a stronger solution of lime-water, and daily drawn up and exposed to the air for several hours during the day, but out of the sun's rays in hot weather. They are then again thrown into the prepared liquid, care being taken to stir up the water previous to their immersion. In this state they continue three or four weeks, or are disposed of in the intermediate time to leathersellers, parchment-makers, or glue-manufacturers, according to their various sizes and condition."

The wool of the different races, families, and breeds of domesticated sheep differs so widely in comparative length of staple as to have occasioned them to be classified into short-woolled, middle-woolled, and long-woolled,—and differs also so widely in comparative softness and tenuity as to have caused them to be classified into coarse-woolled, medium-woolled, and fine-woolled. See the article SHEEP. But the wool of any one breed differs both in length and in fineness, as well as in other properties, according to the circumstances of climate and pasture and treatment in which the breed is reared and maintained; and the wool of each individual of every breed, in all circumstances, has somewhat widely different properties in different parts of the body. The wool of the most steady climate, the most congenial pastures, and the most judicious management, is always bulkier and finer than that of inclement districts, irregular feeding, and bad store husbandry; the wool of light arenaceous or calcareous sheep-walks has always a cleaner texture and a purer colour than that of such soils as those of some parts of Gloucestershire, which impart to it an orange tinge, or that of such soils as those of some parts of Hertfordshire and Warwickshire, which give it a brownish hue, or that of such districts as the fens of Lincolnshire and Cambridgeshire, which give it a dark blue tint; and the wool of the shoulders, back, and sides of any individual sheep, is finer than that of the upper part of the thighs, the upper part of the legs, and the parts extending thence toward nearly the haunch and the tail,—and the wool of these parts, again, is finer than that of the upper part of the neck, the throat, the breast, the belly, and the lower part of the legs. The separating and assorting of the different qualities, whether from one fleece or from a collection of fleeces, is a nice process of art, and is performed

sometimes under the direction of the manufacturers who have purchased and are about to use the wool, but more commonly by a class of persons called wool-staplers, who have qualified for their employment by a regular apprenticeship, and who purchase the raw material from the grower, and sell it in an assorted state to the manufacturer. The operator unrols the fleece on a table, spreads it out full under a clear light, and, under the joint guidance of his sight and his touch, culls out successive locks of uniform fineness of filament, and deposits them in a basket; and he assorts the whole into six or ten or, in some cases, a greater number of kinds, and has beside him a separate basket for each kind, and goes through the whole process with a promptitude, accuracy, and celerity which quite astonish the uninitiated. "In sorting wools," says M'Culloch, "there are frequently eight or ten different species in a single fleece; and if the best wool of one fleece be not equal to the finest sort, it is thrown to a second, third, or fourth, or to a still lower sort, of an equal degree of fineness with it. The best English short native fleeces, such as the fine Norfolk and Southdown, are generally divided by the wool-sorter into the following sorts, all varying in fineness from each other,—viz., first, prime,—second, choice,—third, super,—fourth, head,—fifth, downrights,—sixth, seconds,—seventh, fine abb,—eighth, coarse abb,—ninth, livery,—and tenth, short-coarse or brack wool." But either these divisions, or any others to a lesser or greater amount, would be far better designated by simple numerical names; and all vary in their relative market value, according to the demand for respectively coarse, middle, and fine cloths. The long wools, in an aggregate view, have a staple of seven inches and upwards,—the middle wools, of from four to seven inches,—and the short wools, of from two to four inches.

The comparative properties of wool are very vaguely expressed by the epithets coarse and fine, or by any other two or three general words; and they have been somewhat better designated as follows, by Arthur Young, in the order in which they are esteemed and preferred by the manufacturer:—"First, fineness with close ground, that is, thick-matted ground; second, fineness; third, straight-haired, when broken by drawing; fourth, elasticity, rising after compression in the hand; fifth, staple not too long; sixth, colour; seventh, what coarse is in it to be very coarse; eighth, tenacity; ninth, not much pitch mark, but this is no other disadvantage than the loss of weight in scouring. The bad or disagreeable properties are,—thin, grounded, toppy, curly haired, and, if in a sorted state, little that is very fine, a tender staple, no elasticity, many dead-white hairs, very yolky. Those who buy wool for combing and other light goods that do not want milling, wish to find length of staple, fineness of hair, whiteness, tenacity, firmness, elasticity, and not too many pitch-marks." Another, clearer, and shorter classification of properties may be made into soundness, length, cleanness, colour, softness, and feltability. Soundness arises from the healthy condition and proper feeding of the animal, and comprises uniformity, flexibility, and kindliness of the pile, but perfectly comports with wide diversity of the other properties correspondent to the different families and breeds of sheep. Length or shortness or any medium between the two must be variously suitable according to the different purposes of the manufacturer, but ought always to be uniform in the same specimen, or at least as nearly so as will comport with a due regard to the assortment of the other properties. Cleanness, though mainly desirable for preventing expense and loss in the process of scouring, is desirable also for its appreciable conservation of soundness and softness; and it requires that no dirty or discolouring ingredient be employed in salving, that as little as possible of any ochreous substance should ever get into the shepherd's or store-master's possession, and that the living flock, as well as the separated fleece, should be kept aloof from whatever might pollute them. Colour is important because wool excels cotton and linen and even silk in taking on bright and beautiful hues in the process of dyeing,—and because white wool receives the colouring matter more readily than black, and clear white wool more readily than creamy-coloured or brownish or dingy,—and because any mixture of black filaments with the white mars the harmony of the dye, and renders the whole specimen unsuitable for the reception of the brighter and more delicate hues. Softness has been raised to paramount importance by the demands of fashion; and depends partly on the minuteness of the fibres, partly on the combination of soundness and feltability, and partly on the abundance and tenuity of the lubricating yolk; and it more or less comprises or includes the two properties which Arthur Young and many other popular nomenclators call fineness and elasticity. What we have designated feltability is the most curious of all the properties; and is identical to a certain extent with what is popularly called fineness, but still more so with a peculiar and very beautiful structure of the filaments quite recently discovered; and may be well understood from the following account of it by Mr. Spooner:—"The felting property and other qualities of different wools have long been made known by practical experience; but we are indebted to Mr. Youatt for the discovery, that the felting property depended in a great measure on the number of serrations on its surface. This gentleman, after several laborious attempts, at length succeeded, with the assistance of a powerful achromatic microscope and its scientific maker, in developing the singular structure of wool and the difference between wools of different qualities. Each fibre was found to consist of a number of leaves attached to a central stem or band,

and extending in one direction, viz., from the root to the point. This was the result of examining a filament on an opaque object; but when viewed as a transparent object, the edges of the leaves were more visibly apparent, appearing like so many teeth pointing in one direction, and thence properly termed the serrated edge. The fibre of wool thus magnified appears somewhat like the common fir-apple. On examining different wools, Mr. Youatt found that the number of serrations corresponded to the felting qualities of the wool, being in the Saxony no less than 2,720 in the inch, in the Southdown 2,080, and in the Leicester 1,860 alone. Thus fine wool differs from coarse in having a greater number of serrations and growing in a more spiral form, which, of course, increases the number of curves; but to this we must add the fact of its being actually finer or smaller in its fibres; so that while a fibre of the coarsest wool is $\frac{1}{450}$, the finest is $\frac{1}{1500}$ of an inch in diameter. It can easily be conceived how this curious structure of the wool, particularly its serrated edge, must conduce to its felting property. As long as the filaments are kept in the same direction, these serrations are comparatively inoperative; but torn to pieces by the card and mixed in every direction, the serrated edges must tend to hook and entwine together; and this must be pretty much in proportion to the number of serrations in a given space, particularly when this is added to the fact that the wool is more curved as the serrations are numerous."

Wool is prepared for the spinner, either by the process of combing, to suit it for worsted yarn and worsted stuffs, or by the process of carding, to suit it for woollen yarn and woollen cloths. Combing divides the wool by means of fine steel teeth, and requires the comb to be kept hot and the wool to be oiled; and it frees the wool from all knots and entanglements, renders it smooth and flowing, brings out its softness and elasticity to their maximum, and arranges its filaments in parallel order or side by side, somewhat in the manner in which the fibres of flax and hemp are assorted for spinning. Worsted yarn, formed by the outdrawing and the twisting of combed wool, is of every degree of fineness, from a thickness suitable for the coarsest substances to a thinness suitable for the most delicate stuffs; and, in rare instances, it has been attenuated to the almost incredible rate of upwards of 90 miles of thread from one pound of wool,—and in the case of ordinary superfine spinning is currently drawn out to the rate of about $22\frac{1}{4}$ miles from the pound. Carding is a widely different process from combing; it breaks and divides the wool into a multitude of fragments, which, from the spiral growth of the filaments, necessarily lie together in a curved state; and it co-operates with the serratured structure of the filaments, or the feltability of the wool, to dispose all the fragments to lock together and effect the most thorough coherence on being subjected to moisture and pressure. Carded wool, by means of the due and varied appliance of mere moisture and pressure, is made into hats, beavers, caps, and numerous kinds of carpets, blankets, mantles, and cloths; and when it is first oiled, and then spun and woven, and then fullered, it serves as the material of all the dense and fine kinds of woollen cloth; and in this latter case, it is oiled in order to arrest its felting tendencies from going into action before the spinning and the weaving are effected,—and is afterwards fullered, by means of aluminous matter or clayey earth, for the double purpose of discharging the oil and of bringing its felting coherences into sudden and complete play.

"While the facility of felting is an important property in the case of all wool designed for the manufacture of cloth, and prepared by the card, it is not required in the case of wool intended for worsted, and prepared by the comb. Certain kinds of wool have this property in a higher degree than others, and are consequently better adapted for the making of woollen cloth. In general, the shorter kinds of wool having also fine filaments, are those of which the laminæ are most numerous and distinct, and are those accordingly in which the felting property is the greatest. The property, however, is not in proportion to the tenuity of the fibres, since certain short and slender wools possess it in an inferior degree. Of all known wools, that derived from the Merino race possesses the felting property in the greatest perfection, and is accordingly the best adapted of all others for the making of cloth; while the long and tough wool of the larger sheep is imperfectly adapted to the preparation of woollen yarn, and accordingly is never prepared by the action of the card. It is, therefore, the short and felting wools which alone are fitted for this process; and until a period comparatively recent, they were, with few exceptions in this country, never prepared by any other means. This gave rise to a popular distinction, long in use, and not yet entirely abandoned. The long wools were termed combing wools; the short, carding wools. But these designations are no longer applicable. By improvements in the woollen manufacture, the means have been found to prepare the shorter and more delicate wools by the comb as well as by the card; and now a great proportion of all the short wool of this country is converted into worsted yarn. The Southdown wool, which was formerly, and until a recent period exclusively, prepared by the card, is now in a still larger degree prepared by the comb for the manufacture of worsted. It has fallen in price, indeed, from its being no longer used for the finer cloths; but the range of its utility has been greatly extended. Thus it is also with the wool of the Cheviot, the Norfolk, and other short-woolled breeds; and there cannot be a doubt that, although individual interests may have been injuriously affected by the fall in the price, the

nation has been benefited by an extension of the purposes to which this class of wools can be applied. Nay, the general good of the wool-growers themselves has been eminently served. The demand for their commodity has become more steady, and the trade been placed on a surer basis, by being founded on an enlarged demand, and supported, not by artificial regulations and fiscal restraints, but by an extension of the woollen manufacture. Soon after the peace of 1814, alarm was raised among the British wool-growers lest the price of the raw material should be reduced below what they chose to term a remunerating price. The government of the day, in an evil hour, yielded to the influence exerted; and in the year 1819, heavy duties were imposed on foreign wool, with the design of keeping up the price of the native produce, under the specious pretext of encouraging British agriculture. In six years, this monstrous law was repealed, but not until it had done all that the shortness of the time allowed for establishing the manufactures of foreign rivals, and giving them the ascendancy in the markets of Europe. But the price of short wool continuing to decline, renewed efforts were made by the wool-growers to induce the legislature to restore the former restrictions. This, in 1828, led to a parliamentary inquiry, when a mass of evidence was produced, proving beyond all cavil the danger and evil of interfering, through the medium of duties and fiscal regulations, with the raw material of a manufacture which could only be sustained by freedom of trade and production. It was proved by the concurrent testimony of witnesses from all parts, that the cloth made from British wool alone could no longer find a market in Europe, and was even deemed too coarse for the clothing of the labouring classes at home: and that, without a free command of the wool of other countries, a great part of the woollen export trade of Great Britain would be for ever lost. It may well excite surprise that any class of men amongst us should have dared to demand that the manufacturers of the country should be prevented from procuring the materials of their manufacture where they could be obtained cheapest and best; nay, should not only be prevented from exercising this natural and necessary right, but compelled to take from the wool-growers at home, and at a price enhanced by fiscal regulations, what was absolutely unsuited for the purposes of commerce. The disgraceful law of 1819 had already shown that, by refusing to take the wools of other countries, we depressed the price of the raw material abroad, and thus gave an indirect premium to the foreign manufacturer; and that, by forcing our manufacturers to employ wools of inferior quality and higher price, we directly unfitted them for competition in the general market of the world. It was of the repeal of the law of 1819 that the wool-growers thought fit to complain, as having produced the depreciation which had taken place in the price of the clothing wools, not perceiving that, in admitting the depreciation from this cause, they admitted at the same time the magnitude and injustice of a burden, which had been so heavily taxing the manufacturing industry of our own country, and fostering that of others. What, it may be well asked, did the wool-growers hope for by forcing up the price of wool by such expedients? To the mere occupier of the land a forced rise of the raw material could only be beneficial during a passing term. On the termination of the lease, the benefit would go to the owner of the land in the shape of increased rent. Thus, in order to raise the rent of the land, the wool-growers were prepared to lay a tax on every consumer of wool, that is, on every individual in the kingdom, and to cripple the trader in his means to maintain his equality in the foreign markets. It is known that, in these times, the great danger to the manufacturing prosperity of the country is the progress of other nations in those arts in which we have hitherto excelled, and that our relative superiority in such arts can only be maintained by our being enabled to supply the productions of them on the cheapest terms; and granting that the wool-growers could, by means of an ill-judged monopoly, have forced up for a time the price of the native wool, would they not thereby have abandoned a yet more safe and permanent means of effecting the end, namely, that which would have resulted from increasing the demand for the manufactured commodity? The injurious measure contended for was, however, happily resisted, never, it is to be trusted, to be brought forward again; and the trade of wool, by being thrown open to the world, has been placed on a far surer foundation than if it had been made to rest on the narrow and insecure basis of monopoly and restriction." [Low's Domesticated Animals.]

The earliest dress known to have been made of wool was the simla, an upper garment resembling a blanket, referred to in Exodus xii. 34. and xxii. 26. The art of manufacturing woollen cloth was no doubt derived by the Greeks and Romans from either Egypt or Western Asia, and it probably passed into the central and western regions of Continental Europe about the time of the Roman conquest; but when it obtained footing or began to be understood in the British Islands, cannot be very distinctly conjectured. Britain probably contained few or no sheep till some time after the Roman conquest. No mention is made of them till about the beginning of the 8th century; and they could not be very numerous till a general destruction of wolves took place, which happened about the middle of the 10th century. In the reign of Richard I., they were so far increased, that wool was become one of the capital commodities of the nation; but no sooner did it become plentiful and valuable than it fell a prey, first to arbitrary power, and next to the spirit of monopoly. With the

growth of wool in England, or very soon after, the art of manufacturing it commenced, cloths being certainly made not only in the year 1224, but long before; and towards the close of the 13th century, one Thomas Cole, was distinguished by the name of the Rich Clothier of Reading, in Berkshire. One of the greatest clothiers that England ever produced was also a native of Berkshire, John Winchcomb, commonly called Jack of Newbury; he kept about a hundred looms in his house,—and, in the expedition to Flodden Field against the Scots, marched a hundred of his own men, all armed and clothed at his own expense. "If we may be indulged a conjecture," says Smith, in his Memoirs of Wool, "touching the origin of wool-sacks in the House of Lords, as a notable memorial of great consequence, we should imagine it to have been, if at all, some time during this struggle (namely, the resistance of the people to Edward I. levying, by his own authority, forty shillings on every sack of wool exported), to perpetuate the remembrance of the noble stand made on that occasion, and of an allowed indefeasible right in the subject not to be saddled with any tax or imposition by other authority than that of Parliament." The state of woollen manufactures in Scotland about the year 1705, appears to have been as follows:—"They made, of their own wool, stockings at Aberdeen, from ten to thirty shillings a-pair; broad-cloth, about twelve shillings per yard;—fingrins, bayse, serges, trimmings, and all sorts of fine worsted camlets, and other stuffs, very near as good as in England; besides Glasgow plaids, in which, as well as stockings, they excelled greatly all other nations." About the year 1752, great complaints were made by the wool-staplers of the evil done to the fleece by the practice of branding sheep with pitch and tar, and also of the false and fraudulent binding of the fleece, in which it was the custom, for the purpose of increasing the weight, not only to include the worst kind of the wool, such as tail-wool, shank-locks, coated wool, &c., but also clay, stones, sand, dung, &c. To lessen the former of these evils, it was recommended—and the recommendation is worthy of being attended to in the present day,—first, to confine all brands to the buttocks or hinder leg,—second, to limit the size of the brand,—and third, to prohibit the use of pitch and tar to all other marking thought proper to be put on sheep.

"After the year 1773," says Professor Low, "a revolution occurred in manufacturing industry, which may be said to have changed the condition of human society. Machinery was applied to the fabrication of cotton, and the stupendous power of steam was called into more extended action. First came the spinning-jenny, by which a child could direct a hundred spindles and more, all at a time; then the beautiful frame of Arkwright, which required merely that the raw material should be supplied, in order to be spun into threads of surpassing fineness; then the mule-jenny; and last the power-loom, which substituted mechanical for human power in the forming of the cloth. A similar machinery was applied to the spinning and weaving of wool, and the whole processes of the art were changed. The variety, quality, and cheapness of the productions increased in a wonderful degree; and, notwithstanding the amazing extension of the use of cotton in furniture, clothing, and dress, the consumption of wool in England has not only not diminished, but is at this time greater than in any former age. The number of sheep in the British Islands has been variously computed at from thirty to thirty-five millions. Taking the latter sum, which probably falls below the real amount, and assuming the produce, after making allowance for the deficient weight of the wool of slaughtered sheep and lambs, to be 4½ lbs. the fleece, the total quantity produced will be

	157,500,000 lbs.	
Whereof are exported in the raw state, . . .	4,603,799	
Leaving to be manufactured, .	152,896,201 lbs.	
And assuming the price to be 1s. 3d. per lb., the value of the raw material will be .	£9,556,012	11 3
The value of foreign wool imported, 56,700,895 lbs. at 2s. 6d., is	7,087,611	17 6
	£16,643,624	8 9

Supposing, then, the value of the manufactured commodity to be 2½ times that of the raw material, the value of manufactured woollen goods produced in Britain will be £41,609,061 : 1 : 10. This great national manufacture supplies a larger internal consumption than takes place in any other country; and affords a surplus, valued at between six and seven millions sterling, besides yarn, valued at about half a million, for an export trade to all parts of the world, being more than one-eighth part of the whole export trade of the kingdom. The woollen trade is, therefore, of surpassing importance to the nation. It has to contend with the fiscal regulations, and the increasing production and rivalry of other countries; but hitherto the superior capital, machinery, and industry of the country, and the facilities of an extended commerce, have given advantages to the British manufacturer which no European country as yet possesses."—*Smith's Memoirs of Wool.—Bischoff's Comprehensive History of the Woollen and Worsted Manufactures.—Southey's Treatise on Wool.—MacCulloch's Commercial Dictionary.—Bakewell's Observations on Wool.—Youatt on Sheep.—Spooner on Sheep.—Low's Domesticated Animals.—Luccock on Wool.—The Annals of Agriculture.—Parliamentary Papers.—Anderson's Recreations in Agriculture.—The Farmer's Magazine.—The Quarterly Journal of Agriculture.—The Transactions of the Highland*

WOOLLEN RAGS. See Rags.

WOOLLY BLIGHT. See Aphis.

WOOL-SHEARS. See Shearing of Sheep.

WORM. See Worms.

WORM-GRASS. See Spigelia.

WORMIA. A genus of ornamental tropical plants, of the dillenia tribe. The toothed species, *W. dentata*, was introduced from Ceylon to British collections in 1818; and is an evergreen, yellow-flowered, small tree of naturally about 20 or 25 feet in height; and thrives best in a soil of peaty loam. Three other species are known.

WORMING. An operation performed on young dogs for the purpose of preventing them from biting should they happen to become mad. It consists in making an incision underneath the tongue, and drawing out with a hook a small worm-like ligament. It was regarded by many sportsmen of a very recent period, and is still regarded by some, as a preventive of prime importance and great power; but it really is perfectly useless.

WORMS. Invertebrated animals, with soft elongated bodies. The red-blooded worms or annelides constitute one of Cuvier's four classes of Articulata,—the other classes being crustaceans, spiders, and insects; and they are the only invertebrate animals who have red blood. Their body is more or less elongated, and comprises numerous rings, of the character either of segments or of transverse plicæ; their head consists merely of the first of these rings, and does not seem to differ much from the rest, except in the presence of the mouth and the principal organs of the senses; their systems of locomotion do not compose articulated feet, but consist principally of setæ or fasciculi of stiff and moveable hairs, commanded by the contractility of the body; their oral organs, in some instances, amount to little more than a simple tubular orifice,—but in others comprise jaws, more or less strong; their organs of sense consist principally of fleshy or articulated tentacula, and of certain blackish points, which are thought to be eyes, but which do not exist in all the species; their respiration is performed in organs which, in some cases, are developed externally, and in others lie on the surface or dip into the interior; their circulation is carried on in a double and closed system of arteries and veins, which comprises, in some instances, one or several visible hearts or fleshy ventricles; and their nervous system consists of a double knotted or ganglionic cord, similar to that of insects. Almost all, except the lumbrici or earth-worms, are aquatic animals; and several penetrate into holes at the bottom of the water, or construct tubes there with the ooze or other substances, or even exude a calcareous secretion which envelopes them with a sort of tubular shell. The lumbrici, or terrestrial worms, are better known than almost all the multitude of other species taken together, and are noticed in the article Earthworm; and the leeches are the most interesting aquatic species, and are noticed in the article Leech.—Other worms than the annelides are recognised only in popular nomenclature, or belong only to popular classification; and they comprise widely different groups and do not constitute or comprise any one natural class. A great many are larvæ; and most of the others are entozoons. See the articles Larva, Caterpillar, Wireworm, Grub, Worms (Intestinal), and Parasites (Animal).

WORMS (Intestinal). Larvæ, annelides, or entozoons living in the intestines of the larger animals. They have been regarded by grooms, dairy-men, cattle-men, and cow-doctors as the causes of several troublesome diseases in horses and cattle; but they really do very little harm, and seldom challenge the enlightened veterinarian's serious attention. Some have such an economy as to render them essentially innocuous; and others, though armed with powers of evil, are, in general, either too few in number or too well resisted by the functional energies or the organic defences of the viscera to be able to do serious mischief. All, in a general view, are referred to in the article Parasites (Animal); and some of the principal are particularly noticed in the articles Ascarides, Bots, and Filaria.

The long white worm, or common intestinal round worm, *Lumbricus teres*, sometimes occurs in the small intestines of both the horse and the ox. It greatly resembles the common earthworm, and has usually a length of from 6 to 10 inches, and is a sufficiently repulsive and formidable looking animal. If it be numerous, it may consume so much of the mucus and nutriment of the intestines as to operate like a disease, and may indicate its devastations by tightness of the horse's or the ox's skin, roughness of the coat, and a tucked-up state of the belly; but, in general, it can be detected only by being occasionally voided in the fæces. The best treatment of a horse whom it has been discovered or may be strongly suspected to infest, is to give a drachm of tartar emetic in a bran mash every night for a week, and then administer a brisk purgative.—A small species of strongulus frequently accompanies the long white worm in the ox. The denticulated tapeworm, *Tænia denticulata*, small in size and becoming attenuated and sometimes almost filiform toward the neck, has been found occasionally in the abomasum and the small intestines of the ox, and still more rarely in the intestines of the horse. The *Tricocephalus affinis*, a small long worm, with a minute head and an elongated and thread-like neck, sometimes occurs in the cæcum of the ox. The *Amphistoma conicum*, a frequent and abundant entozoon in birds, but here of considerably larger size, often inhabits the rumen and the reticulum of cattle. But these little creatures are objects of interest chiefly to the naturalist, and need not occasion

farmers or horse-owners any concern. The practice of administering calomel and other mercurials as vermifuges is very bad; the administering of turpentine can be serviceable mainly or only in the case of tape-worm; and, in general, the use of vermifuges of any kind for horses and cattle, except in bad cases of ascarides and lumbricus, may be regarded as doing twenty fold more harm than good.

WORMWOOD,—botanically *Artemisia*. A diversified genus of plants, of the chamomile division of the composite order. Six species are natives of Britain, about one hundred have been introduced from other countries, and a good many more are known. A few of the species in Britain are hardy annuals and biennials, the great majority are hardy annual-stemmed perennials, three or four are hardy deciduous shrubs, and upwards of twenty are evergreen shrubs, some of them hardy and the rest requiring either frame or greenhouse protection. The stems of some are simple, and those of others are branched; the foliage of some is smooth, and that of others is hoary or pubescent; the leaves of some are entire, those of others are palmate, and those of most are either pinnate, bipinnate, pinnatifid, or bipinnatifid; the flowers of a few are white or brown or purple, and those of the vast majority have a yellowish-green or herbaceous colour; the habit and foliage and general appearance of some are uninteresting, and those of others are more or less highly ornamental. A few of the species possess medicinal, fragrant, or culinary properties; and a number have been described in our articles Moxa, Southernwood, and Mugwort.

The common wormwood, *Artemisia absinthium*, is an indigenous, perennial-rooted, annual-stemmed herb, inhabiting road-sides, heaps of rubbish, and dry waste places; and it is cultivated in gardens for medicinal and culinary purposes. Its root is branched and somewhat woody; its stems are branched, angled, furrowed, nearly erect, panicled at the summits, and from 18 to 36 inches high; its lower leaves are bipinnate; its upper leaves are pinnatifid or digitated; its leaflets are entire, oblong, and obtuse; and its flowers grow in erect racemes, and are pedicellated, hemispherical, nodding, and of a brownish-yellow colour, and bloom from July till September. This plant emits a strong odour, which some persons reckon fragrant, and others reckon very disagreeable; it has an intensely bitter, slightly pungent, nauseous taste; it acts internally as a tonic and an anthelmintic, and externally as a discutient and an antiseptic, and it acts beneficially in cases of dyspepsy and hypochondria, and has been extensively used also in cases of gout, scurvy, dropsy, and intermittent fever. It contains an essential oil which possesses narcotic properties; and it is freed from this by decoction. The plant loves a dry soil in a shady border; and may be raised either from seeds sown in spring, or from slips or cuttings planted in June or August.

The sea wormwood, or drooping sea wormwood, *Artemisia maritima*, is a perennial-rooted, annual-stemmed indigen of the sea-shores of Britain; and is cultivated in gardens for the same purposes as the common wormwood. Its stems are branched and about 12 or 18 inches high; its leaves are pinnate and hoary; and its flowers have a brown colour, and bloom in August and September. It will thrive in any ordinary garden soil, and may be raised in the same manner as the common species.—The French wormwood, *Artemisia gallica*, inhabits the muddy shores of Britain, and is very similar to the sea wormwood, but about twice as tall.

The Santonica or Siberian wormwood, or Tartarian southernwood, *Artemisia santonica*, is a native of Siberia, Tartary, and Persia, and was introduced to Britain toward the close of the 16th century, and is cultivated in gardens for the same purposes and in the same way as the common wormwood. It has the habits of indigenous field southernwood, but is erect. Its stem is panicled, rather hoary, and from 12 to 24 inches high; its branches are wand-like; its lower leaves are pinnate, much cut, linear, and hoary; its upper or branch leaves are undivided, linear, and very small; and its flowers are solitary, cylindrical, and of a herbaceous colour, and bloom from September till November.

The Roman or Pontine wormwood, *Artemisia pontica*, is a native of Austria, and was introduced to Britain in 1570, and is also cultivated in gardens for the same purposes and in the same way as the common wormwood. Its root is perennial; its stems are branched and about 3 or 4 feet high; its leaves are bipinnate and pubescent; and its flowers are yellow and bloom in September.

The Tarragon wormwood, or simply Tarragon, *Artemisia dracunculus*, is a native of the South of Europe, and was introduced to Britain about the middle of the 16th century, and is cultivated in gardens as a fine aromatic herb for improving the flavour of soups and salads. Its root is perennial; its stems are herbaceous and about 2 or 3 feet high; its leaves are undivided; and its flowers have a herbaceous colour, and bloom in July and August. This plant thrives in any common garden soil, but requires a shady border; and it is raised from bottom offsets in spring, and from cuttings of the stems in May and June.

The tree wormwood or arborescent wormwood, *Artemisia arborescens*, is a native of the countries round the Mediterranean, and was introduced to Britain in 1640. It is an ornamental evergreen shrub, and has long claimed a place among the denizens of shrubberies and pleasure-grounds. Its stem is upright, and from 6 to 12 feet high; its leaves constitute its chief recommendation, and are of two or three sorts, some very much

divided and others a good deal broader, and all have a singular and agreeable effect during winter; and its flowers have a herbaceous colour, and grow in roundish heads, and have very little beauty, and bloom from June till August. This plant is readily propagated from cuttings, planted in a shady place at any time from May till the early part of autumn.

WORT. The infusion of malt which is fermented into beer or ale. Ground malt is mixed with somewhat more than its own bulk of water, at a temperature of between 160° and 180° Fahrenheit, in a cylindrical vessel called a mash-tun; the mixture is covered from the air, and allowed to stand during two or three hours; the liquid portion of it is then drawn off by a cock at the bottom of the vessel; and successive infusions of the same kind, and in the same way, are made upon the residuum till all its extractive principles are sufficiently withdrawn. The liquid thus obtained is wort; and, as appears from the nature of the process, it is simply a watery solution of the extractive or saccharine and amylaceous matters of the malt. It has a brownish-yellow colour, a peculiar smell, and a lusciously sweet taste; and, if it have been properly made, is perfectly transparent. The chief ingredient in it, or rather its essential constituent, is a sugary substance which, when separated from the other ingredients and dried at a temperature of 160° Fahrenheit, forms a brittle mass with a glazed surface, and has a light brown colour and a specific gravity of 1·552. Another ingredient is starch,—which may readily be precipitated by dropping some infusion of nut-galls into the liquid; another is mucilage,—which may be precipitated by means of alcohol; a fourth is gluten, —which passes during the subsequent process of fermentation into yeast; and a fifth in many specimens of wort—though it ought not to exist in any—is a mixture of insoluble matter drawn off from the sediment in the mash-tun, and rendering the liquid more or less slightly turbid. The proportion of starch approaches to little or nothing in the degree in which the grain was thoroughly malted; and the proportion of mucilage is always greater in the last infusions of any preparation of wort than in the first.

The ordinary process for converting wort into ale or beer is described in the article BREWING, and the chemical changes involved in it are described in the article FERMENTATION; but a remarkable variety of the process practised in Bavaria, together with consequent modifications on the chemical changes and results, may be profitably studied in the following passage from Liebig: — "English, French, and most of the German beers, are converted into vinegar when exposed to the action of air. But this property is not possessed by Bavarian beer, which may be kept in vessels only half-filled without acidifying or experiencing any change. This valuable quality is obtained for it by a peculiar management of the fermentation of the wort. The perfection of experimental knowledge has here led to the solution of one of the most beautiful problems of the theory of fermentation. Wort is proportionally richer in gluten than in sugar, so that during its fermentation in the common way, a great quantity of yeast is formed as a thick scum. The carbonic acid evolved during the process attaches itself to the particles of the yeast, by which they become specifically lighter than the liquid in which they are formed, and rise to its surface. Gluten in the act of oxidation comes in contact with the particles of the decomposing sugar in the interior of the liquid. The carbonic acid from the sugar and insoluble ferment from the gluten are disengaged simultaneously, and cohere together. A great quantity of gluten remains dissolved in the fermented liquid, even after the transformation of the sugar is completed, and this gluten causes the conversion of the alcohol into acetic acid, on account of its strong disposition to attract oxygen, and to undergo decay. Now, it is plain, that with its separation, and that of all substances capable of attracting oxygen, the beer would lose the property of becoming acid. This end is completely attained in the process of fermentation adopted in Bavaria. The wort, after having been treated with hops in the usual manner, is thrown into very wide flat vessels, in which a large surface of the liquid is exposed to the air. The fermentation is then allowed to proceed, while the temperature of the chambers in which the vessels are placed is never allowed to rise above from 45° to 50° F. The fermentation lasts from three to six weeks, and the carbonic acid evolved during its continuance is not in large bubbles which burst upon the surface of the liquid, but in small bubbles like those which escape from an acidulous mineral water, or from a liquid saturated by high pressure. The surface of the wort is scarcely covered with a scum, and all the yeast is deposited on the bottom of the vessel, in the form of a viscous sediment. In order to obtain a clear conception of the great difference between the two kinds of fermentation, it may perhaps be sufficient to recall to mind the fact, that the transformation of gluten or of other azotised matters is a process consisting of several stages. The first stage is the conversion of the gluten into insoluble ferment in the interior of the liquid, and as the transformation of the sugar goes on at the same time, carbonic acid and yeast are simultaneously disengaged. It is known with certainty, that this formation of yeast depends upon oxygen being appropriated by the gluten in the act of decomposition; but it has not been sufficiently shown, whether this oxygen is derived from the water, from the sugar, or from the gluten itself; whether it combines directly with the gluten, or merely with its hydrogen, so as to form water. For the purpose of obtaining a definite idea of the process, we may designate the

first change as the stage of oxidation. This oxidation of the gluten, then, and the transposition of the atoms of the sugar into alcohol and carbonic acid, are necessarily attendant on each other, so that if the one is arrested the other must also cease. Now, the yeast which rises to the surface of the liquid is not the product of a complete decomposition, but is oxidised gluten still capable of undergoing a new transformation by the transposition of its constituent elements. By virtue of this condition it has the power to excite fermentation in a solution of sugar; and if the gluten be also present, the decomposing sugar induces its conversion into fresh yeast, so that, in a certain sense, the yeast appears to reproduce itself. Yeast of this kind is oxidised gluten in a state of putrefaction, and by virtue of this state it induces a similar transformation in the elements of the sugar. The yeast formed during the fermentation of Bavarian beer is oxidised gluten in a state of decay. The process of decomposition which its constituents are suffering, gives rise to a very protracted fermentation in the sugar. The intensity of the action is diminished in so great a degree, that the gluten which the fluid still holds in solution takes no part in it; the sugar in fermentation does not excite a similar state in the gluten. But the contact of the already decaying and precipitated gluten or yeast, causes the eremacausis of the gluten dissolved in the wort; oxygen gas is absorbed from the air, and all the gluten in solution is deposited as yeast. The ordinary frothy yeast may be removed from fermenting beer by filtration, without the fermentation being thereby arrested; but the precipitated yeast of Bavarian beer cannot be removed without the whole process of its fermentation being interrupted. The beer ceases to ferment altogether, or, if the temperature is raised, undergoes the ordinary fermentation. The precipitated yeast does not excite ordinary fermentation, and, consequently, is quite unfitted for the purpose of baking; but the common frothy yeast can cause the kind of fermentation by which the former kind of yeast is produced. When common yeast is added to wort at a temperature of between 40° and 50° F., a slow tranquil fermentation takes place, and a matter is deposited on the bottom of the vessel, which may be employed to excite new fermentation; and when the same operation is repeated several times in succession, the ordinary fermentation changes into that process by which only precipitated yeast is formed. The yeast now deposited has lost the property of exciting ordinary fermentation, but it produces the other process even at a temperature of 50° F. In wort subjected to fermentation, at a low temperature, with this kind of yeast, the condition necessary for the transformation of the sugar is the presence of that yeast; but for the conversion of gluten into ferment by a process of oxidation, something more is required. When the power of gluten to attract oxygen is increased by contact with precipitated yeast in a state of decay, the unrestrained access of air is the only other condition necessary for its own conversion into the same state of decay, that is, for its oxidation. The presence of free oxygen and of gluten are conditions which determine the eremacausis of alcohol and its conversion into acetic acid; but they are incapable of exerting this influence at low temperatures. A low temperature retards the slow combustion of alcohol, while the gluten combines spontaneously with the oxygen of the air, just as sulphurous acid does when dissolved in water. Alcohol undergoes no such change at low temperatures, but during the oxidation of the gluten in contact with it, is placed in the same condition as the gluten itself when sulphurous acid is added to the wine in which it is contained. The oxygen of the air unites both with the gluten and alcohol of wine not treated with sulphurous acid; but when this acid is present, it combines with neither of them, being altogether absorbed by the acid. The same thing happens in the peculiar process of fermentation adopted in Bavaria. The oxygen of the air unites only with the gluten and not with the alcohol, although it would have combined with both at higher temperatures, so as to form acetic acid. Thus, then, this remarkable process of fermentation with the precipitation of a mucous-like ferment consists of a simultaneous putrefaction and decay in the same liquid. The sugar is in a state of putrefaction, and the gluten in that of decay."

WOUND. The consequences and proper treatment of wounds, in the domesticated animals, vary according to the nature of the injuries and the situation of the injured parts. If the skin and cellular substance only be injured, the recovery is generally easy and prompt. Division of the muscular fibres, with the necessary concomitant of lesion of the smaller arteries and nervous trunks, may oppose more obstacles to the cure; but neither are these often of a serious description. But should any of the greater arterial or venous trunks be opened, any of the cavities of the body be penetrated, or the internal organs share in the injury, a wound must be considered as presenting tokens of immediate and extreme risk. One of the results of every wound, unless where it affects a part not naturally endowed with sensibility, as the horny crust of the hoof, is a sensation of pain; farther, as all the organs admit into their texture a greater or smaller number of vessels, no wound can occur without an effusion of some portion of the circulating fluid; and lastly, the greater part of the tissues of the body being endowed with some share of contractility, whether animal or organic, another general result of a wound is a separation of its sides, to an extent proportioned to the magnitude of the injury, and to the degree of contractile force possessed by the part which has suffered lesion.

Nature establishes the cure of wounded parts in two ways. The one process is that of immediate adhesion, which is accomplished in a few days, when the wound is technically said to have been united by the first intention; the other is by the slower means of suppuration and granulation, through which the wound is gradually filled up, and a cicatrix ultimately formed, and the process is then entitled the cure by the second intention. The conditions which are favourable to the healing of a wound by the first intention are, rest, approximation of the divided surfaces, cessation of hæmorrhage, and seclusion from the contact of the air. These conditions being obtained, there follows, for a few hours after the accident, a discharge from the wounded vessels of a serous or watery-looking fluid, which then changes into an effusion of what is termed coagulable lymph. This substance displays a strong tendency to organization; and being gradually thickened by the absorption of its thinner parts, it serves as a glue, to bind together the cut surfaces, which is generally accomplished at the end of two or three days, though the union be not as yet firm and perfect. Through this lymph the blood-vessels prolong themselves, and the organization of the new matter being at length fully established, the cure may be said to be completed, the whole process usually occupying less than a week. For the success of this process, a degree of increased action in the parts, denoted by slight heat and redness, is required; but this increased action ought not to amount to inflammation, or, at least, the inflammation must be to a very trifling extent, otherwise the cure will be greatly retarded, and must be finally completed by the second intention. If, on the other hand, there be a deficiency of action, the healing process ceases to go on, and the wound assumes the appearance of a callous fissure, giving origin to a thin watery discharge. The cure by the first intention is that which ought to be attempted on every occasion, where there is the slightest prospect of its success, as it may be effected with great expedition, and presents a small scar, the part remaining clothed with original skin, a covering much better than any substitute which can be formed to supply its place. But if it should prove impossible to attain the conditions necessary for completing the union by the first intention, we must look for the appearance of a different series of phenomena. The pain arising from the injury continues and increases in severity; and towards the beginning of the second day after the accident, other symptoms of inflammation show themselves, such as increased heat and redness, with swelling of the parts closely adjoining. The discharge is at first thin and nearly colourless, though sometimes tinged with blood; and afterwards the surface becomes covered with an effusion of lymph. About the third day, there begin to display themselves a number of minute red-coloured cones, soft, and bleeding on the slightest contact, which denote the commencement of the process of organization in the effused lymph, and are known by the name of granulations. These, on being subjected to maceration, appear to be composed merely of cellular tissue, and do not present any analogy, in point of structure, with the particular organ from which they proceed, or of which they are henceforward destined to form a part. In the mean time, the discharge becomes opaque, and of a yellowish-white colour, possessing the other properties of what has been termed purulent matter, and becoming thicker, more viscid, and of a purer white, as the cure advances. The process of granulation now proceeds, until the whole cavity of the wound be filled with the newly generated substance. A thin blue pellicle is then observed at the edge, which increases in breadth, and proceeding from the circumference to the centre, gradually completes the covering of the wound. During this period, the sensibility of the wounded part decreases, and the heat and painful distention disappear as the inflammation subsides. The newly formed cellular tissue acquires a contractile power, by which the wound is curtailed in its dimensions, and the divided surfaces are brought closer together, the bond of union putting on finally a fibrous appearance and consistency. Lastly, the new-formed skin, from being of a blue colour, delicate in its texture, and highly vascular, becomes changed into a dense, firm, and almost insensible substance, contracting at the same time its dimensions still farther. With this concludes the healthy and natural process of cure by the second intention, which, it may be observed, admits of division into three stages,—those, viz., of inflammation, usually in large wounds accompanied by general sympathetic fever, and lasting from three to six days; suppuration, the duration of which is irregular; and cicatrization, by which the healing of the wound is at length fully accomplished.

A mild degree of inflammation necessarily, as we have seen, accompanies the process of granulation and suppuration; but should this inflammatory action run to excess, or become deficient, the cure is alike impeded. Hence we have wounds which are prevented from healing by excess of action, and wounds whose cure is impeded by defect of action; or, as every wound secreting matter may be considered as an ulcer, we have what are termed irritable and indolent ulcers. The irritable ulcer is attended with acute pain. Its surface is sometimes whitish or ash-coloured, but oftener of a brownish-red. There are no distinct granulations, the margin is abrupt and irregular, and the discharge is thin and serous, often tinged with blood, and frequently so acrid as to excoriate the neighbouring parts. Irritable ulcers occur in subjects whose powers of life have been too highly fostered, and in animals of a delicate and suscep-

tible habit of body. They are also frequently the effect of improper treatment, such as the application of substances too strongly stimulant, the use of undue pressure of straps or bandages, or want of cleanliness. The indolent ulcer, more rare in animals than the former, is distinguished by its thick, smooth, and callous edges, which cause the sore to wear an appearance of great depth. Its surface is smooth, glistening, and destitute of distinct granulations, varying in colour, but generally dark grey or brownish. The discharge is viscid, and usually adheres tenaciously to the surface of the sore. It is often accompanied by a considerable degree of swelling. Neither of these ulcers shows any tendency to cicatrize, until the nature of its action undergoes the necessary change into what constitutes the condition of the simple healthy ulcer, such as has already been described while detailing the process of cure by the second intention. Ulcers of long standing are apt to assume the indolent form, and in this state are found to be of very tedious and difficult cure. We should also notice, that certain disordered conditions of the system tend to delay the healing of wounds. These will, of course, require to be watched for and obviated where possible. The state of the digestive organs, in particular, will often demand a careful attention.

Wounds receive their most common and appropriate classification from the different manner in which they have been produced. We have thus, first, incised wounds, or such as have been caused by instruments having a sharp edge or point; secondly, contused wounds, or such as owe their origin to contact with bodies which act only by their mass, or by the swiftness of their motion, or, if at rest, by the resistance which they offer to the motions of the animal; and, thirdly, lacerated wounds, where the tissues of the body are subjected to too high a degree of tension, to which they yield, and are forcibly torn asunder.

Incised Wounds.—An incised wound is one of the most common accidents to which the lower animals are exposed, and presents itself in a considerable variety of forms. These will admit of being reduced to three principal divisions, first, the simple incised wound, which is susceptible of cure by the first intention; secondly, the suppurative wound, which can be healed only by the process of granulation and cicatrization; and, thirdly, the punctured wound, which differs from the others by its breadth being small in proportion to its depth, and which admits of cure sometimes by the first, and sometimes by the second intention.

Simple Incised Wounds.—The great object, in all cases of simple incised wounds, ought to be to attain an union by adhesion. Some veterinary surgeons tell us, that, in the lower animals, and especially in the horse, it is impossible to achieve a cure by the first intention. They would have spoken more correctly, had they contented themselves with maintaining that such a cure was often a matter of difficulty. Daily experience shows instances of the wound attending bloodletting being united without the formation of matter; and Blaine, with every other veterinarian of eminence, admits the possibility of thus healing far more extensive injuries. The experiments of Duhamel and Hunter show even that portions may be entirely removed from one part of the animal system to another, and yet perfect adhesion be obtained. Yet it must be allowed, that a considerable obstacle to the success of this process of cure is found in the strong tendency to inflammatory action which seems to characterise the horse; and a still greater obstacle in the restlessness of the animal, and the difficulty of subjecting him to due control. But the proportion of successful cases has been too great, where the immediate union has been judiciously aimed at, for the practice to be allowed to fall into disuse; and the attempt may always be attended with this satisfactory assurance, that, even in cases of failure, matters are placed in no worse condition than before, as the cure by the second intention still remains open to us, and what would otherwise have been our first resource may be accomplished still with the same ease as formerly, while the chance of doing better has not been neglected. No wounds can be said to be capable of union by the first intention, excepting such as are recent, and whose margins can be brought into close approximation. The first care, in dressing a wound of this description, ought to be directed towards ascertaining its extent and depth, and the precise nature of the parts involved, by gently separating its sides, washing away the blood by which it is covered, and removing all foreign substances, such as sand, &c., should any be present. The use of the probe may sometimes be necessary, but should be always sparingly applied. The two sides of the division must then be brought into contact, and so carefully retained. For this purpose, in very slight cases, where the injury extends only to the skin, or to the tissues immediately subjacent, the use of adhesive plasters, either alone or aided by the uniting bandage, may be sufficient; and, in such cases, they ought to be preferred; but it will be generally requisite, in considerable wounds, that one or more sutures or stitches should be employed. What is termed the interrupted suture is that usually resorted to, and is performed by means of curved needles, armed with silk, common thread, or fine tape. The needle should be passed from without inwards, at some distance from the margin, and down to near the bottom of the wound, and the one lip being thus penetrated, it must be carried through from within outwards. The sides of the wound must then be brought together, when the ligature may be tied, and its ends cut away. If the wound be extensive, more than one stich will be required, but they should

seldom be nearer each other than an inch. The suture generally ulcerates out about the third or fourth day. Sutures ought not to be applied where the wound is of great depth, or where they would be required to traverse the substance of a muscle, as, in such cases, they cannot be fixed with sufficient firmness, and would besides be a source of great and constant irritation to the contractile fibre. Where the suture has been applied, the use of strips of adhesive plaster, made of diachylon, and spread upon leather or strong cloth, will be advantageous in affording support to the stitches, while they remain attached, and in supplying their place should they have ulcerated out, or been removed on account of their exciting too high a degree of action, to which they sometimes give rise. In order to fix the plasters, the sides of the wound should be shaved or closely shorn, and the strips applied of sufficient length to pass beyond the reach of the exuding moisture, a small space being left between each, corresponding to the place occupied by the ligatures, by which means a free egress will be allowed to whatever matter may proceed from the wound,—a point which ought always to be attended to, whether the strips be used along with the suture or alone. The whole should be covered by a proper light bandage so as to exclude completely the contact of the air.

The application of bandages is a subject well worthy the attention of the veterinary student, as much may be accomplished by their aid in the cure of wounds. Indeed, in favourable situations, they prove often sufficient of themselves to maintain the divided parts in due approximation, so as to set aside the necessity of having recourse to either stitches or plasters, with which, especially the former, it should always be the object of the dresser to dispense, where possible; and that more particularly in examples where there is reason to dread an excess of high irritative or inflammatory action, which such applications have naturally a tendency to provoke or increase, though not, by any means, in an equal degree. Bandages for the purpose of promoting union can be conveniently applied in most wounds of the extremities, and sometimes in those of the head and trunk, while in injuries of the haunches, the buttocks, the shoulders, the breast, the stifle, the flanks, &c., they are of difficult application, and can only be employed as a covering to the part, without at all conducing to the union of the wound by keeping its sides in contact, which must be left to be accomplished by the other means described. The form of the uniting bandage necessarily varies according to the direction of the wound, whether it be longitudinal, transverse, or oblique. When it is desired to draw together the margins of a wound running parallel to the long axis of the limb, the bandage is composed of a single piece of cloth, of a length and breadth proportioned to the extent of surface to be covered. In the middle of this a longitudinal slit of two or three inches in length should be made. The bandage must then be rolled up at both ends, and the slit being applied over the wound, one of the rolled ends should be passed round the limb, and through the slit, when, by pulling the ends, the whole cut surfaces are approximated; and by passing the roller once or twice round the limb, and securing its extremities, the parts are retained and supported in the proper situation. Before applying the bandage, a light soft pledget, thinly smeared with simple ointment, should be laid over the wound, and a compress placed at a little distance on each side. These compresses will receive the principal part of the pressure from the bandage, and will serve to direct it so as to push together the parts at the bottom of the wound. The bandaging of wounds whose direction is transverse or oblique to that of the limb becomes a process of greater difficulty; and we fear that its complicated aspect will be found sufficient to deter many from the trouble of attempting it. But as there may be cases in which the anxious proprietor of a valuable animal may rightly consider, that scarcely any degree of labour and attention can be ill-bestowed in preserving its soundness and handsome appearance, we subjoin the following directions. For the transverse or oblique wound, two compresses and two rolled bandages are required. One of the compresses should be formed of a piece of cotton or linen cloth, as broad as the wound is long, and folded to a convenient thickness, but having one of its extremities left free, which should be divided into several slips. This should be applied above the superior margin of the wound, in a line parallel to its direction, and fixed there by several turns of one of the rolled bandages, which should be continued down to the edge of the division. The other compress is to be formed in the same way, with the exception, that instead of the free extremity being divided into slips, it should be perforated by a number of holes corresponding to the strips of the upper one. This compress must be applied below the lower lip of the wound, and secured there by several turns of the second roller. A soft pledget, thinly covered with some simple ointment, such as the common or Turner's cerate, is then to be laid over the wound, and the strips of the upper compress being passed through the openings in the lower one, the two ends are to be pulled in opposite directions, by which means the whole divided surfaces will be brought into exact contiguity. The ends of the compresses should then be laid flat along the limb, and held by an assistant until they are fixed by continuing the turns of the rollers, between which they should be several times folded for the sake of greater security. Lastly, the ends of the rollers are to be fastened by pins or by a few stitches at the lower part of that division of the limb which has suffered the injury. The uniting bandage should be applied sufficiently tight to insure its

retaining its situation, but not so as to cause any considerable degree of constriction to the limb.

The proper method of removing the dressings is a matter scarcely less worthy of attention than their first application. It will seldom be necessary to attempt their removal before the second or, more frequently, the third day after the injury. Care must now be taken not to expose the animal to unnecessary torment, or the still imperfect cicatrix to risk of damage, by hasty or violent handling. Let the dressings be softened by tepid water where they adhere through the hardening of effused blood or matter; and where plasters have been applied, they should be removed by raising their extremities, and pulling them from each side towards the line of the wound, so as to avoid all danger of reopening its cavity. Long exposure and much handling of the wound should be avoided, and the probe must be sparingly used, if used at all, which will seldom be necessary. Where stitches have been employed, they should be divided and removed, if they have not already ulcerated out; and the precaution of applying fresh strips of plaster before detaching the stitches, may often be adopted with propriety, as a means of insuring constant support, where it is feared that the cicatrix is still destitute of sufficient solidity to maintain its union. The injured parts should be lightly washed before the application of fresh dressings, as want of cleanliness will often prove a serious obstacle to the cure. The intervals which ought to elapse between the subsequent dressings must be regulated by circumstances. It is seldom that they can be required oftener than once in the twenty-four hours; and where the process of union has gone on successfully, even this need not be long continued, as the cicatrix will speedily acquire that degree of consistence which renders it independent of extraneous support; at which period the cure of the wound may be considered as complete. The success of the plan which has been detailed is not likely, in moderately favourable instances, to disappoint our wishes; but if, after exposing it to a fair trial, it be found that the wound shows no decided tendency to unite, it must now be healed by the slower process of suppuration and granulation.

Suppurative Wounds.—Wherever the margins of a wound cannot be brought into close contact, and its surface covered by sound integuments, there can be no hope of a cure excepting through the medium of the suppurative process. A wound may be in this condition either through a loss of substance which may characterize the injury, through neglect in the first treatment, or through such conditions of the general system, or of the parts injured, as are known to be unfavourable to the adhesive union. But we shall, perhaps, best exemplify the method of treatment which seems to recommend itself most to notice as founded on right principles, by following out a case in which it may be supposed that the union by the first intention has been attempted, and has not been attended with success.—If, as frequently occurs, the union be impeded by an excess of what may be termed simple, healthy, inflammatory action, evinced by considerable swelling of the parts adjoining the wound, and by the prominent, firm, and vividly-red appearance of the granulations on its surface, this will ordinarily be best allayed by the use of warm fomentations or poultices; while, in some cases, it may be necessary to have recourse to general or local bloodletting, and a restricted diet; and, on the action being subdued to its proper pitch, dressings with simple ointment, repeated daily, will serve to complete the cure; or, where the margins admit of being approximated to a certain extent, though not wholly, the adhesive plasters may be used.—But if the excessive action be of that kind which leads to the constituting of what we have described as the irritable ulcer, a more serious obstacle will have been placed in our way, demanding a more patient perseverance in the treatment. Our object must, of course, be to reduce the morbid state of excitement in the parts to the just standard; and to effect this, sometimes cold and sometimes warm applications have been recommended. The warm applications are likely to suit the greater number of cases; and they may consist of fomentations with decoctions of chamomile flowers or poppy heads, and emollient poultices. The fomentations should be repeated at least twice daily, morning and evening, for half an hour at a time, and the sore should be covered during the intervals with warm poultices, frequently renewed, composed of sifted oatmeal, turnips boiled and bruised, or linseed meal, with the addition of a little lard or oil. When the irritability lessens, and healthy granulations begin to cover the sore, a piece of soft dry lint may be placed between it and the poultice; and as soon as the ulcer wears that appearance which has been described as marking the progress of healthy granulation and cicatrization, the poultices should be discontinued altogether, as the action of the part must now be considered as proceeding within due bounds, and the farther use of emollients would be apt to induce the opposite condition of deficiency of excitement. The farther treatment will consist of the simple dressings formerly recommended.—Should the action, on the other hand, be deficient, we shall have presented to us those appearances of the injured part which have been described as constituting the indolent ulcer; or, should the action have suffered diminution in a small degree only, we shall find the sore presenting pale and flabby granulations, endowed with little heat and sensibility, and having little tendency to cicatrize. To remedy either of these conditions, we must now have recourse to stimulating applications, such as the common resinous ointment, &c., or lotions composed of camphorated spirits, or of some of the warm tinctures. The repeated moderate ap-

plication of lunar caustic will often be found highly useful in this kind of sore; and washes composed of white or blue vitriol in solution may sometimes advantageously supply the place of the spirituous lotions. But never, even in this condition of a wounded part, should the sore be crammed with powdered blue vitriol, verdigris, or similar substances, as we find sometimes recommended. Ever studious to avoid extremes, the stimulus should be applied so that its effects can be wisely regulated, and stopped as soon as the appearance of the surface indicates that we have attained that due medium of action which shows that the wound is of itself tending to a cure, when we must again have recourse to simple dressings. As the indolent condition of wounds is one which is not commonly observed in the sound horse, but seems rather to be the attendant on injuries occurring to such animals as are of a sickly habit, as are tainted by glanders, or whose constitution has been enfeebled by improper food, or by any considerable evacuation, regard must be had to the state of the general health of every individual under treatment, and such remedies applied as each particular case may demand or admit. In all conditions of wounds, we repeat, the use of bandages, modified as may be necessary, is advantageous, either with the view of serving as active agents in promoting the cure, or merely as coverings, excluding the contact of the air, which is always observed to cause a state of irritation and dryness in sores exposed to its effects, such as is extremely unfavourable to the establishment of a healthy suppuration. In suppurating wounds, with excessive action, they should be applied loosely, as the parts would then suffer by constriction. In such as show deficient action, a moderate degree of tightness is advisable, and often of great service. In the healthy suppurating wound, the bandages should not exercise greater pressure than is sufficient to maintain them in their place.

Punctured wounds are generally produced by the animal coming into contact with the prong of the common stable-fork, a nail, or a sharpened stake; but of course they may be the effect of a thrust with any pointed weapon. A simple punctured wound which has not injured any important internal organ, or penetrated any of the cavities of the body, is usually of easy cure. Much, however, depends upon the nature of the instrument by which the lesion has been effected. If it have been caused by a narrow weapon, having a very sharp point and polished sides, we may look with some confidence towards obtaining a speedy union by the first intention; but should it have been the consequence of a weapon whose obtuse point and ragged edges do not permit it to penetrate without the exercise of considerable violence, the cure will be likely to be more tedious and more difficult, and will usually be concluded only through the medium of the suppurative process. One of the first points which ought to be ascertained, before proceeding to dress a punctured wound, is the precise direction of the injury; and whether or not its orifice be at its lower or most depending part. It should also be our endeavour to discover whether any of the membranous fasciæ, or sheaths by which the muscles are surrounded, have been penetrated, as such a lesion often gives rise to high inflammatory symptoms, requiring special interference in the after treatment. But, whatever be its precise nature, we believe it will always be prudent to attempt, in the first place, a cure by the adhesive union. Some veterinary surgeons, of deserved eminence, recommend that, in every case of this description, especially where the injury is of considerable depth, the external opening should be enlarged, so as to give the wound a conical or funnel shape, thus affording free issue to any discharge of blood and serum, and preventing constriction of the parts on the occurrence of the usual inflammatory swelling; the wound being encouraged to go on to suppuration. This, however, is a measure which it would perhaps be wiser to delay, until it may be called for by the actual approach of the circumstances which it is intended to obviate, but which may chance never to occur. It will be better, therefore, to commence our treatment by the application of adhesive plaster, if there be any retraction of the edges of the orifice; or, where the wound is close, a piece of soft lint should be secured over it, by a soft compress and bandage. If the wound be severe, the animal may be bled, and a laxative dose administered, as precautionary measures. About the third day, or sooner, if the horse appear feverish and restless, the injury should be examined. If every thing have proceeded favourably, the wound will be found to have adhered, and a little further time and ordinary care will be all that is necessary to establish the cure. But, if the parts inflame, and the animal winces much under pressure, showing the presence of severe pain, it will be proper to have recourse to warm emollient poultices, repeated every three or four hours, and to fomentations with warm water, or with a hot solution of sugar of lead, which should be employed each time the poultice is renewed. Should the wound go on to suppuration, it is to be expected, in cases where the injury has not been inflicted in a direction from below upwards, or where the orifice does not form the most depending part, that we shall have collections of matter, which in such cases cannot attain free egress, and which may extend under the membranous sheaths before alluded to, giving rise to the formation of troublesome sinuses. To prevent this, as soon as the actual presence of matter is detected, it should be evacuated by a free incision. The poultices are then to be continued till the action appears to confine itself steadily to the healthy standard, when the cure may generally be completed with the aid of simple dressings.

Contused Wounds.—Wounds of this description are produced by violent blows with a blunt instrument; or, more frequently, by the horse, while in swift motion, being brought into contact with an obtuse object. The contused wound is generally of an irregular form, its margins appearing unequal and ragged, and not unfrequently presenting flaps partially torn away from the neighbouring parts by a degree of force which leaves them bruised and feelingless, and sets aside all hope of a cure by adhesion. This kind of wound usually leads to the development of high inflammatory action, during the suppuration consequent upon which, such portions of the bruised parts as have been too much injured to retain their vitality, are thrown off, leaving a vacuity which is to be covered by the formation of granulations and a cicatrix. In slight cases, however, it is possible that the lesion may not have gone to so great an extent, and that there may still be some prospect of a complete, or, at least, a partial union by the first intention. In any case, it will be proper to bring the divided surfaces into as close contact as possible, placing over them the usual simple dressings, lint, compress, and bandage. It will rarely be advisable to have recourse to the suture, as it would be apt to provoke that intense degree of inflammation, which, in such wounds, we have especially to fear; but strips of adhesive plaster may often be advantageously applied. Acting thus, even if we do not succeed in obtaining immediate union, we are at least likely to render more moderate the after effects, and to hasten a cure. As soon as any active inflammation shows itself, we must at once take off all pressure of plasters, &c., from the wound, and commence the use of poultices; the rest of the treatment being to be conducted on the plan recommended for suppurative wounds. In this class of wounds we must be especially prepared to expect the occasional appearance of symptomatic fever, which must be met as usual by bloodletting, laxatives, and restricted diet.

Gunshot wounds may with propriety be ranked in the class of contused wounds; but as animals employed in the affairs of peace are rarely subjected to this kind of injury, and as a correct knowledge of the appropriate treatment can only be acquired by those who seek to obtain it through experience in the midst of campaigns, it will be proper to abstain from encroaching here upon what must be held to be the peculiar province of the army veterinary surgeon.

Lacerated wounds may be caused by a nail, or other pointed but blunt-edged substance, penetrating the flesh of an animal while in motion, and tearing itself a passage outwards while the motion continues; or they may be occasioned by the bite of another animal, &c. The edges of a lacerated wound are unequal, and a flap torn and raised from the adjoining parts is a frequent accompaniment. The rules for treating this kind of injury do not differ from those applicable to contused wounds, and need not, therefore, be longer dwelt upon; and we may simply remark, that our chance of obtaining an union by the first intention is greater in the lacerated than in the contused wound. [*Abridged from an Essay by Dr. Wilson of Kelso in the Quarterly Journal of Agriculture.*]

Wounds of joints, particularly of large ones, are generally attended by a high degree of inflammatory action, symptomatic fever, and excruciating pain; and as they are usually small and of the punctured kind, inflicted by a thorn or by a sharp stable-fork, they may most readily be closed by the application of the actual cautery; and when they make such an opening as to permit an escape of the synovia, or yellowish, transparent, slippery secretion which lubricates the joint, they ought to be closed with all possible speed.—Wounds of the abdomen, inflicted by the horns of cattle or by sharp pieces of wood in fences, are sometimes so severe as to let out or even lacerate some part of the intestines. If the bowels merely protrude without being injured, a cure may often or even generally be effected by promptly throwing the patient on his back, replacing the bowels, stitching up the wound, and applying a pledget of tow and a wide bandage; but if the bowels have suffered any laceration or contusion, all hope of cure may be foregone, except possibly by means of skilful treatment on the part of a very judicious and experienced veterinarian.—Wounds of considerable nerves are sometimes followed by tetanus or by some other very severe forms of distress; and partial divisions of nerves are always so much worse than complete divisions, that the symptoms which follow them may usually be alleviated by laying bare the nerve at the injured part, and completely dividing it.—See the articles Inflamed Veins, Cut, Bruise, Fistula, Broken Knees, Poll Evil, Ulcer, Abscess, Quittor, Overreach, Strain, Tumour, Fracture, Purulent Matter, Poultice, and Fomentation.

WOUNDWORT. See Golden-Rod, Kidney-Vetch, and Hedge-Nettle.

WRACKGRASS, — botanically *Zostera*. An indigenous, monocotyledonous, aquatic, economical plant of the order Fluviales. It constitutes a genus of itself, and is specifically called the marine; and it takes its popular name of wrack-grass from its general resemblance to sea-wrack, and its scientific name of zostera from the riband-like form of its leaves. It grows on the sea-shore, and blooms in August and September, and is so like some kinds of algæ that it might almost be mistaken for them. It loves a sandy soil, and may be propagated from seeds.

WREN. A group of small British birds, of the warbler family of Passerinæ.

The common wren, Kitty wren, or Jenny wren, *Troglodytes vulgaris*, is a very diminutive and very well known bird; and inhabits all parts of

Europe, and is able to maintain itself in cold countries throughout the winter. Its total length is rather less than four inches; its general plumage has a brown colour, transversely striated with black; its throat and the edge of its wing contain some white; and its tail is short and perked up. It builds in the corners of outhouses, in stacks of wood, or in holes of walls. Its nest is almost oval, and consists chiefly of moss lined with feathers. The eggs amount to from seven to ten, and are very small, and have a white colour, marked with a few red spots; and two broods are produced in the season. The common wren, besides being readily distinguishable by its diminutive size and its perked up tail, may be easily known by its somewhat peculiar habits; for though it flits up and down among the branches of a hedge, it rarely runs up and around the trunk of a tree like the creeper, *Certhia familiaris*, nor does it usually get so high up as the tits, *Pari*, preferring the root-branches and those which hang over water, where gnats and other night-moving aquatic insects lodge in the day-time, overshadowed from the light. On these it banquets both in summer and in winter; and it may frequently be seen about hedges, barns, stables, farm-yards, walls, and piles of wood. It is said to eat small berries, such as those of the elder, and small seeds; but so long as it can find a gnat or a small beetle, it will rarely touch them. From its being a prolific breeder, and its young, though so small, being voracious eaters, the wren must tend greatly to keep down the numbers of several sorts of destructive insects, particularly in gardens and orchards.

The golden-crested wren, *Regulus cristatus*, is the smallest bird in Europe, and is not uncommon in many parts of Britain. It measures only $3\frac{1}{2}$ inches in length, including the tail, which is $1\frac{1}{4}$ inch. It cannot be mistaken for any other bird, being of a greenish-yellow colour, while the common wren is rusty brown; and though the chiff-chaff and the hay-bird are yellowish-green, neither of these has the golden yellow on the crown of the head, which at once distinguishes this pretty bird. A less conspicuous distinction is formed by two white bars, similar to those of the chaffinch, across the wings, caused by the greenish feathers of the wing-coverts being tipt with white. The gold-crested wren seems to delight most in evergreen shrubs and trees, particularly the spruce-fir and cedar; and it never fails to make daily excursions along the hedges in the vicinity, flitting about through the thickest branches, and uttering its small tinkling chirp of *tee, tee, teehy*, at every change of its position. It is not in the least afraid of being approached, most probably owing to its being very near-sighted—a peculiarity of vision no doubt designed by Providence for enabling it the more readily to distinguish the minute insects on which it exclusively feeds. It may, indeed, be easily approached near enough to see its colours distinctly, or even to catch it with a fishing-rod tipt with bird-lime. In consequence of its minute size, it is rather impatient of cold; yet it does not appear to migrate, except perhaps very partially, even in Scotland, where it remains during the severest winters—one or more families of the tiny little creatures keeping each other warm in cold frosty nights, by huddling together as closely as possible under the thickest branches of a spruce or silver fir, or of a furze or ivy bush. They are said, however, to migrate from Shetland and the Orkneys. It is not a little singular, that though they stand hard frost out of doors, yet exposure to frost kills them when tame, as if the protection of a house rendered them less hardy. They are greatly more abundant in Scotland than in England; and in some districts where fir-plantations have been made, they have multiplied prodigiously within the last half-century. No farmer will be apt to accuse them of injuring his crops; but when a gardener, unacquainted with their habits and food, sees them flitting about among his espaliers, his wall-trees, or his rose-bushes, he may think they are busy eating the blossom-buds, as some other birds are well known to do, while they are really doing him essential benefit, by picking up every straggling aphis and bud-weevil which they can find.

The wood-wren, *Silvia sibilatrix*, and the willow-wren or hay-bird, *Silvia fitis*, have a greenish-yellow colour, darkest on the back and wings, and lightest on the breast and belly; and are much brighter in their hues when young than when of full age. The former is $5\frac{1}{2}$ inches long; and the latter is $5\frac{1}{4}$ inches, and has such an elegant form and such pretty colouring as to be popularly designated in Scotland "the busket leddy." Both are birds of passage, arriving in Britain late in April or early in May, and announcing their arrival by their pleasing notes,—those of the wood-wren being shrill, short, and hurried, accompanied by a peculiar shaking of the wings,—those of the hay-bird consisting of a rather continuous, soft, plaintive warble. The hay-bird uniformly lines its snug little nest with a profusion of loose feathers; the wood-wren, on the contrary, never uses feathers, but lines neatly with hair. The wood-wren is most frequently found among tall trees, and may occasionally be seen among "hedge-row elms," as Milton calls them, and among other tall trees in hedges; but the hay-bird delights in small copsewood, and in what may well be termed copsewood hedges, so common in England,—yet is no less common in shrubberies and gardens, often building in the strawberry beds,—for though it does not seem to care about human neighbourhoods, being found in the most wild and solitary places, it is by no means shy, and will not only allow itself to be approached almost as near as the gold-crest, but will even make its way into greenhouses, and,

when the windows are left open, into rooms where plants are kept in pots. The chief food of both species consists of small flies or small caterpillars, such as roll up leaves of trees and shrubs, and particularly the rose-leaf roller or "worm i' the bud," together with all the most destructive species of aphides. Where the birds are plentiful, therefore, they may prove of no little service to the farmer in thinning, on their first appearance, wheat flies, the blue dolphins, the hop-flies, and the turnip or the pea plant-lice. Yet farmers who are unacquainted with their exclusively feeding on insects, are but too apt to class them without distinction, among inimical birds, as if all birds fed alike, and were ready and eager to devour whatever crop they might find cultivated in the fields. Gardeners are even more prejudiced, particularly against the hay-bird, which in some parts of England, they opprobriously call the cherry-chopper, from a notion that it devours cherries. That it is very frequently found on cherry-trees, is most true; and, if watched, it may be seen busily picking among the fruit; yet it really does not touch the cherries, but is in pursuit of the destructive cherry aphis, a species which is particularly injurious, and which commences its ravages on the cherry-leaves about the end of April, exactly at the time when the hay-bird arrives, as if Providence had ordered the insects to multiply at this season to supply the hay-birds with food. No more does the hay-bird ever taste one of the strawberries in the bed where it may have built its nest, or the pease in the adjoining kitchen-garden, its bill indeed being too slender to bruise pease, and its gullet too narrow to swallow them unbruised, even were it inclined to attack them. White of Selbourne, therefore, did not manifest his usual accuracy of observation, when he said, that the willow-wrens, meaning the hay-bird and chiff-chaff, are horrid pests in a garden, destroying the pease, cherries, and currants,—an opinion which he no doubt adopted without due examination from the gardeners. Had he ever procured tame ones, and tried them, when very hungry, with cherries, currants, strawberries, and with green pease, both raw and boiled, he would have soon had ocular demonstration that they would rather starve than eat fruit or seeds. So far, then, from persecuting and killing these birds, as gardeners so frequently do, every means should be taken to encourage them to breed by protecting their nests.

WRIGHTIA. A genus of ornamental, exotic, ligneous plants, of the dog's-bane tribe. Two species are noticed in the article NERIUM; and several other species, all evergreen shrubs, have been introduced to British collections from India and Australia.

WRYNECK,—scientifically *Yunx Torquilla*. A British bird of passage, belonging to the woodpecker group of climbers. It arrives in Britain in the first or second week of April and departs toward the end of August or in the early part of September. It frequents orchards, coppices, plantations, tree-rows, and tall hedges; and it has the same habits as the woodpeckers, yet seeks its food chiefly on the ground, and seldom climbs. It feeds on caterpillars, ants, and other larvæ and insects; and may often be seen near ant-hills, consuming large quantities of these pests of pastures. It takes its name of wryneck from a habit of making curving motions with its head and neck somewhat similar to the undulatory movements of a snake; and, for the same reason, it is called in some parts of England the snake-bird. Its total length is 7 inches; its bill is straight, pointed, and almost cylindrical; its tongue is extensible, and has the same kind of organic mechanism as that of the woodpeckers, but wants the spines; its plumage, in the upper surfaces of the body, has a brown colour, beautifully vermiculated with small blackish waves, and marked longitudinally with black and fawn-coloured streaks—and, in the under surface, is whitish transversely streaked with black; and its tail quills are similar to those of many other birds. The wryneck does not build a nest, but deposits its eggs on the powdery fragments of decayed wood within the hole of a tree. The eggs amount to from 6 to 10, and are white, smooth, and shining, and measure each $9\frac{1}{2}$ lines in length and 7 in breadth.

WULFENIA. A beautiful hardy annual plant, of the figwort tribe. It constitutes a genus of itself; and takes its specific name from its native country, Carinthia; and was introduced to Britain in 1817. It has a height of about 20 inches; and carries blue flowers in July and August; and it will thrive in any common soil.

WURMBEA. A genus of bulbous-rooted, Cape-of-Good-Hope plants, of the melanthium family. Four species, varying in height from 6 to 15 inches, and all loving a somewhat light soil and propagable from offsets, have been introduced to the gardens of Britain. Three of them have white flowers, and the other has purple flowers; all bloom in May and June; and they may be classed in some instances as curious, and in others as ornamental.

WYCH ELM. See ELM.

X

XANTHIUM. See Burweed.

XANTHOCHYMUS. A genus of yellow-flowered, evergreen, tropical, small fruit-trees, of the guttiferous order. Seven species have been introduced to British hothouse collections from India, and one from Guinea; and all very distinctly possess the well-defined peculiar characters of the order to which they belong, and at the same time produce a fruit sufficiently resembling that of *Garcinia mangostana* to win for them, throughout some parts of the East, the popular name of yellow mangosteens. Their generic botanical name of xanthochymus alludes also to one chief character of their fruit, and signifies "yellow juice." Their fruit is a large rounded or oval berry, similar in appearance to a mango, but flatter, smooth, bright yellow, and in some cases about the size of an ordinary apple; and it contains a copious yellow pulp, of similar appearance to liquid gamboge, and has a pleasant acidulous taste. All the species love a rich soil, and require to be raised from seeds, and refuse to fruit unless treated as analogously as possible to the circumstances of their native regions. The painter's species, *X. pictorius*, was introduced to Britain in 1796, upwards of 20 years prior to the introduction of any of the other species; and the following brief notice, written in 1833, of a freely fruiting small plant of it in M. Boursalt's collection in Paris, may be interesting:—"This plant grows in a round box, 18 inches in diameter, plunged in a bark bed in the stove. The soil which agrees with it is pure heath mould, or rather heath mould mixed with common garden soil or turfy loam. The plant is 5 or 6 feet in height, and is devoid of branches for 2 or 3 feet up; the branches then commence, and form a rounded head, of no very great circumference. It is not upon a trellis. The stem at the bottom is not so thick as one's wrist. The plant bears fruit as large as fine green gage plums (*Belles Reines Claudes*), either single or more frequently united in twos, threes, or fours, and with flavescent flowers. It has borne fruit for several years, and receives no particular treatment. It is necessary that it be kept in a hot and moist atmosphere, in a good hothouse; but, above all, the roots of the plant should be constantly kept very warm. If the heat of the tan be weakened, or if the plant be kept any time out of the tan, it is immediately perceivable by the foliage. The fruit is delicious, and always cool, although gathered in a very warm atmosphere, and eaten immediately."

XANTHORIZA. An ornamental, hardy, North-American, evergreen shrub, of the ranunculus family. It constitutes a genus of itself; and is specifically called *apiifolia*, or the parsley-leaved. It was introduced to Britain upwards of 80 years ago. It has a height of about 3 feet, and blooms from February till April; and it loves a soil of sandy peat, and is propagated from suckers.

XANTHORRHŒA. A genus of curious, white-flowered, spring-blooming, evergreen, Australian plants, of the asphodel family. Six or seven species, varying in height from 2 to 5 feet, some shrubby, others herbaceous, and all loving a soil of sandy peat and propagable from suckers, have been introduced to the gardens of Britain. The name xanthorrhœa signifies "a yellow flowing," and alludes to the exudation of a gummy fluid.

XANTHOXYLUM. See Toothache-Tree.

XERANTHEMUM. A genus of hardy, ornamental, exotic, annual plants, belonging to the thistle division of the composite order. The name signifies 'dry flower,' and alludes to the durability of the flower, which is of the kind popularly called eternal or everlasting. Three species, comprising a number of varieties, principally with either white or purple flowers, and all naturally blooming in July and August, have been introduced to Britain from the South of Europe and the Levant. The stem of the earliest introduced and best known species—which comprises varieties with both white and purple flowers, and with both single and double ones—is slender, branched, angular, furrowed, downy, and about two feet high; the branches usually amount to four or five, and are leafy below and bare above, but carry the flowers on their extremity; the leaves are spear-shaped and hoary,—those of the stem sitting close to it yet spreading out from it, and measuring $1\frac{1}{2}$ inch in length and $\frac{3}{4}$ of an inch in breadth,—and those of the branches similar but smaller; and the flowers are solitary, and comprise each a number of florets in one common, scaly, silvery-coloured calyx, and have such a consistence that, if gathered when perfectly dry and kept from the air, they will retain their beauty during a great length of time.

XEROPHYLLUM. A genus of ornamental, exotic, evergreen herbs, of the melanthium family. The name xerophyllum signifies "dry leaf," and is descriptive. Three hardy species, the grassy, the tough-leaved, and the asphodel-like, all about 18 or 24 inches high, white-flowered, blooming in May and June, loving a soil of sandy peat, and propagable by radical division, have been introduced to Britain from North America; and a hothouse medicinal species, *X.*

sabadilla, mistaken by some botanists for a veratrum or a vellozia, about 3 feet high, white-flowered, loving a soil of peaty loam, and propagable from cuttings, has been introduced from Vera Cruz.

XEROTES. A genus of ornamental, diœcious, evergreen, Australian herbs, of the rush tribe. The name alludes to the aridity of the herbage. Upwards of a dozen species, varying in height from 10 to 40 inches, have been introduced to the horticultural collections of Britain; and all love a soil of rich mould, and are propagable by radical division. Some have the female flowers in heads, and the leaves at the top entire; others have all the flowers in racemes, or the female ones in spikes and the male ones in panicles; and others are stemless, and have the branches opposite or whorled, the leaves at the top denticulate, the flowers spiked or panicled, the male ones sessile and imbricated, and the capsules smooth.

XIMENESIA. A genus of ornamental, yellow-flowered, herbaceous, Mexican plants, of the sunflower division of the composite order. Two annual, one biennial, and two evergreen perennial species, all about 2 or 3 feet high, and blooming in the latter part of summer and in autumn, have been introduced to Britain; and the annuals and biennial thrive in any common soil; and the perennials do best in a soil of loamy peat, and, as well as the others, require to be raised from seeds.

XIMENIA. A small genus of ornamental, tropical, evergreen trees, of the olax tribe. The American species, *X. americana*, is a native of the West Indies, and was introduced to the collections of Britain in 1759. Its stem is branched and about 20 feet high; its branches deflect on all sides, and are armed with thorns, and garnished with lanceolate leaves, standing round them without any regular order; its flowers are produced at the ends of the branches, and have a bell-shaped corolla, cut almost to the bottom into three segments which are yellow inside, hairy, and rolled backward; and its fruit are ovate-oblong fleshy drupes, somewhat similar in appearance to plums, and each enclosing a hard nut of the same form. This plant loves a soil of sandy peat, and is propagated from cuttings.—The unarmed species, *X. inermis*, is also West Indian, but is fully twice the height of the preceding, and was not introduced to Britain till 1810, and loves a comparatively rich or somewhat loamy soil.

XIPHIDIUM. A small genus of ornamental, tropical, evergreen herbs, of the hæmodorum tribe. The name alludes to the sword-shaped form of the leaves. Two species, with respectively white and blue flowers, and both about 20 inches high, loving a soil of sandy peat, and propagable by radical division, have been introduced to Britain from the West Indies and Guiana.

XIPHIUM. See Iris.

XYLOBIUM. A small genus of curious, epiphytous, tropical plants, of the orchis family. It is nearly allied to the genus dendrobium at once in name, structure, and habit; for the word xylobium signifies 'to live upon wood,' while the word dendrobium signifies 'to live upon a tree,'—and both are descriptive. Two species, the dirty-flowered and the long-leaved, have been introduced to the orchis-houses of Britain from tropical America. See the articles Orchis and Dendrobium.

XYLOPHAGI. See Bostrichidæ.

XYLOPHYLLA. A genus of ornamental, exotic, evergreen shrubs, of the spurge tribe. The name signifies 'wood-leaf,' and alludes to the rigidity of the foliage. Two species have been introduced to Britain from Siberia, one from India, one from the Bahama Islands, and seven from Jamaica; and all have a height of about 3 feet, and carry yellow and red flowers, and love a soil of sandy peat, and are propagable from cuttings. The Siberian species bear their flowers on the branches, and bloom in July and August, and require little protection; and the other species carry their flowers on the margin of the leaves, and bloom during a longer period than the Siberian ones, and require the heat and protection of the stove.

XYLOPIA. A genus of ornamental and economical evergreen, tropical shrubs and trees, of the custard-apple tribe. Three species, the frutescent, the rough-fruited, and the smooth-fruited —the last naturally about 25 feet high, and the other two about 4 or 5 feet high, and all loving a soil of peaty loam and propagable from cuttings—have been introduced from the West Indies and Guiana to the botanical collections of Britain; and six or seven other species are known. The bark of the silky species is used in its native country for cordage, and is admirably adapted to that purpose; and the wood of the larger kinds is used as timber.

XYLOSTROMA. See Timber.

XYRIS. A genus of ornamental, exotic, evergreen herbaceous plants, of the rush tribe. Eight or nine species have been introduced to the gardens of Britain from Australia and America; and about twenty more are known. One of the introduced species, *X. altissima*, is about 7 or 8 feet high, and the rest vary in height from 6 to 24 inches; one, *X. americana*, has blue flowers, and all the others have yellow flowers; all inhabit bogs,—and the greater number require to be raised from seeds; *X. altissima* blooms in October, and most of the others bloom from June till August.

Y

YACK. See Ox.

YAM,—botanically *Dioscorea.* A genus of exotic, tuberous-rooted, monocotyledonous plants, constituting the type and the main bulk of the natural order Dioscoreæ or Dioscoreaceæ. The characteristics of this order, which readily distinguish its plants from all other endogens, are a large fleshy root, a climbing stem, cordate or angular leaves, and inconspicuous and for the most part greenish or yellowish flowers. About forty species of it have been introduced to Britain; and all these, excepting five or six, belong to the genus dioscorea; and about twenty other species of that genus are known. Two of the dioscoreas in Britain are hardy, one is suited to the greenhouse, and all the others require the heat and protection of the stove; a few have a height of about 3 or 4 feet, and most of the others have a height of from 8 or 10 to 20 or 25 feet; three have divided leaves, four have lobed leaves, two have oblong leaves, and the others have cordate leaves; four or five have whitish or reddish flowers, and most of the others have green or yellowish flowers; one has an ornamental appearance, six or seven are agricultural or culinary, and the rest are interesting only to botanists; a few love a soil of sandy peat or of peaty loam, the rest love a soil of rich mould, and all are propagated by division of the tuberous roots, more or less in the manner of potatoes. All the interesting and useful kinds, unhappily, belong to the stove, and develope their economical value only or chiefly in tropical countries.

The common or cultivated yam, *Dioscorea sativa,* grows wild in the woods of Ceylon and Malabar, and is supposed to have been artificially introduced thence to the West Indies, and is diffused as a cultivated plant over a large portion of the tropical countries of the world, and was introduced as a botanical curiosity from the West Indies to Britain in 1733. Several varieties of it occur wild; and many varieties are in cultivation. The root of one of the most common is as large as a man's leg, of an irregular form, dirty brown on the outside, and white and mealy within; the stems of all are triangular and winged, and either trail on the ground when they have no support, or climb to a comparatively great height, some so high as 20 or 25 feet, when they grow in the immediate vicinity of trees; the leaves are cordate, and have each two ears somewhat like those of arum; and the flowers have a greenish colour, and bloom in August. The roots of this plant constitute one of the most important articles of ordinary food in tropical countries; and are preferred by many persons, whether Indians or Europeans, to potatoes; and they are cooked and used in a variety of ways, both in substance and when ground into a sort of flour, the solid roots being suitable alike for boiling and for roasting, and the flour serving alike for puddings and for bread. Radical cuttings or sets, each containing an eye or bud, are planted in a manner similar to the sets of potatoes; each cutting usually produces 3 or 4 large roots; and in America, the crop is commonly 6 or 8 months in the ground before the roots are taken up for use. In British horticulture, a cutting or set may be planted in a pot of fresh rich mould, the pot plunged in a hotbed of tan, and a little water given till the shoot appears above the surface; and in this way a plant may be obtained of 10 feet or so in height, but without any considerable sized roots.

The prickly-stemmed yam, *Dioscorea aculeata,* is a native of India, and was introduced thence to the hothouses of Britain in 1803. Its roots are esculent and delicate, similar in taste to fine dry choice ones of the common yam, yet somewhat similar in appearance to those of the battatas; its stems naturally attain a height of about 10 or 12 feet; and its leaves are cordate and somewhat similar to those of the common yam.—The wing-stalked yam, *Dioscorea alata,* was introduced from India to Britain in 1739. Its root is much eaten in Malacca and Java; its stems naturally attain a height of about 15 or 16 feet; and its leaves are cordate, and its flowers green.—The bulb-bearing yam, *Dioscorea bulbifera,* is one of the longest known kinds, and was introduced to Britain in 1692; its stems attain a height of 12 or 14 feet; and its flowers are green and bloom in July and August.—The Brazilian yam, *Dioscorea brasiliensis,* was introduced to Britain from Brazil in 1823. Its roots are esculent; its stems rise to the height of about 8 feet; and its leaves are lobed.—The five-leaved yam, *Dioscorea pentaphylla,* is a native of India, and is there called the wild yam, and was introduced thence to Britain in 1768. Its roots are esculent, yet previous to preparation contain much acrimony; its stems attain a height of about 10 feet; and its leaves are divided and quinquefoliate.

YARD. A court. See Farm-Yard.

YARD. A measure. See Measures.

YARD MANURE. See Farm-Yard Manure.

YARD OF LAND. An old provincial superficial measure, of very variable extent, amounting in some counties to 15 acres, in others to twenty, and in others to twenty-four, thirty, or thirty-four.

YARR. See Spurrey.

YARROW. See Milfoil.

YEARLING. A colt, calf, or other young farm animal, which has completed its first year.

YEAST. A peculiar froth or scum, closely allied in chemical composition to gluten, and possessing the property of easily exciting fermentation. It is always generated during the vinous fermentation of vegetable juices and decoctions; and rises to the surface in the condition of a frothy, flocculent, and somewhat viscid substance. The variety of it most commonly in use is collected from the surface of fermenting or fermented malt liquors; and many other varieties are either incidentally obtained from other fermentations or expressly gathered from decoctions made for the very purpose of yielding them. It is insoluble in water and in alcohol; and when exposed to ordinary atmospheric heat and moisture, it soon and gradually putrefies,—when submitted to a moderate heat, considerably above the ordinary atmospheric temperatures, it becomes a dry, hard, slightly cohesive paste, which may be preserved for a long time without undergoing any change,—when heated to redness in close vessels, it is entirely decomposed, and passes into products similar to those which are obtained in the same circumstances from gluten,—and when exposed for a few minutes to the heat of boiling water, it loses its characteristic property of exciting fermentation, yet suffers little apparent change, and eventually reacquires its characteristic property. Is seems to owe its fermentative power to a nitrogenous principle either quite or very nearly identical with gluten; but, in other respects, it has a variable composition, and is much controlled in character by the kind of juice or decoction from which it is obtained, and by the particular circumstances in which it is collected. A specimen of it analysed by Westrumb yielded potash, lime, carbonic acid, acetic acid, malic acid, alcohol, extractive, mucilage, sugar, gluten, and water; and all the kinds of it proper to be used in medicine, or fresh specimens obtained from fermenting beer, probably owe their therapeutic powers entirely to carbonic acid, alcohol, and the bitter extractive of hops. Good beer yeast has a sour vinous odour and a bitter taste, and reddens vegetable blues; and when filtered, the portion of it which remains on the filter is glutinous, and the portion which passes the filter has no power to excite fermentation unless the glutinous matter is restored to it.

"Yeast," says Liebig, "possesses all the characters of a compound of nitrogen in the state of putrefaction and eremacausis. Like wood in a state of eremacausis, it converts the oxygen of the surrounding air into carbonic acid; but it also evolves this gas from its own mass, like bodies in the state of putrefaction. When kept under water, it emits carbonic acid, accompanied by gases of an offensive smell, and is at last converted into a substance resembling old cheese. But when its own putrefaction is completed, it it has no longer the power of inducing fermentation in other bodies. The presence of water is quite necessary for sustaining its properties; for by simple pressure its power to excite fermentation is much diminished, and is completely destroyed by drying. Its action is arrested also by the temperature of boiling water, by alcohol, common salt, an excess of sugar, oxide of mercury, corrosive sublimate, pyroligneous acid, sulphurous acid, nitrate of silver, volatile oils, and in short substances, all of which possess antiseptic properties. The insoluble part of it does not cause fermentation; for when the yeast from wine or beer is carefully washed with water, care being taken that it is always covered with this fluid, the residue does not produce fermentation. Nor does the soluble part of it excite fermentation; for an aqueous infusion of yeast may be mixed with a solution of sugar, and preserved in vessels from which the air is excluded, without either experiencing the slightest change. What then, we may ask, is the matter in yeast which excites fermentation, if neither the soluble nor insoluble parts possess the power? This question has been answered by Colin in the most satisfactory manner. He has shown that in reality it is the soluble part, but that before it obtains this power, the decanted infusion must be allowed to cool in contact with the air, and to remain some time exposed to its action. When yeast is introduced into a solution of sugar in this state, it produces a brisk fermentation; but without previous exposure to the air, it manifests no such property. The infusion absorbs oxygen during its exposure to the air, and carbonic acid may be found in it after a short time. Yeast produces fermentation in consequence of the progressive decomposition which it suffers from the action of air and water. Now when yeast is made to act on sugar, it is found that after the completion of the transformation of the latter substance into carbonic acid and alcohol, part of the yeast itself has disappeared. From 20 parts of fresh yeast from beer, and 100 parts of sugar, Thénard obtained, after the fermentation was completed, 13·7 parts of an insoluble residue, which diminished to ten parts when employed in the same way with a fresh portion of sugar. These ten parts were white, possessed of the properties of woody fibre, and had no further action on sugar. It is evident, therefore, that, during the fermentation of sugar by yeast, both of these substances suffer decomposition at the same time, and disappear in consequence. But if yeast be a body which excites fermentation by being itself in a state of decomposition, all other matters in the same condition should have a similar action upon sugar; and this is in reality the case. Muscle, urine, isinglass, osmazome, albumen, cheese, gliadine, gluten, legumin, and blood, when in a state of putrefaction, all have the power of producing the putrefaction or fermen-

tation of a solution of sugar. Yeast, which by continued washing has entirely lost the property of inducing fermentation, regains it when its putrefaction has recommenced, in consequence of its being kept in a warm situation for some time. Yeast and putrefying animal and vegetable matters act as peroxide of hydrogen does on oxide of silver, when they induce bodies with which they are in contact to enter into the same state of decomposition. The disturbance in the attraction of the constituents of the peroxide of hydrogen effects a disturbance in the attraction of the elements of the oxide of silver, the one being decomposed on account of the decomposition of the other. Peroxide of hydrogen is rapidly decomposed in contact with moist fibrin of blood, an animal substance in a continuous state of decomposition; the oxygen which it contained, in addition to that necessary to form water, escapes with violent effervescence. Now if we consider the process of the fermentation of pure sugar, in a practical point of view, we meet with two facts of constant occurrence. When the quantity of yeast is too small in proportion to that of the sugar, its putrefaction will be completed before the transformation of all the sugar is effected. Some sugar here remains undecomposed, because the cause of its transformation is absent, viz., contact with a body in a state of decomposition. But when the quantity of yeast predominates, a certain quantity of it remains after all the sugar has fermented, its decomposition proceeding very slowly, on account of its insolubility in water. This residue of yeast is still able to induce fermentation, when introduced into a fresh solution of sugar, and retains the same power until it has passed through all the stages of its own transformation. Hence a certain quantity of yeast is necessary in order to effect the transformation of a certain portion of sugar, not because it acts by its quantity in increasing any affinity, but because its influence depends solely on its presence, and its presence is necessary, until the last atom of sugar is decomposed."

Yeast for making bread, as good as any which can be obtained from brewers, or better, may be made in any of the three following ways. Mash about two quarts of malt in a gallon of water; and let it stand about two hours,—then skim it off into another small tub,—and when it is sufficiently cool, add a table spoonful of yeast. This process is the same as brewing, only without adding hops or boiling the wort; and it must be repeated whenever a fresh supply is wanted,—always keeping a little of the former yeast to make the next ferment. The quantity produced is sufficient for a large baking. If the weather be very cold, the tub may require to be placed near the kitchen fire in order to set up the fermentation. Besides the yeast which rises to the surface of the fluid, some will fall to the bottom. —Another:—Boil half a pound of hops for two hours in ten gallons of water; strain the liquid into a tub, stir in half a pound of ground malt, mix it well, stir it occasionally till the liquid become blood-warm, then add one gallon of yeast obtained from a brewer or preserved from your own last making, add also two pounds of flour, mix the whole well together, allow the mixture to ferment during eight hours, and then stir it up and strain it into a barrel, and keep it as nearly as possible air-tight. The produce will amount to about eight gallons, and will have a medium appearance between that of thin brewer's yeast and thick beer, and, if properly made and properly used, will be found to surpass any brewer's yeast for the purposes of baking. If only a gallon or two be wanted, it may be made from proportionate quantities of the ingredients; and if put into a stone bottle, tightly corked, and placed in a cool situation, it will keep good for a long time.—Another:—Boil one ounce of hops in four quarts of water till the hops fall to the bottom of the pan; strain the liquid, let it stand till blood-warm, add to it six ounces of flour and five of sugar, set the mixture near the fire, stir it frequently, and at the end of forty-eight hours add to it four pounds of boiled and finely bruised potatoes. The yeast will be ready next day; and if properly bottled and stored will keep good during a month. See the articles Bread and Fermentation.

Yeast is both an external and an internal therapeutic. When applied to foul and sphacelating ulcers, in union with farinaceous substances in the form of poultices, it corrects fetor, assists sloughing, and renders the purulent secretion healthful; and when administered internally to the human subject, in doses of about half an ounce every two or three hours, in combination with sugar or porter or wine, it acts as an antiseptic and a tonic, and has been thought particularly serviceable in putrid fevers.

Refuse or putrefied yeast, in a state no longer fit for any of its proper purposes as a ferment, and when either made up with other ingredients into a solid compost or diluted with water and applied in the way of liquid manure, is one of the most powerful of known fertilizers, and, even when used in very small quantity, produces great effects on grass-lands, turnips, cabbages, cauliflowers, oleaginous crops, roses, pelargoniums, dahlias, and many other crops and plants which require rich nitrogenous manure.

YELLOW BIRD'S NEST. See Bird's Nest and Monotropeæ.

YELLOW-HAMMER, — *Emberiza Citrinella.* A well known British bird of the conirostrous family of Passerinæ. It is also called the yellow bunting, the yoyt, and the yoldren. Its head and all the under parts of its body are of a pale yellow or straw colour; the hinder part of its neck is tinged with green; its breast is orange-red; and the inner edge of the two external quills of its tail is white. It builds its nest most

commonly in a tuft of grass or other herbage at the side of a hedge or coppice, sometimes as early as the month of March; and it breeds twice and sometimes thrice a-year. The nest is flat and comparatively large, and consists of dried moss, roots, and horse-hair; and the eggs amount to six, and have a white colour, streaked with purple veins. The old birds feed the young exclusively with larvæ and insects; but they themselves prefer seeds and grain, particularly wheat and oats; and in newly-sown fields, they may be seen very busily picking up the grain, from the moment it is sown till the period of its sprouting or brairding. To the earlier sown crops, as these birds continue in small flocks till they pair and separate, they accordingly do no little injury; but after pairing, as there is seldom more than a pair or two in the neighbourhood of one field, the damage which they effect cannot be great, and is partly compensated by the insects which they destroy to feed their young. When the broods are reared, however, and the corn-crops begin to ripen, the one or two pairs become considerably increased in number, and add to the assemblage of sparrows, buntings, and other plunderers, who leave little alongside the hedges but empty husks on the standing-corn. After this period, the yellow-hammers subsist by frequenting stubble-fields; and when the wheat is sown, they live for some weeks on the seed which they find not sufficiently buried, though they are by no means so fond of wheat as of oats. The yellow-hammer does little or no damage to gardens, inasmuch as it rarely visits these, unless when they are in some very secluded place, or in the wilder parts of the country where there are few hedges except those around farm-house gardens.

YELLOW RATTLE. See RATTLE (YELLOW).

YELLOW ROOT. See XANTHORHIZA.

YELLOWS. See JAUNDICE.

YELLOW SULTAN. See CENTAUREA.

YELLOW UNDERWING. See TRIPHÆNA.

YELLOW VETCHLING. See LATHYRUS.

YELLOW WEED. See DYER'S WEED.

YELLOW-WORT, — botanically *Chlora*. A small genus of hardy, ornamental, annual plants, of the gentian tribe. The perfoliate species, *C. perfoliata*, inhabits chalky hills and clay soils in various parts of Britain; and is well worthy of a place among the annuals of the flower-garden. It is very glaucous, and much subject to mildew. Its stems are about 12 or 18 inches high; its leaves are ovate, acute, combined, and perfoliate; and its flowers grow in upright, leafy, many-forked panicles, and are numerous and elegant, and have a bright yellow colour, and unfold themselves only in sunshine, and bloom in June and July. The imperfoliate species, *C. imperfoliata*, was introduced to Britain from Italy in 1823, and very much resembles the perfoliate. Both love a soil of sandy loam, and are easily raised in the ordinary manner of hardy annuals.

YEOMAN. A cultivator of the soil belonging to a high grade of rural society. Yeomen were formerly understood to be freeholders, who cultivated their own land; but they may now be regarded as comprising all respectable or extensive farmers. Sir Thomas Smith defines a yeoman to be "a free-born Englishman who may lay out of his own free lands in yearly revenue to the sum of 40s."

YEW,—botanically *Taxus*. A small genus of diœcious evergreen trees and tall shrubs, of the coniferous order. The flowers of the male plants have a quadripartite perianth, numerous stamens, and peltate anthers: and the flowers of the female plants have a pitcher-shaped four-leaved perianth, and are each succeeded by a fleshy drupe or baccate cone, scaly at the base and perforated at the top. One species grows wild in Britain; and two other species, as well as some exotic varieties of the indigenous one, have been introduced from other countries.

The common or berried yew, *Taxus baccata*, inhabits moist British woods, in situations where it has good, tenacious, damp soil, and is partially or wholly shaded by taller trees; and it also occurs wild in Canada and throughout most parts of Continental Europe. Its stem is straight, and has a smooth deciduous bark, and readily though slowly lifts up its topmost bough, in favourable situations, to a height of from 20 to 30 feet; its branches are large, and spread almost horizontally, yet are so aggregated as to be capable of forming a massive, regular, elegant head; its leaves are two-ranked or pectinate, crowded, flattened, soft, linear, acuminated, about an inch long, of a pale yellowish hue on the young shoots and branchlets, but of a dark and sombre green on the older boughs and over the great body of the tree; its flowers bloom from February till April; and its fruit are drooping, and have a scarlet colour, a glutinous pulpiness, and a sweet mawkish taste. This tree has usually been seen by the present and the last generations of Britons in a state of tortured growth, or in an old, declining, and diseased condition, or within the walls or immediate vicinity of cemeteries,—and is therefore commonly regarded as either an ungraceful or a gloomy object; yet when it stands singly, and is suffered to form its own shape, and to throw freely out its long branches, and to aggregate its boughs into a grand and natural head, it becomes eminently ornamental, and looks at once massive, elegant, and airy,—and when grown under these conditions in parks or on other gay landscapes, it groups most cheerily with any well-selected and well-arranged assemblage of other trees. It used to be planted in and near burying-grounds in Britain in the same way in which the cypress is in other countries; but, excepting in the Irish variety of it in the more ornate kinds of cemeteries, it is now seldom employed in that way; and when the auracarias and the many recently introduced pendulous and fastigiate trees become better known, it will probably lose al-

together its sepulchral associations, and begin to be regarded as solely a cheerful and ornamental plant. It grows slowly, yet is capable of attaining a great size. A beautiful specimen of it, which so long as 35 years ago was 12 feet in girth, stands by the public road side at the margin of the park of Rossdhu in Dumbartonshire; a specimen of about 28 feet in girth formerly stood in the parish of Arrochar, not many miles from Rossdhu; and a specimen of the enormous girth of 52 feet grew in the church-yard of Fortingal, and still survives though in such a rent and separated state as to appear like two trees. The yew was carefully and extensively cultivated in the age of archery on account of the peculiar suitableness of its strong and elastic wood for making bows; and though now not wanted in that way, it might still make large and profitable contributions of its timber for vastly more useful purposes. It cannot indeed be raised so compensatingly in plantations as most other timber trees, on account of the excessive slowness of its growth; but it is admirably suited for growing as underwood, and might yield more profit in that capacity than almost any other plant. Its wood is hard and durable, and takes on a finer polish than any other kind of our indigenous timber. "Besides the uses of it for boughs," says Evelyn, "for which the close and more deeply dyed is the best, the artists in box, cabinet-makers and inlayers most gladly employ it; and in Germany, they used to wainscot their stoves with boards of it; also for the cogs of mills, posts to be set in moist grounds, and everlasting axle-trees, there is none to be compared with it; likewise for the bodies of lutes, theorboes, bowls, wheels, and pins for pulleys, yea, and for tankards to drink out of." "I have only to add in commendation of this tree," says Gilpin, "that its veins exceed in beauty those of most other trees. Tables made of yew, when the grain is fine, are much superior to mahogany; and its roots vie in beauty with the ancient citron."

The foliage of the yew possesses a very perplexing reputation in reference to the domesticated animals; for in some instances, it seems to be indifferent to them, little eaten and seeming neither to help nor to hurt,—in others, it appears to act as a virulent poison,—and in others, though under limited and cautious conditions, it serves well and long as food; and it probably owes this extraordinary discrepancy of character partly to the different circumstances of soil and situation in which it grows, and partly to the different conditions of maturity and succulency, or of season and vitality, in which it is eaten. One of the most noted instances of its innocuousness has long occurred on Inchlonoch in Lochlomond. "That island," says the General Report of Scotland, "is stated to contain about 2,000 yew trees of very perfect growth, some of them being three feet in diameter. As for centuries past, this island has been used as a deer park, and as both the deer and the forester's cows devour the crops of the branches greedily during the winter storms, without any bad effects, the deleterious qualities of this tree have either been exaggerated, or their effects are diminished by use. Even the berries of the yew are greedily devoured by the field-fare and other birds." Yet very many authentic instances are on record of assured poisonings by the yew-tree, which either have ended fatally or have required prompt medical treatment; and all such cases, as well as the opposite ones of expressly and statedly using the foliage as fodder, may best be stated in the words of Youatt in his Treatise on Cattle. "The yew," says he, "is probably the most destructive poison," more so, that is, than common hemlock, water hemlock, water-dropwort, wild parsnip, black henbane, and all similar plants, "especially when a quantity of it is taken unmixed with other food. M. Husard, however, relates that, in Hanover and Hesse, the cattle are partly fed on the leaves of the yew. He examined the trees as they grew in the mountains of those countries, and he found them to be the true yew. In winter, and especially when fodder is more than usually scarce, a portion of yew leaves and branches is mingled with the other food. The quantity of the yew is small at first, but it is gradually increased until it constitutes the greater part of the food; and it has the reputation of materially contributing to the fattening of the beast. The inhabitants of Hanover and Hesse are, nevertheless, perfectly aware of the poisonous property of the leaves of this tree, and are sometimes taught, by dear experience, that it will destroy their cattle, unless it is managed with this degree of caution. M. Husard adds, that on his return to France he determined to put this matter to the test, but he selected the horse instead of cattle as the subject of his experiment. He gave the yew mixed with oats in the proportion of half a pound of the former to a pound and a half of the latter, and the horse did not appear to be in the slightest degree inconvenienced by what he had eaten. This animal, however, was enfeebled and emaciated previous to the experiment; and it occurred to M. Husard that there might be a deficiency of sensibility in the stomach, and in the frame generally, and that, in consequence of this, the poison might not produce its fatal effects. He, therefore, selected a mare in good health and condition, as the subject of a second experiment. She ate the mingled yew and oats, and suffered no inconvenience. He selected another horse as the subject of a third and decisive experiment. He took seven ounces of the yew, and bruised and mixed it with twelve ounces of water, so as to make a kind of electuary, which he gave to a horse which had fasted four hours; an hour afterwards he fell and died. The British agriculturist will scarcely be tempted to make experiments like these, except in times of the greatest scarcity, and then he would act with all the cau-

tion of the Hanoverian, for several instances occur to the recollection of the writer in which the presence of a considerable quantity of other food in the rumen did not preserve the beast from the fatal effects of the yew. Fortunately, it is seldom that cattle browse upon the green yew; the mischief is usually done by the half-dried clippings of the yew-trees, or hedges, which are too often suffered to lie in the way of cattle, and which they will eat, if not with avidity, yet freely. Little can be done in the way of medicine when cattle have browsed on these poisonous plants, and the only hope of the practitioner must be founded on the early and persevering use of the stomach pump. Plenty of warm water should be injected and pumped out, and that repeated again and again; and at length the stomach should be fully distended with water, for the purpose, and in the hope of, producing vomiting. Whether this succeeds or not, a brisk purgative should be next administered, but as cautiously and gently as possible, that it may pass on over the closed floor of the œsophagean canal into the fourth stomach, and not, by the power with which it descends, force open the pillars that compose that floor, and enter the rumen and be lost. Tonics and aromatics will here also follow the evacuation of the stomach, in order to restore its tone."

Three varieties of the common yew occur in shrubberies,—the short-leaved, with comparatively very short leaves,—the procumbent, with so dwarfish a habit that it seldom can attain a height of more than 8 or 10 feet,—and the variegated-leaved, nearly as tall as the normal plant, but of slower growth, and with light yellow blotched or variegated foliage. The normal plant is raised from seeds, and ought to be transplanted in its third year into a nursery, and kept there three or four years; but the varieties, though they may also be obtained from seed, yet, in order to their being had certainly true to their characters, require to be raised from layers; and while the normal plant and the short-leaved and procumbent varieties will do well in any common soil, the variegated-leaved variety is liable to lose all its characteristic properties unless raised and grown in a very barren soil.

The Irish or fastigiate yew, *Taxus hibernica*, *T. baccata hibernica*, *T. stricta*, or *T. baccata stricta*, is regarded by some botanists as a separate species, and by others as a mere though remarkable variety of the common yew. It is distinguished partly by a peculiar form and aggregation of its foliage, but still more and very greatly by an astricted and erect habit of growth, such as renders it eminently suitable for planting, along with the upright cypress, in the vicinity of buildings and among a profusion of tombs and monuments, where straight horizontal lines predominate. It commonly attains a height of about 12 feet.

The Canadian or American yew, *Taxus canadensis*, was introduced to Britain from Canada about 50 years ago. Its habit of growth is more close and compact than that of the common yew; its general appearance is more handsome; its leaves are shorter, more numerous, regularly pectinate, and of a light green colour; and its natural height and habitat and mode of propagation are the same.

The nut-bearing yew, *Taxus nucifera*, is a native of China, and was introduced thence to Britain in 1820. It naturally attains about the same height as the common and the Canadian yews; but it is too tender to be successfully reared or maintained in the open ground in almost any part of Britain.

YOKE. The appliance for coupling two oxen together and harnessing them to the plough. In the strict sense, indeed, it is merely the thick piece of wood which passes over their neck; but in the popular sense, it comprises also the bow which encompasses their neck, the wreathings or stitchings which form the connections and fastenings, and the ring and chains which afford an attachment to the traces. A yoke, in the mytonymical sense, as in the phrase 'a yoke of oxen,' is the same as a team; and yoking, in all the ordinary senses of the word, whether in reference to oxen or horses, to tillage implements or wheel-carriages, is simply the putting of a draught animal into harness.

YOKE OF LAND. A quantity of land which a yoke of oxen might plough in a day.

YOLK. See Egg and Wool.

YPONOMEUTIDÆ. See Ermine Moth.

YTTRIUM. A very rare metal,—the base of the earth yttria. This earth was first found in 1794 at Ytterby in Sweden; and the metal was first obtained in a separate state in 1828 by Wöhler. Yttrium has a scaly texture, a greyish black colour, and a perfectly metallic lustre; it is brittle, and does not oxidize in either air or water; and when heated to redness, it burns with splendour in common air, and with great brilliance in oxygen. Yttria results from its combustion, and is white and shows marks of fusion; it dissolves in solution of potash and in sulphuric acid; it combines with sulphur, selenium, and phosphorus; and most of its salts have a sweet taste,—and many of them an amethyst colour.

YUCCA. See Adam's Needle.

Z

ZAMIA. A genus of curious, exotic, evergreen plants, of the cycas tribe. See the article CYCAS. Twenty-one species have been introduced to the greenhouses and garden stoves of Britain from South Africa, the Bahama islands, and the West Indies. They vary in height from 1 foot to 15 feet; the majority have confluent leaflets and one-celled anthers, and the rest have basal-jointed leaflets and two-celled anthers; and all love a soil of peaty loam or of loamy peat, and are propagated from suckers. The specific names of most are sufficiently indicative of some of their most obvious distinctive characters; as the broad-leaved, the cycas-leaved, the long-leaved, the cycas-like, the three-toothed, the narrow-leaved, the entire-leaved, the repand, the plum-bearing, the woolly, the spiral, the pricking, the spiny, the slender, and the furfuraceous. The most ornamental are the slender, 1 foot high; the Caffrarian, 4 feet; the spiny, 5 feet; the broad-leaved, 6 feet; the repand, 6 feet; and the plum-bearing, 15 feet. Most are liable, like the cycases, to receive the popular misnomer of sago-palms.

ZANNICHELLIA. See HORNED PONDWEED.

ZANTHOXYLUM. See TOOTHACHE-TREE.

ZAPPANIA. A small genus of exotic, evergreen, herbaceous plants, of the verbena family. Two species, the knot-flowered and the stœchas-leaved, both about a foot high and carrying purple flowers in August, were long ago introduced to British hothouses from America; a beautiful variety of the knot-flowered, about 4 inches high and carrying rosy-coloured flowers, was introduced a few years ago from Chili; and 8 or 9 other species are known.

ZEA. See MAIZE.

ZEBRA. See HORSE.

ZEBRA PLANT. See CALATHEA.

ZEBU. See OX.

ZEDOARY. See TURMERIC.

ZEPHYRANTHES. A genus of ornamental, exotic, bulbous-rooted plants, of the amaryllis family. About a dozen species, chiefly about 6 or 9 inches high, most with either white or red or pink flowers, some hardy, others more or less tender, and all loving a fertile porous soil and propagable from cuttings, have been introduced to Britain from various parts of America. The species called popularly the Atamasco lily, and by the old botanists *Amaryllis Atamasco*, and introduced so long ago as the year 1629, is by far the best known, and may serve as a good specimen of the whole. It is a native of Virginia and Carolina, and grows very plentifully there in the fields and woods, and makes a most beautiful floral display in the months of May and June. It attains a height of only about 6 or 8 inches; yet carries almost as large flowers as those of the small orange lily; and is so hardy as to thrive in the open air in Britain, provided its roots are planted in a warm situation and upon a dry soil. The flowers are produced single; and at their first appearance have a fine carnation colour on their outside; but afterwards fade away to a pale flesh colour, or almost to pure white. This plant sometimes blooms also in August.

ZERUMBET. See TURMERIC.

ZEXMENIA. An ornamental, evergreen, herbaceous, yellow-flowered, Mexican plant, of the sunflower division of the composite order. It constitutes a genus of itself; and is specifically and descriptively called the tagetes-flowered,—*tagetiflora*. It was introduced to Britain about 20 years ago; has a height of about 2 feet, and blooms in September; requires some protection in winter; and is raised from seeds, and will thrive in any common soil.

ZICHYA. See KENNEDIA.

ZIERIA. A genus of ornamental, evergreen, Australian shrubs, of the rue family. About a dozen species, varying in height from 3 to 6 feet, have been introduced to Britain. They are not so showy as some others of the multitudes of ligneous beauties which have been brought to this country from Australia; yet they possess much elegance, and well deserve the attention of refined cultivators. The leaves of most or all are trifoliate; the flowers have a four-cleft calyx and a four-petalled corolla, and in most cases are white; and the capsules are four-celled and four-lobed, and contain each four oval compressed seeds. The smooth species, *Z. lævigata*, is peculiarly handsome, and serves as a favourable representative of the whole genus. Its branches are cylindrical, spreading, slender, and smooth; its leaves are opposite, and stand on short smooth footstalks, and are trifoliately palmate; its leaflets are linear, pointed, reflexed or wavy, from half an inch to one inch long, dark green and smooth above, and whitish and very finely downy below; and its flowers grow in corymbs or little loose bunches of from three to ten, and have a white colour with a slight tinge of pink, and bloom from May till July. All the species love a soil of sandy peat, and are propagated from cuttings.

ZIGADENUS. A small genus of hardy, ornamental, North American, herbaceous plants, of the melanthium family. Several species, all about 12 or 20 inches high, with either white or cream-coloured flowers, have been introduced to

Britain; and they love a soil of sandy peat, and are propagated by radical division.

ZINC. An abundant and very useful metal. It occurs in a metallic state, combined with sulphur and iron, in the form of blende; and in an oxidized state, combined with silica, in the form of red zinc ore,—and combined with carbonic acid, in the forms of electric calamine and common calamine. The sulphuret or blende comprises three varieties,—yellow, brown, and black; and the common calamine also comprises three varieties, — crystallized, compact, and earthy. Zinc was not known to the ancient Greeks, though contained in the cadmia which they used in the manufacture of brass; nor was it known, in its proper or separate state, to any Europeans previous to the third decad of the eighteenth century, though abounding in ores and minerals with which multitudes of them were familiar. It seems indeed to have been worked and used from a somewhat remote period by the Hindoos and the Chinese; but it was not obtained in a separate state in Europe till the year 1721, and was not obtained by the process of distillation till 1742. The ores of it occur in the carboniferous limestone and magnesian limestone formations in England and in many other parts of the world; and are usually associated with the ores of other metals, particularly those of iron, lead, copper, arsenic, and cadmium. It is procured in large quantities from calamine, and in still larger ones from blende, by means of heat and carbonaceous matters, in the process technically called distillation by descent,—the blende being first crushed, picked, and roasted. "The ore is then washed to separate the metallic particles from the lighter parts; and is then ground in a mill with one-eighth of its weight of charcoal; and put into large earthen jars placed in a circular furnace, through the bottom of each of which passes an iron tube, which goes through the floor of the furnace into a vessel of water placed beneath. The cover of each jar is firmly and accurately luted on, so that the reduced zinc, as it is elevated by the strong heat of the furnace, not finding a vent to escape by the top, descends through the iron tube into the water, and is there condensed in small metallic drops, which are afterwards melted and cast into ingots." The portions which first come over are generally very impure, containing admixtures of arsenic and cadmium; and the succeeding continue to be of the same character so long as the vapour burns with what the workmen call a brown blaze,—and should all be rejected as unfit for any of the ordinary uses of zinc;—and even the subsequent and best portions, or those which rise during what the workmen call the blue blaze, are never quite pure,—always containing some iron, and often containing also traces of arsenic, cadmium, lead, copper, charcoal, and sulphur; but they can be freed from their impurities by afterwards exposing them to a white heat in an earthen retort with its receiver full of water, and there subjecting them to re-distillation. A large proportion of the best zinc of commerce, bearing the name of spelter, is imported into Britain from Upper Silesia, by way of Hamburgh and Belgium.

Zinc has a brilliant metallic lustre, and a bluish-white colour. Its fracture is shining and lamellated; its hardness makes strong resistance to the file, yet allows a black stain to be given to the human fingers by rubbing; and its specific gravity varies from 6·861 to 7·1. At low or ordinary temperatures, it is brittle, and may be easily split or broken by a properly directed blow; at any temperature between 212° and 400° Fahrenheit, it is so malleable and ductile that it can be hammered or rolled into sheets of considerable thinness; and at all higher temperatures, it is very brittle, and can be pulverized in a mortar. Its malleability is considerably diminished by the impurities which are naturally combined with it; and is correspondingly increased either by the comparative purity of the ores from which it is obtained, or by the comparative care and refinement of the process in which it is separated. Zinc fuses at 680° Fahrenheit; and, when slowly cooled, crystallises in four-sided or six-sided prisms; and if subjected in close vessels to a white heat, it distils over unchanged. By exposure at ordinary temperatures to the action of air and moisture, it undergoes little change; but by exposure at the temperature of fusion to the air, it rapidly oxidizes, and forms the white oxide popularly called flowers of zinc; and by similar exposure at considerably higher temperatures, probably from about 940° upwards, it burns with a dazzling white flame, and passes with such violence into the state of oxide as to be completely volatilized during the combustion. It dissolves and oxidizes in all the mineral acids; and, when aided by a small portion of sulphuric or of muriatic acid, it decomposes water, and gives off a minute portion of its substance into solution with the liberated hydrogen.

Zinc is extensively used for making baths, water-cisterns, pipes, spouts, filings for fire-works, various kinds of plates, voltaic batteries, and many varieties of objects for which lead and copper were formerly employed. It is used also for covering roofs, and for a number of architectural purposes; and has been introduced, in various ways, to the fitting up and furnishing of the farmery. But though it has the recommendation of being but very slightly tarnishable and of never accumulating a coat of oxide, it is, in many circumstances, a highly objectionable material for pipes and cisterns on account of its voltaic action upon water, and for architectural purposes on account of its comparatively easy and very keen combustibility. Several preparations of it are of great service in medicine; and three of these are noticed in the articles Calamine, White Vitriol, and Tutty.

The protoxide or white oxide or flowers of

zinc obtained by the combustion of the metal, is a light flocculent powder, inodorous, insipid, infusible in the fire, insoluble in water or in alcohol, unalterable in the air, and of a pure white colour at common temperatures, but yellow while cooling from a state of lowered heat. It is a strong salifiable base, combining readily and thoroughly with acids, and forming regular salts, most of which are colourless. It combines also with some of the acids. It appears to consist of one equivalent of zinc and one equivalent of oxygen; but it often contains small portions of carbonic acid; and, as sold in the shops, it is not unfrequently adulterated with chalk or with white lead. It possesses tonic and antispasmodic properties; and has been given in very minute doses in cases of chorea, epilepsy, and hooping-cough; and is the active ingredient in a moderately astringent and stimulating ointment for the cure of ringworm and of chronic inflammation of the eyes.

The acetate of zinc is formed in a state of solution by mixing a solution of sulphate of zinc with a solution of acetate of lead in proper proportions,—the bases and the acids of the two salts making a mutual interchange of combination, and the resulting sulphate of lead being thrown down as a precipitate; and the solution of the acetate of zinc thus formed has long been known as a valuable application for chronic ophthalmia. —A tincture of the same salt is made in a somewhat similar but more operose manner; and serves also in dilution as a good external astringent; and might likewise be advantageously employed as an internal remedy for debility in the digestive system.

The chloride of zinc, popularly called butter of zinc, is formed by the combustion of zinc filings in chlorine gas, and may be obtained also by evaporating muriate of zinc to dryness, and then heating it to redness in a glass tube. It consists of one equivalent of zinc and one equivalent of chlorine; it has a soft consistence,—alluded to in its popular name of butter; and it deliquesces on exposure to the air, being then reconverted into muriate.—Bromide and iodide of zinc may be formed in a similar way to the bromide and the iodide of iron.

ZINGIBER. See Ginger.

ZINNIA. A genus of handsome, hardy, American annual plants, of the sunflower division of the composite order. Eight species, all about 2 feet high, have been introduced to Britain. The few-flowered, *Z. pauciflora*, is the longest known, and has sessile yellow flowers; and all the others have pedunculate and either red or scarlet flowers; while the elegant, *Z. elegans*, comprises both a splendid scarlet-rayed variety and a white-rayed variety. The many-flowered, *Z. multiflora*, blooms so long as from June till October, and the elegant from June till September; and the others bloom either in July and August or in June and July. The slender-leaved, the narrow-leaved, the revolute, and the hybrid thrive in any common soil; and the others, in order to do well, require a soil of rich mould. The elegant combines breadth and beauty of flower more than most hardy or half-hardy annuals; and is a high favourite with many amateur florists, both for the open ground and for small selections of house annuals.

ZIRCONIUM. A rare and simple metallic or quasi-metallic substance,—the base of the earth zirconia. It is prepared from hydrofluate of zirconia with the aid of potassium, potash, and the spirit-lamp; and was first obtained in a separate state in the year 1824. It is a black powder, capable of being pressed into thin shining scales, but with very slight metallic lustre and very feeble coherence of its particles; it does not conduct electricity; it does not oxidize when boiled in water; it yields with great reluctance to the action of sulphuric, muriatic, and nitro-muriatic acids; it readily dissolves in hydro-fluoric acid, with disengagement of hydrogen; and when heated in the open air, it ignites before becoming luminous, burns with a bright flame, and is converted into zirconia.

Zirconia was discovered in 1789 by Klaproth in Ceylon. It has a similar appearance to alumina; is tasteless, odourless, insoluble in water, and so hard that it will scratch glass; it has a specific gravity of 4·3: and, when pure, is of a white colour,—but generally exhibits a yellowish tinge in consequence of the presence of iron. It becomes vividly phosphorescent when strongly heated before the blow-pipe; it combines with acids to form salts, similar in most respects to those of alumina,—but precipitable from solution by any of the pure alkalies; and, when thrown down from any of its salts by ammonia, and afterwards ignited, dried, or even washed with boiling-water, it acquires the power of completely resisting the action of the acids.

ZIZANIA. See Canada Rice.

ZIZIPHORA. A genus of ornamental exotic plants, of the labiate order. Four perennial and six annual species have been introduced to Britain from Siberia, Caucasus, Tauria, Spain, and the Levant; and several more are known. The introduced species are hardy, and vary in height from 6 to 18 inches, and present more or less close resemblances to thyme, basil, savory, and pennyroyal, at once in foliage, flower, and fragrance; and have either red, purple, lilac, or pink flowers. The perennials have a trailing habit and are suitable for rockwork; and three of them, the thick-flowered, the mediate, and the serpyllum-like, are evergreens, and may be propagated from cuttings. All the annuals will thrive in any common soil.

ZIZYPHUS. See Jujube.

ZOOLOGY. That part of natural history which treats of animals. It is not confined to a description of the external forms of animals, but embraces all the phenomena of life and animal

motion; the internal organization of each individual part; the processes of digestion, assimilation, nutrition, secretion, and reproduction; the wonderful instincts, the varied dispositions, and the different degrees of intellect, manifested in the animal creation, from the half-vegetable zoophyte up to man.

Although it cannot be doubted that the attention of men was early attracted to an observation of the habits and natures of the lower order of animals, Aristotle seems to have been the first who furnished the world with any methodical information on this subject. His work contains a great number of facts and observations. He compares the organization of the lower animals, in its different parts, with that of man, and treats of their mode of generation, habits, organs, &c., with great clearness and sagacity; and his principal divisions of the animal kingdom are so well founded that almost all of them are still substantially admitted. Among the Romans, zoology does not appear to have been at all cultivated until the time of Pliny, who is the only Roman zoologist worthy of notice. His work (*Historia Naturalis*) contains multitudes of original traits, though it is only a compilation, and describes the habits and dispositions of animals with great felicity. He adopted, without examination, many fabulous stories, and too often neglected important details. Ælian was far inferior to the two above-mentioned writers, and his Natural History of Animals may be considered as the source of all the falsehood and error which so long disgraced this branch of natural history. Apuleius, and Athenæus the grammarian, are the only names that deserve mention, from the time of Ælian and Pliny to the beginning of the sixteenth century; and they added nothing to the stock of zoological science. At the latter period, flourished, among others, Belon, a French physician, who made the closest approach of any author of that time to anything like systematic classification, in his *De Aquatilibus*, and particularly in his *De la Nature des Oiseaux* (Paris, 1555, folio); Salviani, author of a treatise, *Aquatilium Animalium Historia* (Rome, 1554, folio), which is superbly illustrated; Conrad Gesner, whose *Historia Animalium* (Zürich, 1550—1587, 4 vols. folio), arranged in alphabetical order, forms the foundation of modern zoology; and Aldovrandus, the most laborious of compilers, who devoted sixty years to his work on natural history, in fourteen volumes, folio, of which the greater part was published after his death. These earlier writers were followed, in the next century, by Redi and Swammerdam, to whom entomology is so much indebted, and by Ray, the first naturalist, from the time of Aristotle, who produced anything like a scientific arrangement. The works of Ray, under his own name, are *Synopsis Quadrupedum et Serpentum* (1683, 8vo.); *Synopsis Avium et Piscium* (1713); and *Historia Insectorum;* and he is also considered to have had a large share in the compositions of his pupil Willoughby. But it was reserved for Linnæus to raise natural history to the rank of a science. Gifted with extraordinary powers of invention and discrimination, a most retentive memory, an unrelaxing industry, and the most ardent zeal in the cause of science, this great man observed, with the acutest sagacity, the subtlest affinities of organized nature. The general character of his works is order, precision, clearness, exactness of description, and an accurate knowledge of relations in detail. Buffon adorned natural history with the charms of eloquence, and was the first who extended its popularity beyond mere scholars and men of science. He was occasionally carried, by the force of his imagination, into unfounded hypotheses; yet he had a truly philosophical spirit, could observe facts, and compare results, and possessed extensive information. The four great naturalists whom we have had occasion to mention, have exhibited nature under different aspects. Aristotle has shown us the profound combination of its laws; Pliny its inexhaustible riches; Linnæus its wonderful details; and Buffon its majesty and power. Since the time of Buffon, all the departments of zoology have been cultivated with a zeal, a minute accuracy, and an extensiveness of research, before unequalled. Our limits will not allow us to mention all those who have distinguished themselves in the cultivation of the whole field of the science, much less those who, confining themselves to particular branches of it, have yet rendered most important services by the exactness of their researches and the novelty of their views. Among the Germans, Illiger and Blumenbach hold the first rank as zoologists; but it is to France that we are chiefly indebted for the strong impulse which has been given, in our times, to the progress of natural science, and of zoology in particular. The name of Cuvier alone sufficiently indicates the brilliant triumphs of natural history in that country.

We have already treated, at some length, of some parts of this extensive subject, in the articles Animals, Generation, Gestation, &c., and of the nomenclature of particular classes of animals in the articles Insects, Ornithology, &c.; and we shall now proceed to give some notice of the principal methods of classification pursued by eminent zoologists, and shall make particular mention of the classification of the mammiferous animals. The immense number of facts embraced by natural history could never be retained in the memory without an arrangement of divisions and subdivisions founded upon some distinguishing characteristics. Aristotle's system of arrangement was simple, resting on divisions derived mainly from the external structure, food, habits, and locality. But though neither human nor comparative anatomy was then sufficiently cultivated to enable him to make the internal structure of animals the basis of his divisions, yet Aristotle was not insensible to the advantages of a more scientific distribution, and, with his usual sagacity, recommends to succeeding writers to turn their attention in that direction. Ray followed the advice of the great master, and remarked the great distinction, that some animals possessed lungs and a sanguineous system, while others were destitute of both. Linnæus, proceeding on the general arrangement of Ray, but with many extensions and improvements, divided the animal kingdom into six classes, founded mainly on the differences in the respiratory and sanguineous systems.

Class I. *Mammalia.* All suckle their young; the heart has two auricles and two ventricles; blood red and warm; viviparous.

Class II. *Aves* (Birds). Characters of sanguineous system as in first class; viviparous.

Class III. *Amphibia.* Heart one auricle and one ventricle; blood red and cold; respiration voluntary.

Class IV. *Pisces* (Fishes). Heart and blood as in *amphibia;* respiration by gills.

Class V. *Insecta.* Heart one ventricle and no auricle; sanies cold, colourless; antennæ, or feelers.

Class VI. *Vermes* (Worms). Characters as in V., except no antennæ, but tentacula.

He then subdivides the *Mammalia* into seven orders, the distinctions of which are taken from the difference in the number, form, and situation of the teeth, without, however, neglecting the feet.

Order 1. *Primates.* Four incisors in each jaw, and one canine.—Genera: *homo, simia, lemur, vespertilio.*

Order 2. *Bruta.* No incisors.—Genera: *rhinoceros, elephas, trichechus, bradypus, myrmecophaga, manis, dasypus.*

Order 3. *Feræ.* Six conical incisors in each jaw, for the most part.—Genera: *phoca, canis, felis, viverra, mustela, ursus, didelphis, talpa, sorex, erinaceus.*

Order 4. *Glires.* Two incisors in each jaw; no canines.—Genera: *hystrix, lepus, castor, mus, sciurus, myoxus, cavia, arctomys, dipus, hyrax.*

Order 5. *Pecora.* No fore-teeth in the upper jaw; six or eight in the under.—Genera: *camelus, moschus, giraffa, cervus, antilope, capra, ovis, bos.*

Order 6. *Bellucæ.* Obtuse fore-teeth in each jaw.—Genera: *equus, hippopotamus, sus, tapir.*

Order 7. *Cete.* No uniform character of teeth; aquatic pectoral fins; spiracula.—Genera: *monodon, balæna, physeter, delphinus.*

The other classes are subdivided in a similar manner. We shall enumerate only the orders. The distinctions of the *Aves* are taken chiefly from the beak; but the tongue, nostrils, feet, and other parts, are sometimes called in.

Order 1. *Accipitres.*
——— 2. *Picæ.*
——— 3. *Anseres.*
——— 4. *Grallæ.*
——— 5. *Gallinæ.*
——— 6. *Passeres.*

(See Ornithology.)

The *Amphibia* are divided into two orders.

Order 1. *Reptilia.* Furnished with feet, and breathing through the mouth. (See Reptiles.)

Order 2. *Serpentes.* Destitute of feet, and breathing through the mouth.

The fourth class, *Pisces*, is subdivided into six orders, the characters of which are taken from the belly-fins.

Order 1. *Apodes.* No ventral fins; embraces the eel kind, torpedo, &c.

Order 2. *Jugulares.* Ventral fins placed before the pectoral; cod, blenny, &c.

Order 3. *Thoracici.* Ventral fins under the pectoral; sucking-fish, goby, plaice, doree, &c.

Order 4. *Abdominales.* Ventral fins placed behind the pectoral; skate, salmon, pike, &c.

Order 5. *Branchiostegi.* Gills destitute of long rays; sun-fish, pipe fish, &c.

Order 6. *Chondropterygii.* Cartilaginous gills; lamprey, ray, shark, &c.

The fifth class, that of *Insects*, is divided into seven orders, the characters of which are mostly taken from the differences observed in the number and texture of the wings.

Order 1. *Coleoptera.*
——— 2. *Hemiptera.*
——— 3. *Lepidoptera.*
——— 4. *Neuroptera.*
Order 5. *Hymenoptera.*
——— 6 *Diptera.*
——— 7. *Aptera.*

The sixth class, *Vermes*, is subdivided into five orders.

Order 1. *Intestina.*
——— 2. *Mollusca.*
——— 3. *Testacea.*
——— 4. *Zoophyta.*
——— 5. *Infusoria.*

The arrangement of Linnæus, with all its advantages, had its defects. By confining himself too much to one kind of character, he often throws together subjects widely remote in their general appearance and economy; but he has carried the art of distribution, and the management of characters, to such a degree of clearness and brevity, that any person familiarized to his language may easily find the name and place of any being he wishes to observe. It still remained a desideratum to arrange the facts, of which the science treats, in a series of propositions, so graduated and successively subordinate, that the whole might represent the actual relations of living beings. For this purpose, it was necessary to group animals according to their different properties or organizations, so that those contained in such a group should bear a stronger natural resemblance to each other than to any individual of a different group. This arrangement is termed the *natural* method, for the formation of which zoology offers great facilities. In the arrangement of Cuvier, the completest and most scientific yet presented to the world, the great division of the animal world rests on the nervous and sensorial, and not on the circulatory and respiratory systems. From the study of the physiology of the natural classes of vertebrated animals, Cuvier discovered the respective quantity of respiration, the reason of the quantity or degree of motion, and, consequently, the peculiar nature of that motion. This last gives rise to the peculiar form of their skeletons and muscles; and with it the energy of their sensations, and the force of their digestion, are in a necessary relation. Thus zoological arrangement, which had hitherto rested on observation alone, assumed a truly scientific form. Calling in the aid of comparative anatomy, it involves propositions applicable to new cases, and thus becomes a means of discovery as well as a register of facts; and, by correct reasoning, founded on copious induction, it partakes of the demonstration of mathematics, and the certainty of experimental knowledge. Having examined the modifications which take place in the organs of circulation, respiration and sensation in the invertebrated animals (a title first given by Lamarck, instead of the erroneous one of *white-blooded* animals, by which they were previously distinguished), Cuvier has formed a new division, in which these animals are arranged according to their actual relations. The following is a view of the system as exhibited in the

second edition of the *Règne Animal*, published in 1829 (5 vols., 8vo.) Of the four great divisions into which the animal kingdom is divided—*Vertebrated*, *Molluscous*, *Articulated*, and *Radiated* animals—and of their general subdivisions, an account is given in the article ANIMAL.—Four classes are comprised in the *Vertebrata*,—*Mammalia* or suck-giving animals, *Aves* or birds, *Reptilia* or reptiles, and *Pisces* or fishes. See the articles ORNITHOLOGY, REPTILES, and FISHES. The class *Mammalia*, is subdivided into eight orders, as follows:—

ORDER I.
BIMANA.

Having hands at the anterior extremities alone. One species—man.

ORDER II.
QUADRUMANA.

Having hands at the four extremities.
Simia (Monkey).
Ouistiti.
Makis, or *Lemurs*.

ORDER III.
CARNASSIERS.
FAMILY 1.
CHEIROPTERA.
Vespertilio (Bat).
Galeopithecus.

FAMILY 2.
INSECTIVORA.
Erinaceus (Hedgehog).
Tendrac (*Centenes*, Illig.).
Cladobates (Tupaia).
Sorex (Shrew).
Mygale (Desman).
Chrysochloris.
Talpa (Mole).
Condylura.
Scalops (Shrew-Mole).

FAMILY 3.
CARNIVORA.
TRIBE 1.
PLANTIGRADE.
Ursus (Bear).

TRIBE 2.
DIGITIGRADE.
Mustela (Marten).
Canis (Dog).
Viverra (Civet).
Hyæna.
Felis (Cat).

TRIBE 3.
AMPHIBIOUS ANIMALS.
Phoca (Seal).
Trichecus (Morse).

ORDER IV.
MARSUPIAL ANIMALS.
Didelphis (Opossum).
Dasyurus.
Phalangista.
Potorous (*Hypsiprymnus*, Illig.).
Macropus (Kangaroo).
Koala (*Lipurus*, Goldf.) *Phascolarctos*.
Phascolomys (Wombat).

ORDER V.
GLIRES (RODENTIA).
Sciurus (Squirrel).
Mus (Rat).
Helamys (*Pedetes*, Illig.).
Spalax.
Orycterus.
Geomys (*Pseudostoma*, Say).
Diplostoma.
Castor (Beaver).
Couia (*Myopotamus*, Comm.).
Hystrix (Porcupine).
Lepus (Hare).
Cavia (Guinea Pig).

ORDER VI.
EDENTATA.
TRIBE 1.
TARDIGRADE.
Bradypus (Sloth).
Megatherium (fossil).

TRIBE 2.
COMMON EDENTATA.
Dasypus (Tatou).
Orycteropus.
Myrmecophaga (Anteater).
Manis (Pangolin).

TRIBE 3.
MONOTREMA.
Echidna (Spinous Anteater).
Ornithorhynchus (*Platypus*, Shaw).

ORDER VII.
PACHYDERMATA.
FAMILY 1.
PROBOSCIDIANA.
Elephas.
Mastodon (fossil).

FAMILY 2.
COMMON PACHYDERMATA.
Hippopotamus.
Sus (Hog).
Phacochœrus.
Dicotyles (Peccary).
Anoplotherium (fossil).
Rhinoceros.
Hyrax.
Palæotherium (fossil).
Lophiodon (fossil).
Tapir.

FAMILY 3.
SOLIPED.
Equus (Horse).

ORDER VIII.
RUMINANTIA.
(Without horns.)
Camelus.
Moschus.

(Horned.)
Cervus (Deer).
Camelopardalis (Giraffe).
Antelope.
Capra (Goat).
Ovis (Sheep).
Bos (Ox).

ORDER IX.
CETACEA.

FAMILY 1.
HERBIVOROUS.

Manatus (Lamantin).
Dugong (*Halicorus*, Illig.).
Stelleras (*Rytina*, Illig.).

FAMILY 2.
COMMON CETACEA.

Delphinus (Dolphin).
Narwhal (*Monodon*, L.).
Cachalot (*Physeter*, L.).
Balæna.

ZORNIA. A genus of curious, exotic, herbaceous plants, of the hedysarum division of the leguminous order. Seven species have been introduced to Britain from the Indies, Australia, North America, and Southern Africa; and four or five more are known. Two of the introduced species have perennial roots and quadrifoliate leaves, and require the protection of the greenhouse; the other five have annual roots and bifoliate leaves, and require the protection of the stove; both of the former, and most of the latter have yellow flowers; and all love a somewhat light soil, and bloom in July and August.

ZOSTERA. See WRACKGRASS.

ZUBR. See OX.

ZUCCAGNIA. A small genus of ornamental, exotic, bulbous-rooted plants, of the asphodel tribe. The green species, *Z. viridis*, was introduced to Britain from the Cape of Good Hope about 75 years ago; and has a height of 8 or 10 inches, and carries green flowers in August.

ZYGOPETALUM, a genus of ornamental, tropical, epiphytous plants, of the orchis family. It takes its name from the petals being joined at the base. Several species of great beauty, with flowers of variegated colours, have been introduced to British gardens from Demerara and Brazil. See the article ORCHIS.

ZYGOPHYLLUM. A diversified genus of ornamental, exotic, thalamiflorous plants, constituting the type of the natural order Zygophylleæ or Zygophylleaceæ. This order is nearly allied to the rue family; it belongs wholly to the tropics and to the warm parts of the temperate zones; and it comprises within the gardens of Britain 9 or 10 stove species, nearly 30 greenhouse species, and 3 or 4 hardy or half-hardy species belonging to the seven genera Zygophyllum, guiacum, tribulus, melianthus, fagonia, larrea, and porlieria. Some of the species are herbs, remarkable for the softness of their stems, and others are shrubs still more remarkable for the excessive hardness of their wood. A few are medicinal, some are curious, and many are ornamental. The name Zygophyllum signifies "yoked leaf," and alludes to the circumstance of the leaves growing in pairs. One herbaceous species of the genus zygophyllum, three low trailing species, and nine or 10 shrubby species, varying in height from 1 foot to 7 feet, have been introduced to Britain from Syria, Egypt, St. Jago, the Canary Islands, and the Cape of Good Hope. Most have yellow or orange-coloured flowers; and nearly all may be propagated from cuttings.

The herbaceous zygophyllum, or bean caper, *Z. fabago*, is the species best known, and possesses some medicinal reputation as an anthelmintic, and may be selected as a sufficient specimen of the whole genus. It is a native of Syria; and was introduced to Britain toward the close of the 16th century. Its root is thick and fleshy, and strikes deep into the ground, and will grow as thick as a man's arm; its stems are annual, and are proportionate in number to the age and size and vigour of the root, and are smooth, green, and jointed, and send out a few side branches, and usually attain a height of 3 or 4 feet; its leaves stands in pairs on footstalks of about an inch in length, and are smooth and fleshy like those of purslane, and have a bluish green colour; its flowers come out in twos and threes on short footstalks from the wings of the stems, and have each five roundish concave petals of a reddish or orange and white colour, and bloom from July till September; and its fruit are oblong, prismatic, five-sided capsules, and have their cells full of roundish seeds.

THE END.

EDINBURGH:
FULLARTON AND MACNAB, PRINTERS, LEITH WALK.

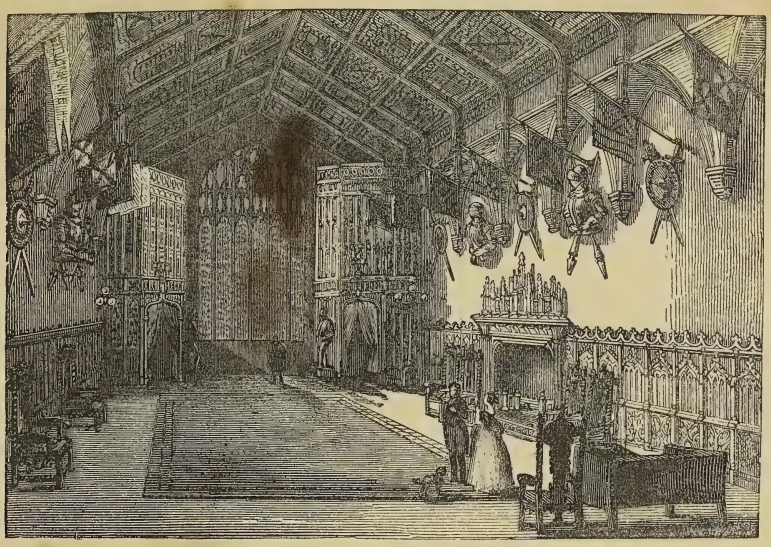
WORKS

PUBLISHED BY A. FULLARTON AND CO.,

STEAD'S PLACE, LEITH WALK, EDINBURGH;

22 EUSTACE STREET, DUBLIN;

AND 106 NEWGATE STREET, LONDON.



BANQUETING-ROOM, TAYMOUTH CASTLE.

Scotland. Scotland Illustrated, in a Series of Picturesque Views, with Descriptive Letterpress, and an Essay upon the Scenery of the Highlands, by Professor WILSON. In one volume demy 4to., Eighty Splendid Engravings on Steel, and numerous wood-cuts, elegant and rich cloth boards, price £1 5s., or in twenty Parts at 1s. each.

"In this *beautiful, cheap, and strictly national Work*, few localities, remarkable for their history, scenery, fame, or beauty, have been omitted; the letterpress tells their stories, and tells them well."—*Glasgow Courier.*

Rural Cyclopedia. *In course of publication.* The Rural Cyclopedia; *or a General Dictionary of Agriculture, and of the Arts, Sciences, Instruments, and Practice, necessary to the Farmer, Stockfarmer, Gardener, Forester, Landsteward, &c. &c.* Edited by the Rev. JOHN M. WILSON. Richly illustrated with appropriate Engravings. In four volumes, imperial 8vo., price 22s. 6d. each; or in Divisions at 5s. and Parts at 2s. 6d. each.

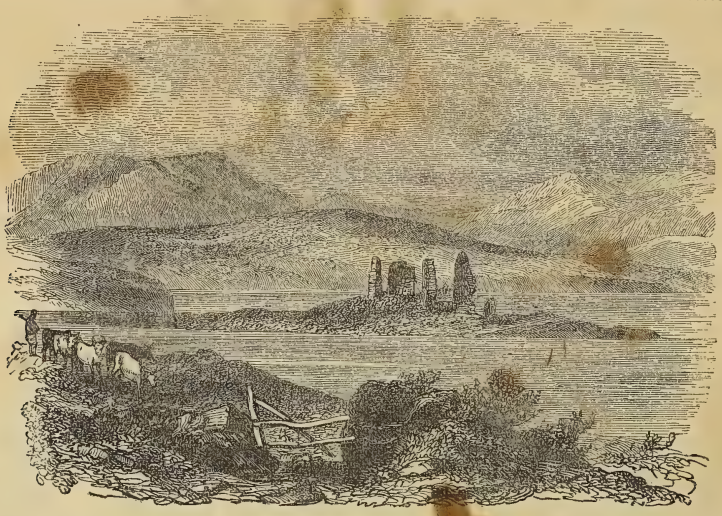
"This is one of a class of publications of the day, having reference to agriculture, which indicates the higher tone and wider range of topics now deemed pertinent to the business of husbandry."—*Economist.*

"Laboriously and intelligently is the Editor going through his arduous work, establishing in its progress not only that he is an extensive reader, but a philosophic and practical observer of nature. His suggestions and advice on the culture of our most valuable crops, and, indeed on the general management of farms and gardens, if generally adopted, would make the labour of the agriculturist much more profitable than it now is."—*Sheffield Iris.*

Maclean. The Miscellaneous Works of ARCHIBALD MACLEAN, one of the Pastors of the Baptist Church, Edinburgh, with a Memoir of the Author. In six volumes, 12mo., at 3s. 6d. each, boards.

"Archibald Maclean is one of a class who have done great things for true Christianity."—*British Banner.*

Map-making. A Manual of Map-making and Mechanical Geography, with Map of the World and numerous Wood-cuts. By ALEXANDER JAMIESON, LL.D., *second edition*, 12mo. boards, 2s.; cloth, gilt, 2s. 6d.



CASTLE FINLAGGAN, ISLAY.

Highlands. A History of the Highlands and Highland Clans, comprising Curious and Interesting Selections from the Stuart Papers. *Illustrated Edition, on Fine Paper, with Portraits, Armorial Bearings, Map of Clan Territories, Coloured Specimens of Clan Tartans, Scenery of Important Localities, and numerous Wood-cuts.* By JAMES BROWNE, Esq., LL.D., Advocate. In four volumes, Royal 8vo., price £3 cloth elegant; or in 11 divisions at 5s., or 22 parts at 2s. 6d. each.

No other Publication exists in which the subject of the HIGHLANDS AND HIGHLANDERS is treated of in all its branches, or to which reference may be conveniently made for information respecting them, presented in an elegant, agreeable, and accessible form. His late Majesty was pleased to allow access, *for the first time*, to the STUART PAPERS, for the use of the Author in preparing this NATIONAL WORK.

Highlands. A History of the Highlands and Highland Clans, by JAMES BROWNE, Esq., LL.D., Advocate. *A Cheaper Edition of the above*, containing the Selections from the Stuart Papers, Armorial Bearings, Portraits and Maps. In four volumes, Demy 8vo., price £1 14s. cloth, or in 30 parts at 1s. each.

Ireland. The Parliamentary Gazetteer of Ireland. Adapted to the most recent Arrangements. *Illustrated by a Series of Maps and Plates, and presenting the Results in detail of the Census of* 1841 *as compared with that of* 1831. In three volumes, Imperial 8vo., numerous Maps, Views, &c., price £2 14s. handsome cloth boards; or in 9 divisions at 6s. cloth, (the last at 4s.) or 5s. stout paper, (the last at 3s.); also in 24 parts at 2s. each.

Bible. The Self-Interpreting Bible; The celebrated Family Bible by the Rev. JOHN BROWN of Haddington, without abridgment or omission. *A new and beautiful Edition, just issued, with Portrait, and many new Engravings of Scripture Scenery and Subjects.* In one handsome volume, large Royal Quarto, £2 5s., or in 42 parts at 1s. and 21 at 2s. each.

A Memoir of the Author, above 5,300 Critical and Explanatory Notes, and concluding Remarks on each Book of Scripture, have been prepared expressly for this Edition, by the Rev. J. B. PATTERSON and the Rev. A. S. PATTERSON, his Grandsons.

Bible. The Evangelical Expositor, or a Practical Commentary on the Holy Bible, by the Rev. THOMAS HAWEIS, LL.B., M.D. In three volumes, Quarto, illustrated with numerous Engravings of Scripture Scenery and Subjects, £3 10s. boards, or in 31 parts at 2s. each.

To this edition are annexed an Introduction, Marginal References, &c., by the Rev. JOHN BROWN of Haddington, and numerous additional Notes not to be found in any other.

"None of the Commentators on the Scripture is, for common people, equally useful with Henry, or *which is more evangelical*, HAWEIS."—*Rev. John Brown of Haddington.*

Colonization of America. The History of the Colonization of the United States. By GEORGE BANCROFT, Esq., Minister of the United States in London. In one volume, Royal 8vo., with Illustrations, Portraits, Maps, &c. price 12s. cloth.

"A reprint of the best History of the United States that has yet appeared."—*Critic.* "A Work of the deepest interest to any student of these times, and executed in a manner that must elevate in general esteem the national literature of America."—*The Statesmen of the Commonwealth, by John Foster, Esq. of the Middle Temple.*

Conchology. The Conchologist's Text Book. By Captain THOMAS BROWN, Manchester. Sixth Edition. Edited by Professor MACGILLIVRAY, Aberdeen. Illustrated by Engravings on Steel, Royal 18mo. price 5s. cloth boards.

Burns. The Life and Works of Robert Burns. Edited by the Ettrick Shepherd and William Motherwell, Esq. *A new and improved edition* in 5 vols. Imperial 18mo. with 15 appropriate Engravings, 3s. 6d. each, cloth elegant, or in 15 parts at 1s. each.

The most complete collection of the Works of Burns ever published. It contains various pieces not to be found in any other.

Ramsay. The Works of Allan Ramsay, with Life of the Author, by George Chalmers; and an Essay on his Genius and Writings, by Lord Woodhouselee. *A new edition, with Illustrative Notes, Map of Scenery of Gentle Shepherd, Portrait, and other appropriate Engravings.* In three volumes, imperial 18mo., price 3s. 6d. each, cloth, or in 9 Parts at 1s. each.

Geography. A System of Geography Popular and Scientific, or a Physical, Political, and Statistical Account of the World. *A new Edition*, Corrected and Revised to 1847. By James Bell, Author of "Critical Researches in Geography." In six volumes, 8vo. *with Atlas of Maps, and numerous Illustrations*, rich cloth, 13s. each, or in twelve half volumes at 6s. 6d. each, £3 18s.; also in 28 parts at 2s. 6d. each.

"In precision, in interesting detail, in faithful adherence to facts, and justness of representation, it far surpasses that of Malte-Brun. It is at the same time the most recent Work on this subject."—*American Review.*

"Nothing can exceed the interest and the value of the Work of Mr. Bell which is now before us; indeed, as a System of Geography, it has no rival in this country."—*Dublin University Magazine.*

"The Author of the System of Geography now before us, is certainly one of the first critical geographers in this country. It is the best Work on Geography in the English language."—*Edinburgh Journal of Natural and Geographical Science.*

The present Edition of this celebrated work is the most complete System of Geography at present in course of publication.

Devotions. The Manual of Family and Private Devotions. By the Very Rev. D. Dewar, D.D., Aberdeen. *Illustrated Edition, on Superfine Paper, including Watts' Psalms and Hymns.* In one volume, Small Quarto, richly bound in Morocco, price 36s.; in handsome cloth boards, with a series of highly finished and appropriate Engravings, 27s. 6d.; or in 13 parts at 2s. each.

Contains a Prayer, a Selection and an Exposition of a portion of Scripture, with Directions to suitable Psalms or Hyms, for the Morning and Evening of every Day throughout the Year. The Readings are in a *consecutive* series of Scripture History and Gospel Doctrine, an arrangement peculiar to this Work as a Manual of Family Devotion.

Devotions. The Manual of Family and Private Devotions. By the Very Rev. D. Dewar, D.D., Aberdeen. *The same Work as above, in another form, and without Watts' Psalms and Hymns.* In one volume, Imperial 8vo., Engraved Vignette, price 22s. or in 20 parts at 1s. each.

The extensive sale which this work has obtained in Scotland and England, *amounting to upwards of Forty Thousand copies*, is the surest test of its great usefulness and merit. *One more appropriate to be acquired by, or presented to, a Young Man or Woman commencing life, it would be difficult to point out.*

England. Biographical History of England in a series of Lives of Eminent and Illustrious Englishmen. Edited by George Godfrey Cunningham, Esq. In eight volumes, or in sixteen half volumes, with Fifty-six Portrait Illustrations, £3 12s., cloth boards.

"In originality, and excellence of plan, this Work is entitled to command an extensive sale. The matter for copiousness and condensation, and the style for clearness, vigour, and impartiality, are eminently distinguished. The introductions are excellent and not unworthy of our very best constitutional writers."—*Monthly Review.*

"One of the most meritorious historical Works that has lately been projected. It is a *mine of valuable information* presented in the *most attractive form.*"—*Tait's Edinburgh Magazine.*

Erskine. The Beauties of Ralph Erskine, Minister of the Gospel at Dunfermline. Edited by the Rev. SAMUEL M'MILLAN of Aberdeen. In two volumes 8vo. cloth boards, price 18s.; or in 16 parts at 1s. each.

Family Physician. The Family Physician: being a Guide to the Regulation of Health and Prevention of Disease, by a MEMBER OF THE FACULTY. In one volume, Demy 8vo. price 5s.

St. John. Lectures on Chapters XIV., XV., and XVI. of St. John's Gospel. From the Manuscripts of the late J. B. PATTERSON, Minister of Falkirk. In one volume, 12mo., price 5s. cloth boards.

Engineering. An Elementary Course of Civil Engineering. By D. H. MAHAN, Professor of Engineering, United States. *A New Edition with Supplementary Additions* by PETER BARLOW, Esq., F.R.S., F.R.A.S., M.C.P.S. In one volume, Quarto, with numerous Illustrations on Steel, price 14s. cloth boards; or in 7 parts at 2s. each.

RAILWAY VIADUCT OVER THE VALLEY OF THE ALMOND.

Scotland. The Topographical, Statistical, and Historical Gazetteer of Scotland, adapted to all the recent arrangements, and illustrated with Maps, Plans of Cities, and numerous Views. In two volumes, imperial 8vo., price £2, cloth boards; or in 18 Parts, at 2s.; or 36 at 1s. each.

"Beyond all comparison the most perfect Book of the kind in existence. Without a rival for the completeness of its details, while in type, size, paper, and illustrations, it is altogether a superb production."—*Glasgow Courier.*

"The standard authority as a TOPOGRAPHICAL, STATISTICAL, AND HISTORICAL GAZETTEER OF SCOTLAND. The most complete, and for its size, the cheapest Work of this description ever published."—*Scotsman.*

"The very best Work of the kind I ever read in any language."—*Letter of Mr. Sheriff Alison to the Publishers.*

Scotland. The Comprehensive Gazetteer of Scotland; being a complete Geographical, Historical, and Statistical Account of the Counties, Parishes, Cities, &c. of Scotland. In one thick volume, imperial 18mo, price 14s.; or in 12 Parts at 1s. each.

Ireland. A Descriptive View and Comprehensive Gazetteer of Ireland, containing the Latest Information from the most Authentic Sources. By the Rev. J. M. WILSON and JOHN PARKER LAWSON, M.A. In two handsome volumes, Imperial 18mo. with Maps andIllustrations, price 16s.; or in 14 parts at 1s. each.
